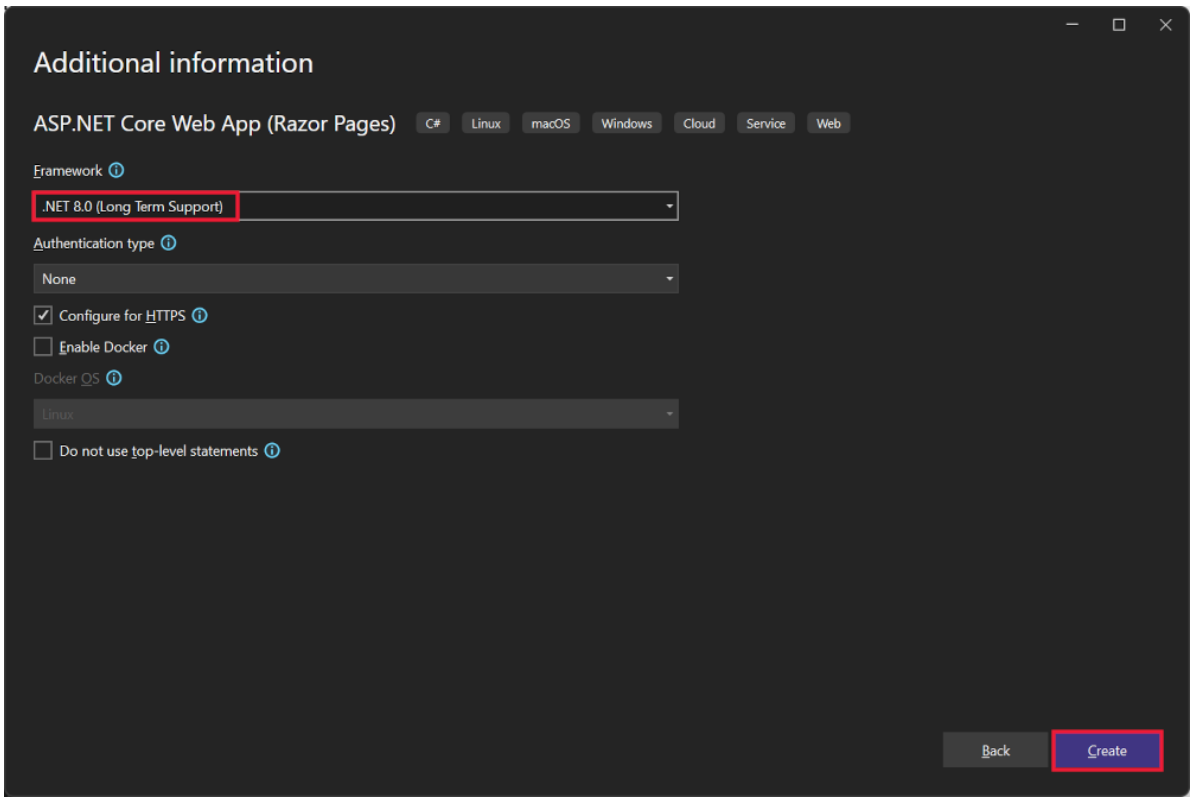
Start Visual Studio 2022 and select **Create a new project**.



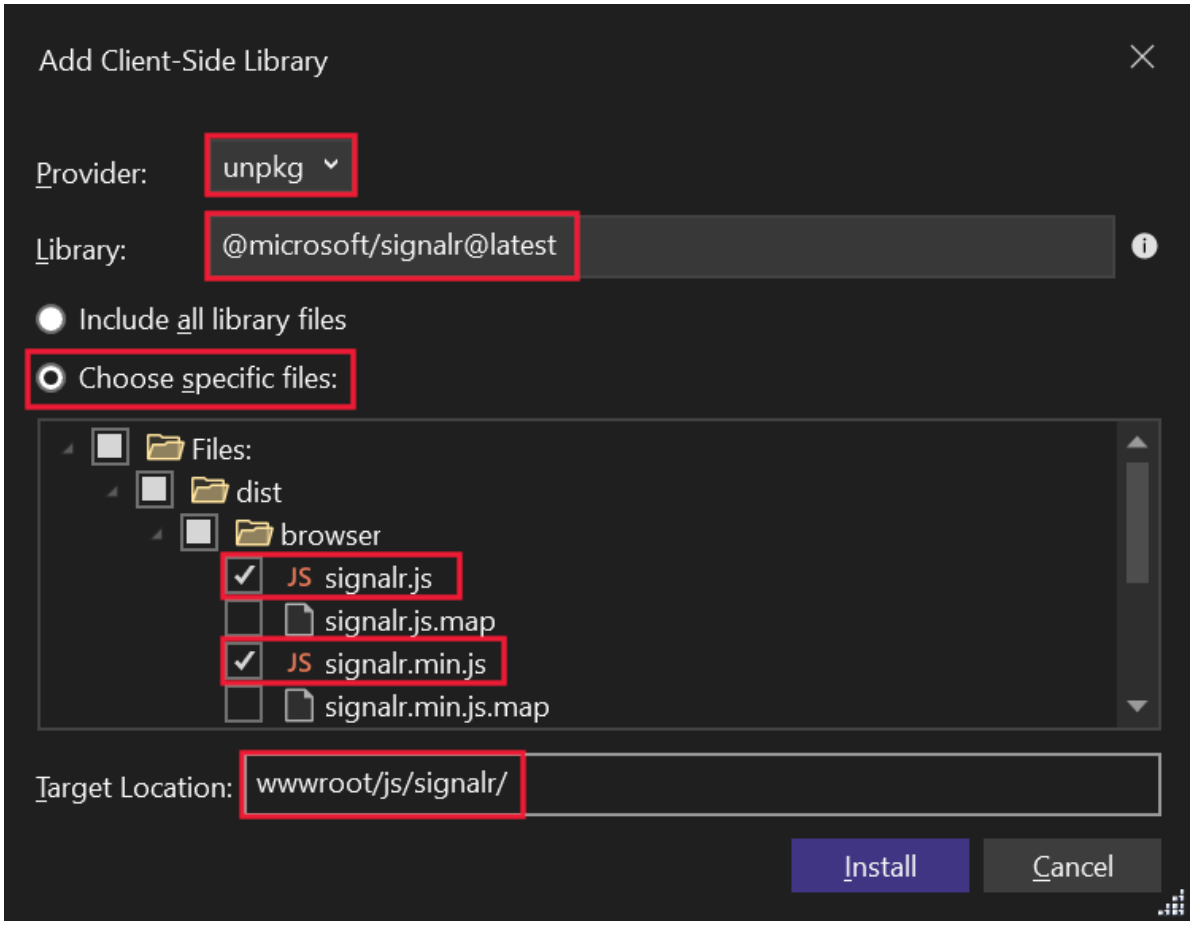
In the **Create a new project** dialog, select **ASP.NET Core Web App (Razor Pages)**, and then select **Next**.

In the **Configure your new project** dialog, enter `SignalRChat` for **Project name**. It's important to name the project `SignalRChat`, including matching the capitalization, so the namespaces match the code in the tutorial.

Select **Next**.

In the **Additional information** dialog, select **.NET 8.0 (Long Term Support)** and then select **Create**.

Add the SignalR client library



The SignalR server library is included in the ASP.NET Core shared framework. The JavaScript client library isn't automatically included in the project. For this tutorial, use Library Manager (LibMan) to get the client library from unpkg. `unpkg` is a fast, global content delivery network for everything on npm.

Visual Studio

In **Solution Explorer**, right-click the project, and select **Add** > **Client-Side Library**.

In the **Add Client-Side Library** dialog:

- Select **unpkg** for **Provider**
- Enter `@microsoft/signalr@latest` for **Library**.
- Select **Choose specific files**, expand the *dist/browser* folder, and select `signalr.js` and `signalr.min.js`.
- Set **Target Location** to `wwwroot/js/signalr/`.
- Select **Install**.

LibMan creates a `wwwroot/js/signalr` folder and copies the selected files to it.

Create a SignalR hub

A *hub* is a class that serves as a high-level pipeline that handles client-server communication.

In the SignalRChat project folder, create a `Hubs` folder.

In the `Hubs` folder, create the `ChatHub` class with the following code:

C#

```
using Microsoft.AspNetCore.SignalR;

namespace SignalRChat.Hubs
{
    public class ChatHub : Hub
    {
        public async Task SendMessage(string user, string message)
        {
            await Clients.All.SendAsync("ReceiveMessage", user, message);
        }
    }
}
```

The `ChatHub` class inherits from the SignalR Hub class. The `Hub` class manages connections, groups, and messaging.

The `SendMessage` method can be called by a connected client to send a message to all clients. JavaScript client code that calls the method is shown later in the tutorial. SignalR code is asynchronous to provide maximum scalability.

Configure SignalR

The SignalR server must be configured to pass SignalR requests to SignalR. Add the following highlighted code to the `Program.cs` file.

C#

```
using SignalRChat.Hubs;

var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddSignalR();

var app = builder.Build();
```

```
// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for
production scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();
app.MapHub<ChatHub>("/chatHub");

app.Run();
```

The preceding highlighted code adds SignalR to the ASP.NET Core dependency injection and routing systems.

Add SignalR client code

Replace the content in `Pages/Index.cshtml` with the following code:

CSHTML

```
@page
<div class="container">
    <div class="row p-1">
        <div class="col-1">User</div>
        <div class="col-5"><input type="text" id="userInput" /></div>
    </div>
    <div class="row p-1">
        <div class="col-1">Message</div>
        <div class="col-5"><input type="text" class="w-100"
id="messageInput" /></div>
    </div>
    <div class="row p-1">
        <div class="col-6 text-end">
            <input type="button" id="sendButton" value="Send Message" />
        </div>
    </div>
    <div class="row p-1">
        <div class="col-6">
            <hr />
        </div>
```

```
    </div>
    <div class="row p-1">
        <div class="col-6">
            <ul id="messagesList"></ul>
        </div>
    </div>
</div>
<script src="~/js/signalr/dist/browser/signalr.js"></script>
<script src="~/js/chat.js"></script>
```

The preceding markup:

- Creates text boxes and a submit button.
- Creates a list with `id="messagesList"` for displaying messages that are received from the SignalR hub.
- Includes script references to SignalR and the `chat.js` app code is created in the next step.

In the `wwwroot/js` folder, create a `chat.js` file with the following code:

JavaScript

```
"use strict";

var connection = new
signalR.HubConnectionBuilder().withUrl("/chatHub").build();

//Disable the send button until connection is established.
document.getElementById("sendButton").disabled = true;

connection.on("ReceiveMessage", function (user, message) {
    var li = document.createElement("li");
    document.getElementById("messagesList").appendChild(li);
    // We can assign user-supplied strings to an element's textContent
because it
    // is not interpreted as markup. If you're assigning in any other way,
you
    // should be aware of possible script injection concerns.
    li.textContent = `${user} says ${message}`;
});

connection.start().then(function () {
    document.getElementById("sendButton").disabled = false;
}).catch(function (err) {
    return console.error(err.toString());
});

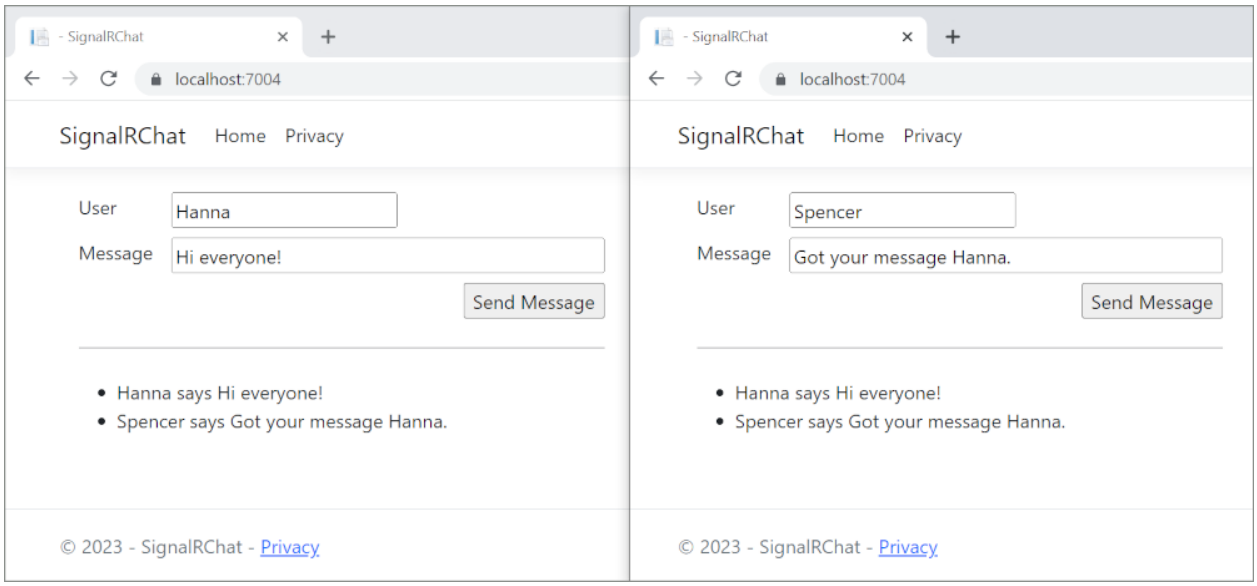
document.getElementById("sendButton").addEventListener("click", function
(event) {
    var user = document.getElementById("userInput").value;
    var message = document.getElementById("messageInput").value;
```

```
    connection.invoke("SendMessage", user, message).catch(function (err) {
        return console.error(err.toString());
    });
    event.preventDefault();
});
```

The preceding JavaScript:

- Creates and starts a connection.
- Adds to the submit button a handler that sends messages to the hub.
- Adds to the connection object a handler that receives messages from the hub and adds them to the list.

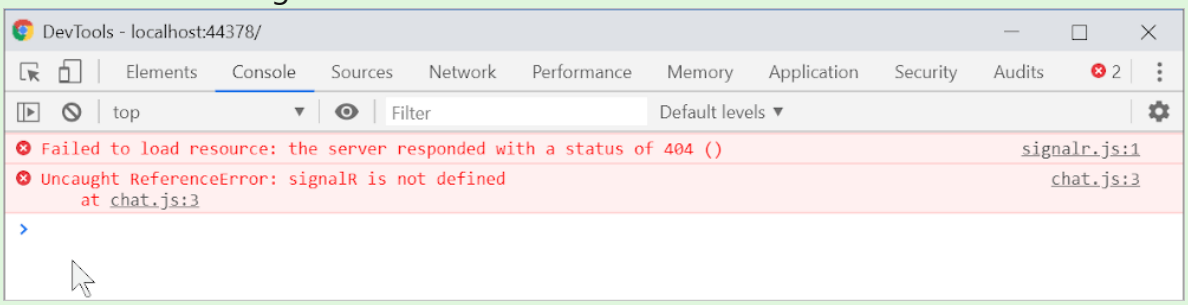
Run the app



Visual Studio

Select `Ctrl`+`F5` to run the app without debugging.

Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.



Choose either browser, enter a name and message, and select the **Send Message** button.

The name and message are displayed on both pages instantly.

Tip

If the app doesn't work, open the browser developer tools (F12) and go to the console. Look for possible errors related to HTML and JavaScript code. For example, if `signalr.js` was put in a different folder than directed, the reference to that file won't work resulting in a 404 error in the console.

If an `ERR_SPDY_INADEQUATE_TRANSPORT_SECURITY` error has occurred in Chrome, run the following commands to update the development certificate:

.NET CLI

```
dotnet dev-certs https --clean
dotnet dev-certs https --trust
```

Publish to Azure

For information on deploying to Azure, see Quickstart: Deploy an ASP.NET web app. For more information on Azure SignalR Service, see What is Azure SignalR Service?.

Tutorial: Get started with ASP.NET Core SignalR using TypeScript and Webpack

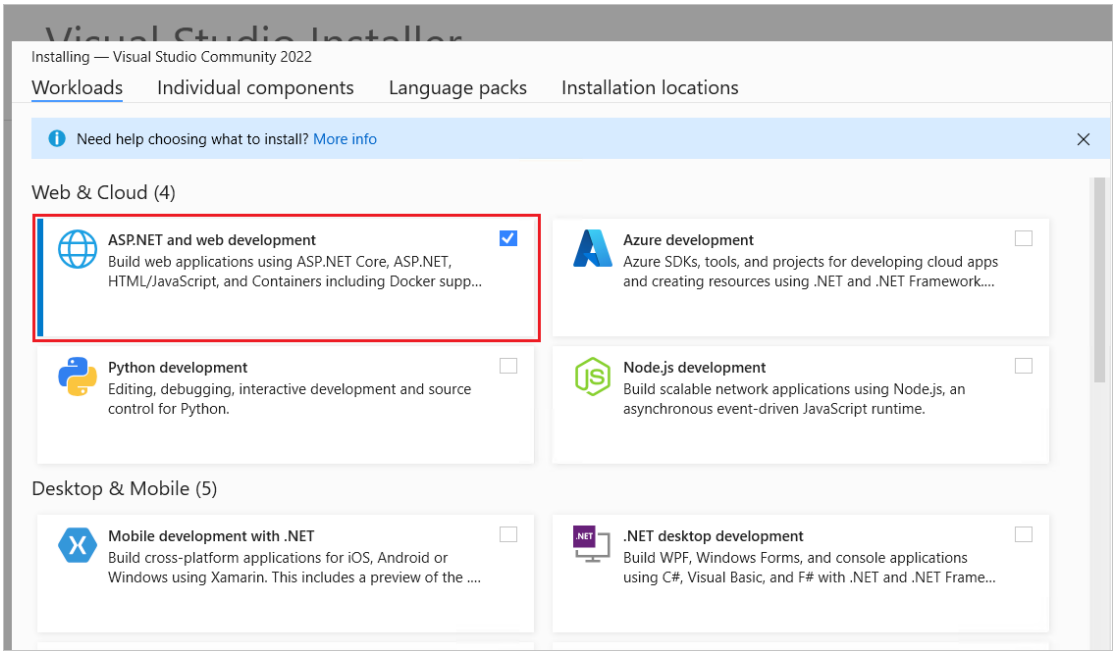
Article • 11/16/2023

By Sébastien Sougnez

This tutorial demonstrates using Webpack in an ASP.NET Core SignalR web app to bundle and build a client written in TypeScript. Webpack enables developers to bundle and build the client-side resources of a web app.

In this tutorial, you learn how to:

- ✓ Create an ASP.NET Core SignalR app
- ✓ Configure the SignalR server
- ✓ Configure a build pipeline using Webpack
- ✓ Configure the SignalR TypeScript client
- ✓ Enable communication between the client and the server



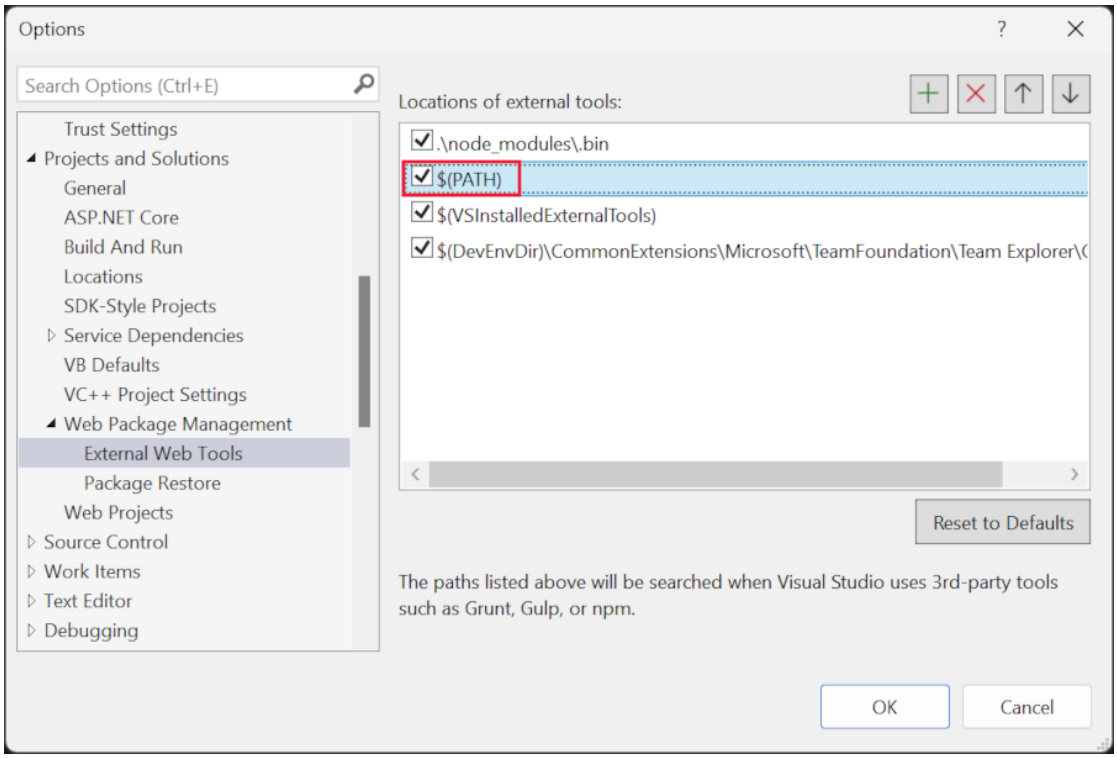
View or download sample code (how to download)

Prerequisites

- Node.js with npm

Visual Studio

- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.



Create the ASP.NET Core web app

Visual Studio

By default, Visual Studio uses the version of npm found in its installation directory. To configure Visual Studio to look for npm in the `PATH` environment variable:

Launch Visual Studio. At the start window, select **Continue without code**.

1. Navigate to **Tools** > **Options** > **Projects and Solutions** > **Web Package Management** > **External Web Tools**.
2. Select the `$(PATH)` entry from the list. Select the up arrow to move the entry to the second position in the list, and select **OK**:

.

To create a new ASP.NET Core web app:

1. Use the **File** > **New** > **Project** menu option and choose the **ASP.NET Core Empty** template. Select **Next**.
2. Name the project `SignalRWebpack`, and select **Create**.
3. Select **.NET 8.0 (Long Term Support)** from the **Framework** drop-down. Select **Create**.

Add the Microsoft.TypeScript.MSBuild NuGet package to the project:

1. In **Solution Explorer**, right-click the project node and select **Manage NuGet Packages**. In the **Browse** tab, search for `Microsoft.TypeScript.MSBuild` and then select **Install** on the right to install the package.

Visual Studio adds the NuGet package under the **Dependencies** node in **Solution Explorer**, enabling TypeScript compilation in the project.

Configure the server

In this section, you configure the ASP.NET Core web app to send and receive SignalR messages.

1. In `Program.cs`, call AddSignalR:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddSignalR();
```

2. Again, in `Program.cs`, call UseDefaultFiles and UseStaticFiles:

```
C#

var app = builder.Build();

app.UseDefaultFiles();
app.UseStaticFiles();
```

   The preceding code allows the server to locate and serve the `index.html` file. The file is served whether the user enters its full URL or the root URL of the web app.

3. Create a new directory named `Hubs` in the project root, `SignalRWebpack/`, for the SignalR hub class.

4. Create a new file, `Hubs/ChatHub.cs`, with the following code:

```
C#

using Microsoft.AspNetCore.SignalR;

namespace SignalRWebpack.Hubs;

public class ChatHub : Hub
{
    public async Task NewMessage(long username, string message) =>
        await Clients.All.SendAsync("messageReceived", username,
message);
}
```

   The preceding code broadcasts received messages to all connected users once the server receives them. It's unnecessary to have a generic `on` method to receive all the messages. A method named after the message name is enough.

   In this example:

   - The TypeScript client sends a message identified as `newMessage`.
   - The C# `NewMessage` method expects the data sent by the client.
   - A call is made to SendAsync on Clients.All.
   - The received messages are sent to all clients connected to the hub.

5. Add the following `using` statement at the top of `Program.cs` to resolve the `ChatHub` reference:

```C#
using SignalRWebpack.Hubs;
```

6. In `Program.cs`, map the `/hub` route to the `ChatHub` hub. Replace the code that displays `Hello World!` with the following code:

```C#
app.MapHub<ChatHub>("/hub");
```

Configure the client

In this section, you create a Node.js project to convert TypeScript to JavaScript and bundle client-side resources, including HTML and CSS, using Webpack.

1. Run the following command in the project root to create a `package.json` file:

```Console
npm init -y
```

2. Add the highlighted property to the `package.json` file and save the file changes:

```JSON
{
  "name": "SignalRWebpack",
  "version": "1.0.0",
  "private": true,
  "description": "",
  "main": "index.js",
  "scripts": {
    "test": "echo \"Error: no test specified\" && exit 1"
  },
  "keywords": [],
  "author": "",
  "license": "ISC"
}
```

Setting the `private` property to `true` prevents package installation warnings in the next step.

3. Install the required npm packages. Run the following command from the project root:

```
Console

npm i -D -E clean-webpack-plugin css-loader html-webpack-plugin mini-
css-extract-plugin ts-loader typescript webpack webpack-cli
```

The `-E` option disables npm's default behavior of writing semantic versioning range operators to `package.json`. For example, `"webpack": "5.76.1"` is used instead of `"webpack": "^5.76.1"`. This option prevents unintended upgrades to newer package versions.

For more information, see the npm-install documentation.

4. Replace the `scripts` property of `package.json` file with the following code:

```
JSON

"scripts": {
  "build": "webpack --mode=development --watch",
  "release": "webpack --mode=production",
  "publish": "npm run release && dotnet publish -c Release"
},
```

The following scripts are defined:

- `build`: Bundles the client-side resources in development mode and watches for file changes. The file watcher causes the bundle to regenerate each time a project file changes. The `mode` option disables production optimizations, such as tree shaking and minification. use `build` in development only.
- `release`: Bundles the client-side resources in production mode.
- `publish`: Runs the `release` script to bundle the client-side resources in production mode. It calls the .NET CLI's publish command to publish the app.

5. Create a file named `webpack.config.js` in the project root, with the following code:

```
JavaScript

const path = require("path");
const HtmlWebpackPlugin = require("html-webpack-plugin");
const { CleanWebpackPlugin } = require("clean-webpack-plugin");
```

```
const MiniCssExtractPlugin = require("mini-css-extract-plugin");

module.exports = {
    entry: "./src/index.ts",
    output: {
        path: path.resolve(__dirname, "wwwroot"),
        filename: "[name].[chunkhash].js",
        publicPath: "/",
    },
    resolve: {
        extensions: [".js", ".ts"],
    },
    module: {
        rules: [
            {
                test: /\.ts$/,
                use: "ts-loader",
            },
            {
                test: /\.css$/,
                use: [MiniCssExtractPlugin.loader, "css-loader"],
            },
        ],
    },
    plugins: [
        new CleanWebpackPlugin(),
        new HtmlWebpackPlugin({
            template: "./src/index.html",
        }),
        new MiniCssExtractPlugin({
            filename: "css/[name].[chunkhash].css",
        }),
    ],
};
```

The preceding file configures the Webpack compilation process:

- The `output` property overrides the default value of `dist`. The bundle is instead emitted in the `wwwroot` directory.
- The `resolve.extensions` array includes `.js` to import the SignalR client JavaScript.

6. Create a new directory named `src` in the project root, `SignalRWebpack/`, for the client code.

7. Copy the `src` directory and its contents from the sample project into the project root. The `src` directory contains the following files:

    - `index.html`, which defines the homepage's boilerplate markup:

HTML

```
<!DOCTYPE html>
<html lang="en">
  <head>
    <meta charset="utf-8" />
    <title>ASP.NET Core SignalR with TypeScript and
Webpack</title>
  </head>
  <body>
    <div id="divMessages" class="messages"></div>
    <div class="input-zone">
      <label id="lblMessage" for="tbMessage">Message:</label>
      <input id="tbMessage" class="input-zone-input" type="text"
/>
      <button id="btnSend">Send</button>
    </div>
  </body>
</html>
```

- `css/main.css`, which provides CSS styles for the homepage:

CSS

```
*,
*::before,
*::after {
  box-sizing: border-box;
}

html,
body {
  margin: 0;
  padding: 0;
}

.input-zone {
  align-items: center;
  display: flex;
  flex-direction: row;
  margin: 10px;
}

.input-zone-input {
  flex: 1;
  margin-right: 10px;
}

.message-author {
  font-weight: bold;
}

.messages {
```

```
  border: 1px solid #000;
  margin: 10px;
  max-height: 300px;
  min-height: 300px;
  overflow-y: auto;
  padding: 5px;
}
```

- `tsconfig.json`, which configures the TypeScript compiler to produce ECMAScript 5-compatible JavaScript:

JSON

```
{
  "compilerOptions": {
    "target": "es5"
  }
}
```

- `index.ts`:

TypeScript

```
import * as signalR from "@microsoft/signalr";
import "./css/main.css";

const divMessages: HTMLDivElement =
document.querySelector("#divMessages");
const tbMessage: HTMLInputElement =
document.querySelector("#tbMessage");
const btnSend: HTMLButtonElement =
document.querySelector("#btnSend");
const username = new Date().getTime();

const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();

connection.on("messageReceived", (username: string, message:
string) => {
  const m = document.createElement("div");

  m.innerHTML = `<div class="message-author">${username}</div>
<div>${message}</div>`;

  divMessages.appendChild(m);
  divMessages.scrollTop = divMessages.scrollHeight;
});

connection.start().catch((err) => document.write(err));
```

```
tbMessage.addEventListener("keyup", (e: KeyboardEvent) => {
  if (e.key === "Enter") {
    send();
  }
});

btnSend.addEventListener("click", send);

function send() {
  connection.send("newMessage", username, tbMessage.value)
    .then(() => (tbMessage.value = ""));
}
```

The preceding code retrieves references to DOM elements and attaches two event handlers:

- `keyup`: Fires when the user types in the `tbMessage` textbox and calls the `send` function when the user presses the **Enter** key.
- `click`: Fires when the user selects the **Send** button and calls `send` function is called.

The `HubConnectionBuilder` class creates a new builder for configuring the server connection. The `withUrl` function configures the hub URL.

SignalR enables the exchange of messages between a client and a server. Each message has a specific name. For example, messages with the name `messageReceived` can run the logic responsible for displaying the new message in the messages zone. Listening to a specific message can be done via the `on` function. Any number of message names can be listened to. It's also possible to pass parameters to the message, such as the author's name and the content of the message received. Once the client receives a message, a new `div` element is created with the author's name and the message content in its `innerHTML` attribute. It's added to the main `div` element displaying the messages.

Sending a message through the WebSockets connection requires calling the `send` method. The method's first parameter is the message name. The message data inhabits the other parameters. In this example, a message identified as `newMessage` is sent to the server. The message consists of the username and the user input from a text box. If the send works, the text box value is cleared.

8. Run the following command at the project root:

```
Console
```

```
npm i @microsoft/signalr @types/node
```

The preceding command installs:

- The SignalR TypeScript client, which allows the client to send messages to the server.
- The TypeScript type definitions for Node.js, which enables compile-time checking of Node.js types.

Test the app

Confirm that the app works with the following steps:

Visual Studio

1. Run Webpack in `release` mode. Using the **Package Manager Console** window, run the following command in the project root.

   Console

   ```
   npm run release
   ```

   This command generates the client-side assets to be served when running the app. The assets are placed in the `wwwroot` folder.

   Webpack completed the following tasks:

   - Purged the contents of the `wwwroot` directory.
   - Converted the TypeScript to JavaScript in a process known as *transpilation*.
   - Mangled the generated JavaScript to reduce file size in a process known as *minification*.
   - Copied the processed JavaScript, CSS, and HTML files from `src` to the `wwwroot` directory.
   - Injected the following elements into the `wwwroot/index.html` file:
     - A `<link>` tag, referencing the `wwwroot/main.<hash>.css` file. This tag is placed immediately before the closing `</head>` tag.
     - A `<script>` tag, referencing the minified `wwwroot/main.<hash>.js` file. This tag is placed immediately after the closing `</title>` tag.

2. Select **Debug** > **Start without debugging** to launch the app in a browser without attaching the debugger. The `wwwroot/index.html` file is served at `https://localhost:<port>`.

   If there are compile errors, try closing and reopening the solution.

3. Open another browser instance (any browser) and paste the URL in the address bar.

4. Choose either browser, type something in the **Message** text box, and select the **Send** button. The unique user name and message are displayed on both pages instantly.

Use ASP.NET Core SignalR with Blazor

Article • 06/19/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This tutorial provides a basic working experience for building a real-time app using SignalR with Blazor. This article is useful for developers who are already familiar with SignalR and are seeking to understand how to use SignalR in a Blazor app. For detailed guidance on the SignalR and Blazor frameworks, see the following reference documentation sets and the API documentation:

- Overview of ASP.NET Core SignalR
- ASP.NET Core Blazor
- .NET API browser

Learn how to:

- ✓ Create a Blazor app
- ✓ Add the SignalR client library
- ✓ Add a SignalR hub
- ✓ Add SignalR services and an endpoint for the SignalR hub
- ✓ Add a Razor component code for chat

At the end of this tutorial, you'll have a working chat app.

Prerequisites

Visual Studio

Visual Studio (latest release) with the **ASP.NET and web development** workload

Sample app

Downloading the tutorial's sample chat app isn't required for this tutorial. The sample app is the final, working app produced by following the steps of this tutorial. When you open the samples repository, open the version folder that you plan to target and find the sample named `BlazorSignalRApp`.

View or download sample code (how to download)

Create a Blazor Web App

Follow the guidance for your choice of tooling:

Visual Studio

> **Note**
>
> Visual Studio 2022 or later and .NET Core SDK 8.0.0 or later are required.

In Visual Studio:

- Select **Create a new project** from the **Start Window** or select **File** > **New** > **Project** from the menu bar.
- In the **Create a new project** dialog, select **Blazor Web App** from the list of project templates. Select the **Next** button.
- In the **Configure your new project** dialog, name the project `BlazorSignalRApp` in the **Project name** field, including matching the capitalization. Using this exact project name is important to ensure that the namespaces match for code that you copy from the tutorial into the app that you're building.
- Confirm that the **Location** for the app is suitable. Leave the **Place solution and project in the same directory** checkbox selected. Select the **Next** button.
- In the **Additional information** dialog, use the following settings:
  - **Framework**: Confirm that the latest framework is selected. If Visual Studio's **Framework** dropdown list doesn't include the latest available .NET framework, update Visual Studio and restart the tutorial.
  - **Authentication type**: **None**
  - **Configure for HTTPS**: Selected
  - **Interactive render mode**: **WebAssembly**
  - **Interactivity location**: **Per page/component**
  - **Include sample pages**: Selected
  - **Do not use top-level statements**: Not selected

- Select **Create**.

The guidance in this article uses a WebAssembly component for the SignalR client because it doesn't make sense to use SignalR to connect to a hub from an Interactive Server component in the same app, as that can lead to server port exhaustion.

Add the SignalR client library

Visual Studio

In **Solution Explorer**, right-click the `BlazorSignalRApp.Client` project and select **Manage NuGet Packages**.

In the **Manage NuGet Packages** dialog, confirm that the **Package source** is set to `nuget.org`.

With **Browse** selected, type `Microsoft.AspNetCore.SignalR.Client` in the search box.

In the search results, select the latest release of the Microsoft.AspNetCore.SignalR.Client package. Select **Install**.

If the **Preview Changes** dialog appears, select **OK**.

If the **License Acceptance** dialog appears, select **I Accept** if you agree with the license terms.

Add a SignalR hub

In the server `BlazorSignalRApp` project, create a `Hubs` (plural) folder and add the following `ChatHub` class (`Hubs/ChatHub.cs`):

C#

```
using Microsoft.AspNetCore.SignalR;

namespace BlazorSignalRApp.Hubs;

public class ChatHub : Hub
{
    public async Task SendMessage(string user, string message)
    {
        await Clients.All.SendAsync("ReceiveMessage", user, message);
```

```
    }
}
```

Add services and an endpoint for the SignalR hub

Open the `Program` file of the server `BlazorSignalRApp` project.

Add the namespaces for Microsoft.AspNetCore.ResponseCompression and the `ChatHub` class to the top of the file:

C#

```
using Microsoft.AspNetCore.ResponseCompression;
using BlazorSignalRApp.Hubs;
```

Add SignalR and Response Compression Middleware services:

C#

```
builder.Services.AddSignalR();

builder.Services.AddResponseCompression(opts =>
{
   opts.MimeTypes = ResponseCompressionDefaults.MimeTypes.Concat(
       ["application/octet-stream"]);
});
```

Use Response Compression Middleware at the top of the processing pipeline's configuration. Place the following line of code immediately after the line that builds the app (`var app = builder.Build();`):

C#

```
app.UseResponseCompression();
```

Add an endpoint for the hub immediately before the line that runs the app (`app.Run();`):

C#

```
app.MapHub<ChatHub>("/chathub");
```

Add Razor component code for chat

Add the following `Pages/Chat.razor` file to the `BlazorSignalRApp.Client` project:

razor

```razor
@page "/chat"
@rendermode InteractiveWebAssembly
@using Microsoft.AspNetCore.SignalR.Client
@inject NavigationManager Navigation
@implements IAsyncDisposable

<PageTitle>Chat</PageTitle>

<div class="form-group">
    <label>
        User:
        <input @bind="userInput" />
    </label>
</div>
<div class="form-group">
    <label>
        Message:
        <input @bind="messageInput" size="50" />
    </label>
</div>
<button @onclick="Send" disabled="@(!IsConnected)">Send</button>

<hr>

<ul id="messagesList">
    @foreach (var message in messages)
    {
        <li>@message</li>
    }
</ul>

@code {
    private HubConnection? hubConnection;
    private List<string> messages = new List<string>();
    private string? userInput;
    private string? messageInput;

    protected override async Task OnInitializedAsync()
    {
        hubConnection = new HubConnectionBuilder()
            .WithUrl(Navigation.ToAbsoluteUri("/chathub"))
            .Build();

        hubConnection.On<string, string>("ReceiveMessage", (user, message)
=>
        {
            var encodedMsg = $"{user}: {message}";
```

```
            messages.Add(encodedMsg);
            InvokeAsync(StateHasChanged);
        });

        await hubConnection.StartAsync();
    }

    private async Task Send()
    {
        if (hubConnection is not null)
        {
            await hubConnection.SendAsync("SendMessage", userInput,
messageInput);
        }
    }

    public bool IsConnected =>
        hubConnection?.State == HubConnectionState.Connected;

    public async ValueTask DisposeAsync()
    {
        if (hubConnection is not null)
        {
            await hubConnection.DisposeAsync();
        }
    }
}
```

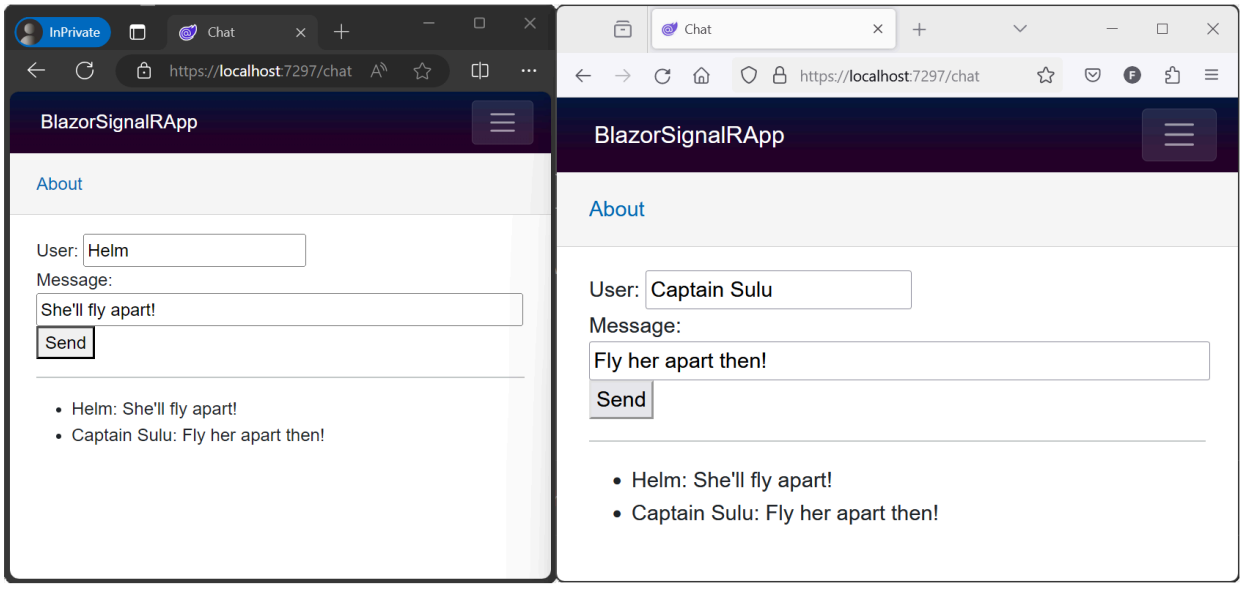
Add an entry to the `NavMenu` component to reach the chat page. In `Components/Layout/NavMenu.razor` immediately after the `<div>` block for the `Weather` component, add the following `<div>` block:

razor

```
<div class="nav-item px-3">
    <NavLink class="nav-link" href="chat">
        <span class="bi bi-list-nested-nav-menu" aria-hidden="true"></span>
Chat
    </NavLink>
</div>
```

> ⓘ Note
>
> Disable Response Compression Middleware in the `Development` environment when using Hot Reload. For more information, see ASP.NET Core Blazor SignalR guidance.

Run the app



Follow the guidance for your tooling:

Visual Studio

With the server `BlazorSignalRApp` project selected in **Solution Explorer**, press `F5` to run the app with debugging or `Ctrl`+`F5` (Windows)/`⌘`+`F5` (macOS) to run the app without debugging.

Copy the URL from the address bar, open another browser instance or tab, and paste the URL in the address bar.

Choose either browser, enter a name and message, and select the button to send the message. The name and message are displayed on both pages instantly:

Quotes: *Star Trek VI: The Undiscovered Country* ©1991 Paramount

Next steps

In this tutorial, you learned how to:

- ✓ Create a Blazor app
- ✓ Add the SignalR client library
- ✓ Add a SignalR hub
- ✓ Add SignalR services and an endpoint for the SignalR hub
- ✓ Add a Razor component code for chat

For detailed guidance on the SignalR and Blazor frameworks, see the following reference documentation sets:

Overview of ASP.NET Core SignalR | ASP.NET Core Blazor

Use hubs in SignalR for ASP.NET Core

Article • 06/18/2024

By Rachel Appel and Kevin Griffin

The SignalR Hubs API enables connected clients to call methods on the server, facilitating real-time communication. The server defines methods that are called by the client, and the client defines methods that are called by the server. SignalR also enables indirect client-to-client communication, always mediated by the SignalR Hub, allowing messages to be sent between individual clients, groups, or to all connected clients. SignalR takes care of everything required to make real-time client-to-server and server-to-client communication possible.

Configure SignalR hubs

To register the services required by SignalR hubs, call AddSignalR in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddSignalR();
```

To configure SignalR endpoints, call MapHub, also in `Program.cs`:

C#

```
app.MapRazorPages();
app.MapHub<ChatHub>("/Chat");

app.Run();
```

> **Note**
>
> ASP.NET Core SignalR server-side assemblies are now installed with the .NET Core SDK. See SignalR assemblies in shared framework for more information.

Create and use hubs

Create a hub by declaring a class that inherits from Hub. Add `public` methods to the class to make them callable from clients:

C#

```
public class ChatHub : Hub
{
    public async Task SendMessage(string user, string message)
        => await Clients.All.SendAsync("ReceiveMessage", user, message);
}
```

> **Note**
>
> Hubs are transient:
>
> - Don't store state in a property of the hub class. Each hub method call is executed on a new hub instance.
> - Don't instantiate a hub directly via dependency injection. To send messages to a client from elsewhere in your application use an IHubContext.
> - Use `await` when calling asynchronous methods that depend on the hub staying alive. For example, a method such as `Clients.All.SendAsync(...)` can fail if it's called without `await` and the hub method completes before `SendAsync` finishes.

The Context object

The Hub class includes a Context property that contains the following properties with information about the connection:

Expand table

Property	Description
ConnectionId	Gets the unique ID for the connection, assigned by SignalR. There's one connection ID for each connection.
UserIdentifier	Gets the user identifier. By default, SignalR uses the ClaimTypes.NameIdentifier from the ClaimsPrincipal associated with the connection as the user identifier.
User	Gets the ClaimsPrincipal associated with the current user.

Property	Description
Items	Gets a key/value collection that can be used to share data within the scope of this connection. Data can be stored in this collection and it will persist for the connection across different hub method invocations.
Features	Gets the collection of features available on the connection. For now, this collection isn't needed in most scenarios, so it isn't documented in detail yet.
ConnectionAborted	Gets a CancellationToken that notifies when the connection is aborted.

Hub.Context also contains the following methods:

Expand table

Method	Description
GetHttpContext	Returns the HttpContext for the connection, or `null` if the connection isn't associated with an HTTP request. For HTTP connections, use this method to get information such as HTTP headers and query strings.
Abort	Aborts the connection.

The Clients object

The Hub class includes a Clients property that contains the following properties for communication between server and client:

Expand table

Property	Description
All	Calls a method on all connected clients
Caller	Calls a method on the client that invoked the hub method
Others	Calls a method on all connected clients except the client that invoked the method

Hub.Clients also contains the following methods:

Expand table

Method	Description
AllExcept	Calls a method on all connected clients except for the specified connections

Method	Description
Client	Calls a method on a specific connected client
Clients	Calls a method on specific connected clients
Group	Calls a method on all connections in the specified group
GroupExcept	Calls a method on all connections in the specified group, except the specified connections
Groups	Calls a method on multiple groups of connections
OthersInGroup	Calls a method on a group of connections, excluding the client that invoked the hub method
User	Calls a method on all connections associated with a specific user
Users	Calls a method on all connections associated with the specified users

Each property or method in the preceding tables returns an object with a `SendAsync` method. The `SendAsync` method receives the name of the client method to call and any parameters.

The object returned by the `Client` and `Caller` methods also contain an `InvokeAsync` method, which can be used to wait for a result from the client.

Send messages to clients

To make calls to specific clients, use the properties of the `Clients` object. In the following example, there are three hub methods:

- `SendMessage` sends a message to all connected clients, using `Clients.All`.
- `SendMessageToCaller` sends a message back to the caller, using `Clients.Caller`.
- `SendMessageToGroup` sends a message to all clients in the `SignalR Users` group.

C#

```
public async Task SendMessage(string user, string message)
    => await Clients.All.SendAsync("ReceiveMessage", user, message);

public async Task SendMessageToCaller(string user, string message)
    => await Clients.Caller.SendAsync("ReceiveMessage", user, message);

public async Task SendMessageToGroup(string user, string message)
    => await Clients.Group("SignalR Users").SendAsync("ReceiveMessage",
user, message);
```

Strongly typed hubs

A drawback of using `SendAsync` is that it relies on a string to specify the client method to be called. This leaves code open to runtime errors if the method name is misspelled or missing from the client.

An alternative to using `SendAsync` is to strongly type the Hub class with Hub<T>. In the following example, the `ChatHub` client method has been extracted out into an interface called `IChatClient`:

C#

```
public interface IChatClient
{
    Task ReceiveMessage(string user, string message);
}
```

This interface can be used to refactor the preceding `ChatHub` example to be strongly typed:

C#

```
public class StronglyTypedChatHub : Hub<IChatClient>
{
    public async Task SendMessage(string user, string message)
        => await Clients.All.ReceiveMessage(user, message);

    public async Task SendMessageToCaller(string user, string message)
        => await Clients.Caller.ReceiveMessage(user, message);

    public async Task SendMessageToGroup(string user, string message)
        => await Clients.Group("SignalR Users").ReceiveMessage(user,
message);
}
```

Using `Hub<IChatClient>` enables compile-time checking of the client methods. This prevents issues caused by using strings, since `Hub<T>` can only provide access to the methods defined in the interface. Using a strongly typed `Hub<T>` disables the ability to use `SendAsync`.

> **Note**
>
> The `Async` suffix isn't stripped from method names. Unless a client method is defined with `.on('MyMethodAsync')`, don't use `MyMethodAsync` as the name.

Client results

In addition to making calls to clients, the server can request a result from a client. This requires the server to use `ISingleClientProxy.InvokeAsync` and the client to return a result from its `.On` handler.

There are two ways to use the API on the server, the first is to call `Client(...)` or `Caller` on the `Clients` property in a Hub method:

C#

```
public class ChatHub : Hub
{
    public async Task<string> WaitForMessage(string connectionId)
    {
        var message = await Clients.Client(connectionId).InvokeAsync<string>
(
            "GetMessage");
        return message;
    }
}
```

The second way is to call `Client(...)` on an instance of IHubContext<T>:

C#

```
async Task SomeMethod(IHubContext<MyHub> context)
{
    string result = await
context.Clients.Client(connectionID).InvokeAsync<string>(
        "GetMessage");
}
```

Strongly-typed hubs can also return values from interface methods:

C#

```
public interface IClient
{
    Task<string> GetMessage();
}

public class ChatHub : Hub<IClient>
{
    public async Task<string> WaitForMessage(string connectionId)
    {
        string message = await Clients.Client(connectionId).GetMessage();
        return message;
```

```
    }
}
```

Clients return results in their `.On(...)` handlers, as shown below:

.NET client

C#

```
hubConnection.On("GetMessage", async () =>
{
    Console.WriteLine("Enter message:");
    var message = await Console.In.ReadLineAsync();
    return message;
});
```

Typescript client

TypeScript

```
hubConnection.on("GetMessage", async () => {
    let promise = new Promise((resolve, reject) => {
        setTimeout(() => {
            resolve("message");
        }, 100);
    });
    return promise;
});
```

Java client

Java

```
hubConnection.onWithResult("GetMessage", () -> {
    return Single.just("message");
});
```

Change the name of a hub method

By default, a server hub method name is the name of the .NET method. To change this default behavior for a specific method, use the HubMethodName attribute. The client should use this name instead of the .NET method name when invoking the method:

C#

```
[HubMethodName("SendMessageToUser")]
public async Task DirectMessage(string user, string message)
    => await Clients.User(user).SendAsync("ReceiveMessage", user, message);
```

Inject services into a hub

Hub constructors can accept services from DI as parameters, which can be stored in properties on the class for use in a hub method.

When injecting multiple services for different hub methods or as an alternative way of writing code, hub methods can also accept services from DI. By default, hub method parameters are inspected and resolved from DI if possible.

C#

```
services.AddSingleton<IDatabaseService, DatabaseServiceImpl>();

// ...

public class ChatHub : Hub
{
    public Task SendMessage(string user, string message, IDatabaseService
dbService)
    {
        var userName = dbService.GetUserName(user);
        return Clients.All.SendAsync("ReceiveMessage", userName, message);
    }
}
```

If implicit resolution of parameters from services isn't desired, disable it with DisableImplicitFromServicesParameters. To explicitly specify which parameters are resolved from DI in hub methods, use the DisableImplicitFromServicesParameters option and use the `[FromServices]` attribute or a custom attribute that implements `IFromServiceMetadata` on the hub method parameters that should be resolved from DI.

C#

```
services.AddSingleton<IDatabaseService, DatabaseServiceImpl>();
services.AddSignalR(options =>
{
    options.DisableImplicitFromServicesParameters = true;
});

// ...
```

```
public class ChatHub : Hub
{
    public Task SendMessage(string user, string message,
        [FromServices] IDatabaseService dbService)
    {
        var userName = dbService.GetUserName(user);
        return Clients.All.SendAsync("ReceiveMessage", userName, message);
    }
}
```

> **Note**
>
> This feature makes use of IServiceProviderIsService, which is optionally implemented by DI implementations. If the app's DI container doesn't support this feature, injecting services into hub methods isn't supported.

Keyed services support in Dependency Injection

Keyed services refers to a mechanism for registering and retrieving Dependency Injection (DI) services using keys. A service is associated with a key by calling AddKeyedSingleton (or `AddKeyedScoped` or `AddKeyedTransient`) to register it. Access a registered service by specifying the key with the [FromKeyedServices] attribute. The following code shows how to use keyed services:

C#

```
using Microsoft.AspNetCore.SignalR;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddKeyedSingleton<ICache, BigCache>("big");
builder.Services.AddKeyedSingleton<ICache, SmallCache>("small");

builder.Services.AddRazorPages();
builder.Services.AddSignalR();

var app = builder.Build();

app.MapRazorPages();
app.MapHub<MyHub>("/myHub");

app.Run();

public interface ICache
{
    object Get(string key);
}
public class BigCache : ICache
```

```
{
    public object Get(string key) => $"Resolving {key} from big cache.";
}

public class SmallCache : ICache
{
    public object Get(string key) => $"Resolving {key} from small cache.";
}

public class MyHub : Hub
{
    public void SmallCacheMethod([FromKeyedServices("small")] ICache cache)
    {
        Console.WriteLine(cache.Get("signalr"));
    }

    public void BigCacheMethod([FromKeyedServices("big")] ICache cache)
    {
        Console.WriteLine(cache.Get("signalr"));
    }
}
```

Handle events for a connection

The SignalR Hubs API provides the OnConnectedAsync and OnDisconnectedAsync virtual methods to manage and track connections. Override the `OnConnectedAsync` virtual method to perform actions when a client connects to the hub, such as adding it to a group:

C#

```
public override async Task OnConnectedAsync()
{
    await Groups.AddToGroupAsync(Context.ConnectionId, "SignalR Users");
    await base.OnConnectedAsync();
}
```

Override the `OnDisconnectedAsync` virtual method to perform actions when a client disconnects. If the client disconnects intentionally, such as by calling `connection.stop()`, the `exception` parameter is set to `null`. However, if the client disconnects due to an error, such as a network failure, the `exception` parameter contains an exception that describes the failure:

C#

```
public override async Task OnDisconnectedAsync(Exception? exception)
{
```

```
    await base.OnDisconnectedAsync(exception);
}
```

RemoveFromGroupAsync doesn't need to be called in OnDisconnectedAsync, it's automatically handled for you.

Handle errors

Exceptions thrown in hub methods are sent to the client that invoked the method. On the JavaScript client, the `invoke` method returns a JavaScript Promise. Clients can attach a `catch` handler to the returned promise or use `try`/`catch` with `async`/`await` to handle exceptions:

JavaScript

```
try {
  await connection.invoke("SendMessage", user, message);
} catch (err) {
  console.error(err);
}
```

Connections aren't closed when a hub throws an exception. By default, SignalR returns a generic error message to the client, as shown in the following example:

Output

```
Microsoft.AspNetCore.SignalR.HubException: An unexpected error occurred
invoking 'SendMessage' on the server.
```

Unexpected exceptions often contain sensitive information, such as the name of a database server in an exception triggered when the database connection fails. SignalR doesn't expose these detailed error messages by default as a security measure. For more information on why exception details are suppressed, see Security considerations in ASP.NET Core SignalR.

If an exceptional condition must be propagated to the client, use the HubException class. If a `HubException` is thrown in a hub method, SignalR **sends the entire exception message to the client**, unmodified:

C#

```
public Task ThrowException()
    => throw new HubException("This error will be sent to the client!");
```

> **Note**
>
> SignalR only sends the `Message` property of the exception to the client. The stack trace and other properties on the exception aren't available to the client.

Send messages from outside a hub

Article • 06/18/2024

The SignalR hub is the core abstraction for sending messages to clients connected to the SignalR server. It's also possible to send messages from other places in your app using the `IHubContext` service. This article explains how to access a SignalR `IHubContext` to send notifications to clients from outside a hub.

> **Note**
>
> The `IHubContext` is for sending notifications to clients, it is not used to call methods on the `Hub`.

View or download sample code (how to download)

Get an instance of `IHubContext`

In ASP.NET Core SignalR, you can access an instance of `IHubContext` via dependency injection. You can inject an instance of `IHubContext` into a controller, middleware, or other DI service. Use the instance to send messages to clients.

Inject an instance of `IHubContext` in a controller

You can inject an instance of `IHubContext` into a controller by adding it to your constructor:

C#

```
public class HomeController : Controller
{
    private readonly IHubContext<NotificationHub> _hubContext;

    public HomeController(IHubContext<NotificationHub> hubContext)
    {
        _hubContext = hubContext;
    }
}
```

With access to an instance of `IHubContext`, call client methods as if you were in the hub itself:

C#

```
public async Task<IActionResult> Index()
{
    await _hubContext.Clients.All.SendAsync("Notify", $"Home page loaded at:
{DateTime.Now}");
    return View();
}
```

Get an instance of `IHubContext` in middleware

Access the `IHubContext` within the middleware pipeline like so:

C#

```
app.Use(async (context, next) =>
{
    var hubContext = context.RequestServices
                            .GetRequiredService<IHubContext<ChatHub>>();
    //...

    if (next != null)
    {
        await next.Invoke();
    }
});
```

> ⓘ Note
>
> When client methods are called from outside of the `Hub` class, there's no caller associated with the invocation. Therefore, there's no access to the `ConnectionId`, `Caller`, and `Others` properties.
>
> Apps that need to map a user to the connection ID and persist that mapping can do one of the following:
>
> - Persist mapping of single or multiple connections as groups. See Groups in SignalR for more information.
> - Retain connection and user information through a singleton service. See Inject services into a hub for more information. The singleton service can use any storage method, such as:
>   - In-memory storage in a dictionary.
>   - Permanent external storage. For example, a database or Azure Table storage using the Azure.Data.Tables NuGet package.

- Pass the connection ID between clients.

Get an instance of `IHubContext` from IHost

Accessing an `IHubContext` from the web host is useful for integrating with areas outside of ASP.NET Core, for example, using third-party dependency injection frameworks:

C#

```
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();
            var hubContext =
host.Services.GetService(typeof(IHubContext<ChatHub>));
            host.Run();
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder => {
                    webBuilder.UseStartup<Startup>();
                });
    }
```

Inject a strongly-typed HubContext

To inject a strongly-typed HubContext, ensure your Hub inherits from `Hub<T>`. Inject it using the `IHubContext<THub, T>` interface rather than `IHubContext<THub>`.

C#

```
public class ChatController : Controller
{
    public IHubContext<ChatHub, IChatClient> _strongChatHubContext { get; }

    public ChatController(IHubContext<ChatHub, IChatClient> chatHubContext)
    {
        _strongChatHubContext = chatHubContext;
    }

    public async Task SendMessage(string user, string message)
    {
        await _strongChatHubContext.Clients.All.ReceiveMessage(user,
message);
```

```
    }
}
```

See Strongly typed hubs for more information.

Use `IHubContext` in generic code

An injected `IHubContext<THub>` instance can be cast to `IHubContext` without a generic `Hub` type specified.

C#

```
class MyHub : Hub
{ }

class MyOtherHub : Hub
{ }

app.Use(async (context, next) =>
{
    var myHubContext = context.RequestServices
                              .GetRequiredService<IHubContext<MyHub>>();
    var myOtherHubContext = context.RequestServices
                              .GetRequiredService<IHubContext<MyOtherHub>>();
    await CommonHubContextMethod((IHubContext)myHubContext);
    await CommonHubContextMethod((IHubContext)myOtherHubContext);

    await next.Invoke();
}

async Task CommonHubContextMethod(IHubContext context)
{
    await context.Clients.All.SendAsync("clientMethod", new Args());
}
```

This is useful when:

- Writing libraries that don't have a reference to the specific `Hub` type the app is using.
- Writing code that is generic and can apply to multiple different `Hub` implementations

Manage users and groups in SignalR

Article • 06/18/2024

By Brennan Conroy

SignalR allows messages to be sent to all connections associated with a specific user and to named groups of connections.

View or download sample code (how to download)

Users in SignalR

A single user in SignalR can have multiple connections to an app. For example, a user could be connected on their desktop as well as their phone. Each device has a separate SignalR connection, but they're all associated with the same user. If a message is sent to the user, all of the connections associated with that user receive the message. The user identifier for a connection can be accessed by the `Context.UserIdentifier` property in the hub.

By default, SignalR uses the `ClaimTypes.NameIdentifier` from the `ClaimsPrincipal` associated with the connection as the user identifier. To customize this behavior, see Use claims to customize identity handling.

Send a message to a specific user by passing the user identifier to the `User` function in a hub method, as shown in the following example:

> **Note**
>
> The user identifier is case-sensitive.

C#

```
public Task SendPrivateMessage(string user, string message)
{
    return Clients.User(user).SendAsync("ReceiveMessage", message);
}
```

Groups in SignalR

A group is a collection of connections associated with a name. Messages can be sent to all connections in a group. Groups are the recommended way to send to a connection or multiple connections because the groups are managed by the application. A connection can be a member of multiple groups. Groups are ideal for something like a chat application, where each room can be represented as a group.

Add or remove connections from a group

Connections are added to or removed from groups via the `AddToGroupAsync` and `RemoveFromGroupAsync` methods:

C#

```
public async Task AddToGroup(string groupName)
{
    await Groups.AddToGroupAsync(Context.ConnectionId, groupName);

    await Clients.Group(groupName).SendAsync("Send", $"
{Context.ConnectionId} has joined the group {groupName}.");
}

public async Task RemoveFromGroup(string groupName)
{
    await Groups.RemoveFromGroupAsync(Context.ConnectionId, groupName);

    await Clients.Group(groupName).SendAsync("Send", $"
{Context.ConnectionId} has left the group {groupName}.");
}
```

It's safe to add a user to a group multiple times, no exception is thrown in the case that the user already exists in the group.

Group membership isn't preserved when a connection reconnects. The connection needs to rejoin the group when it's re-established. It's not possible to count the members of a group, since this information isn't available if the application is scaled to multiple servers.

Groups are kept in memory, so they won't persist through a server restart. Consider the Azure SignalR service for scenarios requiring group membership to be persisted. For more information, see Azure SignalR

To protect access to resources while using groups, use authentication and authorization functionality in ASP.NET Core. If a user is added to a group only when the credentials are valid for that group, messages sent to that group will only go to authorized users. However, groups are not a security feature. Authentication claims have features that

groups don't, such as expiry and revocation. If a user's permission to access the group is revoked, the app must remove the user from the group explicitly.

> **Note**
>
> Group names are case-sensitive.

SignalR API design considerations

Article • 06/18/2024

By Andrew Stanton-Nurse

This article provides guidance for building SignalR-based APIs.

Use custom object parameters to ensure backwards-compatibility

Adding parameters to a SignalR hub method (on either the client or the server) is a *breaking change*. This means older clients/servers will get errors when they try to invoke the method without the appropriate number of parameters. However, adding properties to a custom object parameter is **not** a breaking change. This can be used to design compatible APIs that are resilient to changes on the client or the server.

For example, consider a server-side API like the following:

C#

```
public int GetTotalLength(string param1)
{
    return param1.Length;
}
```

The JavaScript client calls this method using `invoke` as follows:

TypeScript

```
connection.invoke("GetTotalLength", "value1");
```

If you later add a second parameter to the server method, older clients won't provide this parameter value. For example:

C#

```
public int GetTotalLength(string param1, string param2)
{
    return param1.Length + param2.Length;
}
```

When the old client tries to invoke this method, it will get an error like this:

```
Microsoft.AspNetCore.SignalR.HubException: Failed to invoke 'GetTotalLength'
due to an error on the server.
```

On the server, you'll see a log message like this:

```
System.IO.InvalidDataException: Invocation provides 1 argument(s) but target
expects 2.
```

The old client only sent one parameter, but the newer server API required two parameters. Using custom objects as parameters gives you more flexibility. Let's redesign the original API to use a custom object:

C#

```
public class TotalLengthRequest
{
    public string Param1 { get; set; }
}

public int GetTotalLength(TotalLengthRequest req)
{
    return req.Param1.Length;
}
```

Now, the client uses an object to call the method:

TypeScript

```
connection.invoke("GetTotalLength", { param1: "value1" });
```

Instead of adding a parameter, add a property to the `TotalLengthRequest` object:

C#

```
public class TotalLengthRequest
{
    public string Param1 { get; set; }
    public string Param2 { get; set; }
}

public int GetTotalLength(TotalLengthRequest req)
{
```

```
    var length = req.Param1.Length;
    if (req.Param2 != null)
    {
        length += req.Param2.Length;
    }
    return length;
}
```

When the old client sends a single parameter, the extra `Param2` property will be left `null`. You can detect a message sent by an older client by checking the `Param2` for `null` and apply a default value. A new client can send both parameters.

TypeScript

```
connection.invoke("GetTotalLength", { param1: "value1", param2: "value2" });
```

The same technique works for methods defined on the client. You can send a custom object from the server side:

C#

```
public async Task Broadcast(string message)
{
    await Clients.All.SendAsync("ReceiveMessage", new
    {
        Message = message
    });
}
```

On the client side, you access the `Message` property rather than using a parameter:

TypeScript

```
connection.on("ReceiveMessage", (req) => {
    appendMessageToChatWindow(req.message);
});
```

If you later decide to add the sender of the message to the payload, add a property to the object:

C#

```
public async Task Broadcast(string message)
{
    await Clients.All.SendAsync("ReceiveMessage", new
    {
        Sender = Context.User.Identity.Name,
```

```
        Message = message
    });
}
```

The older clients won't be expecting the `Sender` value, so they'll ignore it. A new client can accept it by updating to read the new property:

TypeScript

```
connection.on("ReceiveMessage", (req) => {
    let message = req.message;
    if (req.sender) {
        message = req.sender + ": " + message;
    }
    appendMessageToChatWindow(message);
});
```

In this case, the new client is also tolerant of an old server that doesn't provide the `Sender` value. Since the old server won't provide the `Sender` value, the client checks to see if it exists before accessing it.

Use hub filters in ASP.NET Core SignalR

Article • 06/18/2024

Hub filters:

- Are available in ASP.NET Core 5.0 or later.
- Allow logic to run before and after hub methods are invoked by clients.

This article provides guidance for writing and using hub filters.

Configure hub filters

Hub filters can be applied globally or per hub type. The order in which filters are added is the order in which the filters run. Global hub filters run before local hub filters.

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR(options =>
    {
        // Global filters will run first
        options.AddFilter<CustomFilter>();
    }).AddHubOptions<ChatHub>(options =>
    {
        // Local filters will run second
        options.AddFilter<CustomFilter2>();
    });
}
```

A hub filter can be added in one of the following ways:

- Add a filter by concrete type:

  C#

  ```
  hubOptions.AddFilter<TFilter>();
  ```

  This will be resolved from dependency injection (DI) or type activated.

- Add a filter by runtime type:

  C#

```
hubOptions.AddFilter(typeof(TFilter));
```

This will be resolved from DI or type activated.

- Add a filter by instance:

```
C#
hubOptions.AddFilter(new MyFilter());
```

This instance will be used like a singleton. All hub method invocations will use the same instance.

Hub filters are created and disposed per hub invocation. If you want to store global state in the filter, or no state, add the hub filter type to DI as a singleton for better performance. Alternatively, add the filter as an instance if you can.

Create hub filters

Create a filter by declaring a class that inherits from `IHubFilter`, and add the `InvokeMethodAsync` method. There is also `OnConnectedAsync` and `OnDisconnectedAsync` that can optionally be implemented to wrap the `OnConnectedAsync` and `OnDisconnectedAsync` hub methods respectively.

```
C#
public class CustomFilter : IHubFilter
{
    public async ValueTask<object> InvokeMethodAsync(
        HubInvocationContext invocationContext, Func<HubInvocationContext,
ValueTask<object>> next)
    {
        Console.WriteLine($"Calling hub method
'{invocationContext.HubMethodName}'");
        try
        {
            return await next(invocationContext);
        }
        catch (Exception ex)
        {
            Console.WriteLine($"Exception calling
'{invocationContext.HubMethodName}': {ex}");
            throw;
        }
    }
```

```
    // Optional method
    public Task OnConnectedAsync(HubLifetimeContext context,
Func<HubLifetimeContext, Task> next)
    {
        return next(context);
    }

    // Optional method
    public Task OnDisconnectedAsync(
        HubLifetimeContext context, Exception exception,
Func<HubLifetimeContext, Exception, Task> next)
    {
        return next(context, exception);
    }
}
```

Filters are very similar to middleware. The `next` method invokes the next filter. The final filter will invoke the hub method. Filters can also store the result from awaiting `next` and run logic after the hub method has been called before returning the result from `next`.

To skip a hub method invocation in a filter, throw an exception of type `HubException` instead of calling `next`. The client will receive an error if it was expecting a result.

Use hub filters

When writing the filter logic, try to make it generic by using attributes on hub methods instead of checking for hub method names.

Consider a filter that will check a hub method argument for banned phrases and replace any phrases it finds with `***`. For this example, assume a `LanguageFilterAttribute` class is defined. The class has a property named `FilterArgument` that can be set when using the attribute.

1. Place the attribute on the hub method that has a string argument to be cleaned:

   C#

   ```
   public class ChatHub
   {
       [LanguageFilter(filterArgument = 0)]
       public async Task SendMessage(string message, string username)
       {
           await Clients.All.SendAsync("SendMessage", $"{username} says:
   {message}");
       }
   }
   ```

2. Define a hub filter to check for the attribute and replace banned phrases in a hub method argument with `***`:

```
C#
```

```
public class LanguageFilter : IHubFilter
{
    // populated from a file or inline
    private List<string> bannedPhrases = new List<string> { "async
void", ".Result" };

    public async ValueTask<object>
InvokeMethodAsync(HubInvocationContext invocationContext,
        Func<HubInvocationContext, ValueTask<object>> next)
    {
        var languageFilter =
(LanguageFilterAttribute)Attribute.GetCustomAttribute(
            invocationContext.HubMethod,
typeof(LanguageFilterAttribute));
        if (languageFilter != null &&
            invocationContext.HubMethodArguments.Count >
languageFilter.FilterArgument &&

invocationContext.HubMethodArguments[languageFilter.FilterArgument] is
string str)
        {
            foreach (var bannedPhrase in bannedPhrases)
            {
                str = str.Replace(bannedPhrase, "***");
            }

            var arguments =
invocationContext.HubMethodArguments.ToArray();
            arguments[languageFilter.FilterArgument] = str;
            invocationContext = new
HubInvocationContext(invocationContext.Context,
                invocationContext.ServiceProvider,
                invocationContext.Hub,
                invocationContext.HubMethod,
                arguments);
        }

        return await next(invocationContext);
    }
}
```

3. Register the hub filter in the `Startup.ConfigureServices` method. To avoid reinitializing the banned phrases list for every invocation, the hub filter is registered as a singleton:

```
C#
```

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddSignalR(hubOptions =>
    {
        hubOptions.AddFilter<LanguageFilter>();
    });

    services.AddSingleton<LanguageFilter>();
}
```

The HubInvocationContext object

The `HubInvocationContext` contains information for the current hub method invocation.

Expand table

Property	Description	Type
`Context`	The `HubCallerContext` contains information about the connection.	`HubCallerContext`
`Hub`	The instance of the Hub being used for this hub method invocation.	`Hub`
`HubMethodName`	The name of the hub method being invoked.	`string`
`HubMethodArguments`	The list of arguments being passed to the hub method.	`IReadOnlyList<string>`
`ServiceProvider`	The scoped service provider for this hub method invocation.	`IServiceProvider`
`HubMethod`	The hub method information.	`MethodInfo`

The HubLifetimeContext object

The `HubLifetimeContext` contains information for the `OnConnectedAsync` and `OnDisconnectedAsync` hub methods.

Expand table

Property	Description	Type
`Context`	The `HubCallerContext` contains information about the connection.	`HubCallerContext`

Property	Description	Type
`Hub`	The instance of the Hub being used for this hub method invocation.	`Hub`
`ServiceProvider`	The scoped service provider for this hub method invocation.	`IServiceProvider`

Authorization and filters

Authorize attributes on hub methods run before hub filters.

ASP.NET Core SignalR clients

Article • 06/18/2024

Versioning, support, and compatibility

The SignalR clients ship alongside the server components and are versioned to match. Any supported client can safely connect to any supported server, and any compatibility issues would be considered bugs to be fixed. SignalR clients are supported in the same support lifecycle as the rest of .NET Core. See the .NET Core Support Policy for details.

Many features require a compatible client **and** server. See below for a table showing the minimum versions for various features.

The 1.x versions of SignalR map to the 2.1 and 2.2 .NET Core releases and have the same lifetime. For version 3.x and above, the SignalR version exactly matches the rest of .NET and has the same support lifecycle.

Expand table

SignalR version	.NET Core version	Support level	End of support
1.0.x	2.1.x	Long Term Support	August 21, 2021
1.1.x	2.2.x	End Of Life	December 23, 2019
3.x or higher	*same as SignalR version*	See the the .NET Core Support Policy	

NOTE: In ASP.NET Core 3.0, the JavaScript client *moved* to the `@microsoft/signalr` npm package.

Feature distribution

The table below shows the features and support for the clients that offer real-time support. For each feature, the *minimum* version supporting this feature is listed. If no version is listed, the feature isn't supported.

Expand table

Feature	Server	.NET client	JavaScript client	Java client
Azure SignalR Service Support	2.1.0	1.0.0	1.0.0	1.0.0
Server-to-client Streaming	2.1.0	1.0.0	1.0.0	1.0.0
Client-to-server Streaming	3.0.0	3.0.0	3.0.0	3.0.0
Automatic Reconnection (.NET, JavaScript)	3.0.0	3.0.0	3.0.0	❌
WebSockets Transport	2.1.0	1.0.0	1.0.0	1.0.0
Server-Sent Events Transport	2.1.0	1.0.0	1.0.0	❌
Long Polling Transport	2.1.0	1.0.0	1.0.0	3.0.0
JSON Hub Protocol	2.1.0	1.0.0	1.0.0	1.0.0
MessagePack Hub Protocol	2.1.0	1.0.0	1.0.0	5.0.0
Client Results	7.0.0	7.0.0	7.0.0	7.0.0

Support for enabling additional client features is tracked in our issue tracker.

Browsers that don't support ECMAScript 6 (ES6)

SignalR targets ES6. For browsers that don't support ES6, transpile the library to ES5. For more information, see Getting Started with ES6 – Transpiling ES6 to ES5 with Traceur and Babel.

ASP.NET Core SignalR .NET Client

Article • 06/18/2024

The ASP.NET Core SignalR .NET client library lets you communicate with SignalR hubs from .NET apps.

View or download sample code (how to download)

The code sample in this article is a WPF app that uses the ASP.NET Core SignalR .NET client.

Install the SignalR .NET client package

The Microsoft.AspNetCore.SignalR.Client package is required for .NET clients to connect to SignalR hubs.

Visual Studio

To install the client library, run the following command in the **Package Manager Console** window:

PowerShell

```
Install-Package Microsoft.AspNetCore.SignalR.Client
```

Connect to a hub

To establish a connection, create a `HubConnectionBuilder` and call `Build`. The hub URL, protocol, transport type, log level, headers, and other options can be configured while building a connection. Configure any required options by inserting any of the `HubConnectionBuilder` methods into `Build`. Start the connection with `StartAsync`.

C#

```
using System;
using System.Threading.Tasks;
using System.Windows;
using Microsoft.AspNetCore.SignalR.Client;

namespace SignalRChatClient
{
    public partial class MainWindow : Window
```

```
    {
        HubConnection connection;
        public MainWindow()
        {
            InitializeComponent();

            connection = new HubConnectionBuilder()
                .WithUrl("http://localhost:53353/ChatHub")
                .Build();

            connection.Closed += async (error) =>
            {
                await Task.Delay(new Random().Next(0,5) * 1000);
                await connection.StartAsync();
            };
        }

        private async void connectButton_Click(object sender,
RoutedEventArgs e)
        {
            connection.On<string, string>("ReceiveMessage", (user, message)
=>
            {
                this.Dispatcher.Invoke(() =>
                {
                   var newMessage = $"{user}: {message}";
                   messagesList.Items.Add(newMessage);
                });
            });

            try
            {
                await connection.StartAsync();
                messagesList.Items.Add("Connection started");
                connectButton.IsEnabled = false;
                sendButton.IsEnabled = true;
            }
            catch (Exception ex)
            {
                messagesList.Items.Add(ex.Message);
            }
        }

        private async void sendButton_Click(object sender, RoutedEventArgs
e)
        {
            try
            {
                await connection.InvokeAsync("SendMessage",
                    userTextBox.Text, messageTextBox.Text);
            }
            catch (Exception ex)
            {
                messagesList.Items.Add(ex.Message);
            }
```

```
        }
    }
}
```

Handle lost connection

Automatically reconnect

The HubConnection can be configured to automatically reconnect using the `WithAutomaticReconnect` method on the HubConnectionBuilder. It won't automatically reconnect by default.

C#

```
HubConnection connection= new HubConnectionBuilder()
    .WithUrl(new Uri("http://127.0.0.1:5000/chathub"))
    .WithAutomaticReconnect()
    .Build();
```

Without any parameters, `WithAutomaticReconnect()` configures the client to wait 0, 2, 10, and 30 seconds respectively before trying each reconnect attempt, stopping after four failed attempts.

Before starting any reconnect attempts, the `HubConnection` will transition to the `HubConnectionState.Reconnecting` state and fire the `Reconnecting` event. This provides an opportunity to warn users that the connection has been lost and to disable UI elements. Non-interactive apps can start queuing or dropping messages.

C#

```
connection.Reconnecting += error =>
{
    Debug.Assert(connection.State == HubConnectionState.Reconnecting);

    // Notify users the connection was lost and the client is reconnecting.
    // Start queuing or dropping messages.

    return Task.CompletedTask;
};
```

If the client successfully reconnects within its first four attempts, the `HubConnection` will transition back to the `Connected` state and fire the `Reconnected` event. This provides an

opportunity to inform users the connection has been reestablished and dequeue any queued messages.

Since the connection looks entirely new to the server, a new `ConnectionId` will be provided to the `Reconnected` event handlers.

> ⚠ **Warning**
>
> The `Reconnected` event handler's `connectionId` parameter will be null if the `HubConnection` was configured to skip negotiation.

C#

```
connection.Reconnected += connectionId =>
{
    Debug.Assert(connection.State == HubConnectionState.Connected);

    // Notify users the connection was reestablished.
    // Start dequeuing messages queued while reconnecting if any.

    return Task.CompletedTask;
};
```

`WithAutomaticReconnect()` won't configure the `HubConnection` to retry initial start failures, so start failures need to be handled manually:

C#

```
public static async Task<bool> ConnectWithRetryAsync(HubConnection
connection, CancellationToken token)
{
    // Keep trying to until we can start or the token is canceled.
    while (true)
    {
        try
        {
            await connection.StartAsync(token);
            Debug.Assert(connection.State == HubConnectionState.Connected);
            return true;
        }
        catch when (token.IsCancellationRequested)
        {
            return false;
        }
        catch
        {
            // Failed to connect, trying again in 5000 ms.
            Debug.Assert(connection.State ==
```

```
HubConnectionState.Disconnected);
            await Task.Delay(5000);
        }
    }
}
```

If the client doesn't successfully reconnect within its first four attempts, the `HubConnection` will transition to the `Disconnected` state and fire the Closed event. This provides an opportunity to attempt to restart the connection manually or inform users the connection has been permanently lost.

C#

```
connection.Closed += error =>
{
    Debug.Assert(connection.State == HubConnectionState.Disconnected);

    // Notify users the connection has been closed or manually try to
restart the connection.

    return Task.CompletedTask;
};
```

In order to configure a custom number of reconnect attempts before disconnecting or change the reconnect timing, `WithAutomaticReconnect` accepts an array of numbers representing the delay in milliseconds to wait before starting each reconnect attempt.

C#

```
HubConnection connection= new HubConnectionBuilder()
    .WithUrl(new Uri("http://127.0.0.1:5000/chathub"))
    .WithAutomaticReconnect(new[] { TimeSpan.Zero, TimeSpan.Zero,
TimeSpan.FromSeconds(10) })
    .Build();

    // .WithAutomaticReconnect(new[] { TimeSpan.Zero,
TimeSpan.FromSeconds(2), TimeSpan.FromSeconds(10), TimeSpan.FromSeconds(30)
}) yields the default behavior.
```

The preceding example configures the `HubConnection` to start attempting reconnects immediately after the connection is lost. This is also true for the default configuration.

If the first reconnect attempt fails, the second reconnect attempt will also start immediately instead of waiting 2 seconds like it would in the default configuration.

If the second reconnect attempt fails, the third reconnect attempt will start in 10 seconds which is again like the default configuration.

The custom behavior then diverges again from the default behavior by stopping after the third reconnect attempt failure. In the default configuration there would be one more reconnect attempt in another 30 seconds.

If you want even more control over the timing and number of automatic reconnect attempts, `WithAutomaticReconnect` accepts an object implementing the `IRetryPolicy` interface, which has a single method named `NextRetryDelay`.

`NextRetryDelay` takes a single argument with the type `RetryContext`. The `RetryContext` has three properties: `PreviousRetryCount`, `ElapsedTime` and `RetryReason`, which are a `long`, a `TimeSpan` and an `Exception` respectively. Before the first reconnect attempt, both `PreviousRetryCount` and `ElapsedTime` will be zero, and the `RetryReason` will be the Exception that caused the connection to be lost. After each failed retry attempt, `PreviousRetryCount` will be incremented by one, `ElapsedTime` will be updated to reflect the amount of time spent reconnecting so far, and the `RetryReason` will be the Exception that caused the last reconnect attempt to fail.

`NextRetryDelay` must return either a TimeSpan representing the time to wait before the next reconnect attempt or `null` if the `HubConnection` should stop reconnecting.

C#

```
public class RandomRetryPolicy : IRetryPolicy
{
    private readonly Random _random = new Random();

    public TimeSpan? NextRetryDelay(RetryContext retryContext)
    {
        // If we've been reconnecting for less than 60 seconds so far,
        // wait between 0 and 10 seconds before the next reconnect attempt.
        if (retryContext.ElapsedTime < TimeSpan.FromSeconds(60))
        {
            return TimeSpan.FromSeconds(_random.NextDouble() * 10);
        }
        else
        {
            // If we've been reconnecting for more than 60 seconds so far,
stop reconnecting.
            return null;
        }
    }
}
```

C#

```
HubConnection connection = new HubConnectionBuilder()
    .WithUrl(new Uri("http://127.0.0.1:5000/chathub"))
```

```
    .WithAutomaticReconnect(new RandomRetryPolicy())
    .Build();
```

Alternatively, you can write code that will reconnect your client manually as demonstrated in Manually reconnect.

Manually reconnect

Use the Closed event to respond to a lost connection. For example, you might want to automate reconnection.

The `Closed` event requires a delegate that returns a `Task`, which allows async code to run without using `async void`. To satisfy the delegate signature in a `Closed` event handler that runs synchronously, return `Task.CompletedTask`:

C#

```
connection.Closed += (error) => {
    // Do your close logic.
    return Task.CompletedTask;
};
```

The main reason for the async support is so you can restart the connection. Starting a connection is an async action.

In a `Closed` handler that restarts the connection, consider waiting for some random delay to prevent overloading the server, as shown in the following example:

C#

```
connection.Closed += async (error) =>
{
    await Task.Delay(new Random().Next(0,5) * 1000);
    await connection.StartAsync();
};
```

Call hub methods from client

`InvokeAsync` calls methods on the hub. Pass the hub method name and any arguments defined in the hub method to `InvokeAsync`. SignalR is asynchronous, so use `async` and `await` when making the calls.

C#

```
await connection.InvokeAsync("SendMessage",
    userTextBox.Text, messageTextBox.Text);
```

The `InvokeAsync` method returns a `Task` which completes when the server method returns. The return value, if any, is provided as the result of the `Task`. Any exceptions thrown by the method on the server produce a faulted `Task`. Use `await` syntax to wait for the server method to complete and `try...catch` syntax to handle errors.

The `SendAsync` method returns a `Task` which completes when the message has been sent to the server. No return value is provided since this `Task` doesn't wait until the server method completes. Any exceptions thrown on the client while sending the message produce a faulted `Task`. Use `await` and `try...catch` syntax to handle send errors.

> **Note**
>
> Calling hub methods from a client is only supported when using the Azure SignalR Service in *Default* mode. For more information, see Frequently Asked Questions (azure-signalr GitHub repository).

Call client methods from hub

Define methods the hub calls using `connection.On` after building, but before starting the connection.

C#

```
connection.On<string, string>("ReceiveMessage", (user, message) =>
{
    this.Dispatcher.Invoke(() =>
    {
        var newMessage = $"{user}: {message}";
        messagesList.Items.Add(newMessage);
    });
});
```

The preceding code in `connection.On` runs when server-side code calls it using the `SendAsync` method.

C#

```
public async Task SendMessage(string user, string message)
{
    await Clients.All.SendAsync("ReceiveMessage", user,message);
}
```

> **Note**
>
> While the hub side of the connection supports strongly-typed messaging, the client must register using the generic method HubConnection.On with the method name. For an example, see Host ASP.NET Core SignalR in background services.

Error handling and logging

Handle errors with a try-catch statement. Inspect the `Exception` object to determine the proper action to take after an error occurs.

C#

```
try
{
    await connection.InvokeAsync("SendMessage",
        userTextBox.Text, messageTextBox.Text);
}
catch (Exception ex)
{
    messagesList.Items.Add(ex.Message);
}
```

ASP.NET Core SignalR Java client

Article • 06/18/2024

By Mikael Mengistu

The Java client enables connecting to an ASP.NET Core SignalR server from Java code, including Android apps. Like the JavaScript client and the .NET client, the Java client enables you to receive and send messages to a hub in real time. The Java client is available in ASP.NET Core 2.2 and later.

The sample Java console app referenced in this article uses the SignalR Java client.

View or download sample code (how to download)

Install the SignalR Java client package

The *signalr-7.0.0* JAR file allows clients to connect to SignalR hubs. To find the latest JAR file version number, see the Maven search results.

If using Gradle, add the following line to the `dependencies` section of your *build.gradle* file:

Gradle

```
implementation 'com.microsoft.signalr:signalr:7.0.0'
```

If using Maven, add the following lines inside the `<dependencies>` element of your `pom.xml` file:

XML

```
<dependency>
    <groupId>com.microsoft.signalr</groupId>
    <artifactId>signalr</artifactId>
    <version>1.0.0</version>
</dependency>
```

Connect to a hub

To establish a `HubConnection`, the `HubConnectionBuilder` should be used. The hub URL and log level can be configured while building a connection. Configure any required

options by calling any of the `HubConnectionBuilder` methods before `build`. Start the connection with `start`.

```
Java

HubConnection hubConnection = HubConnectionBuilder.create(input)
        .build();
```

Call hub methods from client

A call to `send` invokes a hub method. Pass the hub method name and any arguments defined in the hub method to `send`.

```
Java

hubConnection.send("Send", input);
```

> **Note**
>
> Calling hub methods from a client is only supported when using the Azure SignalR Service in *Default* mode. For more information, see Frequently Asked Questions (azure-signalr GitHub repository).

Call client methods from hub

Use `hubConnection.on` to define methods on the client that the hub can call. Define the methods after building but before starting the connection.

```
Java

hubConnection.on("Send", (message) -> {
    System.out.println("New Message: " + message);
}, String.class);
```

Add logging

The SignalR Java client uses the SLF4J library for logging. It's a high-level logging API that allows users of the library to choose their own specific logging implementation by

bringing in a specific logging dependency. The following code snippet shows how to use `java.util.logging` with the SignalR Java client.

Gradle

```
implementation 'org.slf4j:slf4j-jdk14:1.7.25'
```

If you don't configure logging in your dependencies, SLF4J loads a default no-operation logger with the following warning message:

```
SLF4J: Failed to load class "org.slf4j.impl.StaticLoggerBinder".
SLF4J: Defaulting to no-operation (NOP) logger implementation
SLF4J: See http://www.slf4j.org/codes.html#StaticLoggerBinder for further
details.
```

This can safely be ignored.

Android development notes

With regards to Android SDK compatibility for the SignalR client features, consider the following items when specifying your target Android SDK version:

- The SignalR Java Client will run on Android API Level 16 and later.
- Connecting through the Azure SignalR Service will require Android API Level 20 and later because the Azure SignalR Service requires TLS 1.2 and doesn't support SHA-1-based cipher suites. Android added support for SHA-256 (and above) cipher suites in API Level 20.

Configure bearer token authentication

In the SignalR Java client, you can configure a bearer token to use for authentication by providing an "access token factory" to the HttpHubConnectionBuilder. Use withAccessTokenFactory to provide an RxJava Single<String>. With a call to Single.defer, you can write logic to produce access tokens for your client.

Java

```
HubConnection hubConnection = HubConnectionBuilder.create("YOUR HUB URL
HERE")
    .withAccessTokenProvider(Single.defer(() -> {
        // Your logic here.
```

```
        return Single.just("An Access Token");
    })).build();
```

Passing Class information in Java

When calling the `on`, `invoke`, or `stream` methods of `HubConnection` in the Java client, users should pass a `Type` object rather than a `Class<?>` object to describe any generic `Object` passed to the method. A `Type` can be acquired using the provided `TypeReference` class. For example, using a custom generic class named `Foo<T>`, the following code gets the `Type`:

Java

```
Type fooType = new TypeReference<Foo<String>>() { }).getType();
```

For non-generics, such as primitives or other non-parameterized types like `String`, you can simply use the built-in `.class`.

When calling one of these methods with one or more object types, use the generics syntax when invoking the method. For example, when registering an `on` handler for a method named `func`, which takes as arguments a String and a `Foo<String>` object, use the following code to set an action to print the arguments:

Java

```
hubConnection.<String, Foo<String>>on("func", (param1, param2) ->{
    System.out.println(param1);
    System.out.println(param2);
}, String.class, fooType);
```

This convention is necessary because we can not retrieve complete information about complex types with the `Object.getClass` method due to type erasure in Java. For example, calling `getClass` on an `ArrayList<String>` would not return `Class<ArrayList<String>>`, but rather `Class<ArrayList>`, which does not give the deserializer enough information to correctly deserialize an incoming message. The same is true for custom objects.

Known limitations

- Transport fallback and the Server Sent Events transport aren't supported.

ASP.NET Core SignalR JavaScript client

Article • 06/18/2024

By Rachel Appel

The ASP.NET Core SignalR JavaScript client library enables developers to call server-side SignalR hub code.

Install the SignalR client package

The SignalR JavaScript client library is delivered as an npm package. The following sections outline different ways to install the client library.

Install with npm

Visual Studio

Run the following commands from **Package Manager Console**:

Bash

```
npm init -y
npm install @microsoft/signalr
```

npm installs the package contents in the *node_modules\@microsoft\signalr\dist\browser* folder. Create the *wwwroot/lib/signalr* folder. Copy the `signalr.js` file to the *wwwroot/lib/signalr* folder.

Reference the SignalR JavaScript client in the `<script>` element. For example:

HTML

```
<script src="~/lib/signalr/signalr.js"></script>
```

Use a Content Delivery Network (CDN)

To use the client library without the npm prerequisite, reference a CDN-hosted copy of the client library. For example:

HTML

```
<script src="https://cdnjs.cloudflare.com/ajax/libs/microsoft-
signalr/6.0.1/signalr.js"></script>
```

The client library is available on the following CDNs:

- cdnjs
- jsDelivr
- unpkg

Install with LibMan

LibMan can be used to install specific client library files from the CDN-hosted client library. For example, only add the minified JavaScript file to the project. For details on that approach, see Add the SignalR client library.

Connect to a hub

The following code creates and starts a connection. The hub's name is case insensitive:

JavaScript

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging(signalR.LogLevel.Information)
    .build();

async function start() {
    try {
        await connection.start();
        console.log("SignalR Connected.");
    } catch (err) {
        console.log(err);
        setTimeout(start, 5000);
    }
};

connection.onclose(async () => {
    await start();
});

// Start the connection.
start();
```

Cross-origin connections (CORS)

Typically, browsers load connections from the same domain as the requested page. However, there are occasions when a connection to another domain is required.

When making cross domain requests, the client code ***must*** use an absolute URL instead of a relative URL. For cross domain requests, change `.withUrl("/chathub")` to `.withUrl("https://{App domain name}/chathub")`.

To prevent a malicious site from reading sensitive data from another site, cross-origin connections are disabled by default. To allow a cross-origin request, enable CORS:

C#

```
using SignalRChat.Hubs;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddSignalR();

builder.Services.AddCors(options =>
{
    options.AddDefaultPolicy(
        builder =>
        {
            builder.WithOrigins("https://example.com")
                .AllowAnyHeader()
                .WithMethods("GET", "POST")
                .AllowCredentials();
        });
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

// UseCors must be called before MapHub.
app.UseCors();

app.MapRazorPages();
app.MapHub<ChatHub>("/chatHub");
```

```
app.Run();
```

UseCors must be called before calling MapHub.

Call hub methods from the client

JavaScript clients call public methods on hubs via the invoke method of the HubConnection. The `invoke` method accepts:

- The name of the hub method.
- Any arguments defined in the hub method.

In the following highlighted code, the method name on the hub is `SendMessage`. The second and third arguments passed to `invoke` map to the hub method's `user` and `message` arguments:

JavaScript

```
try {
    await connection.invoke("SendMessage", user, message);
} catch (err) {
    console.error(err);
}
```

Calling hub methods from a client is only supported when using the ***Azure SignalR Service in Default*** mode. For more information, see Frequently Asked Questions (azure-signalr GitHub repository).

The `invoke` method returns a JavaScript Promise. The `Promise` is resolved with the return value (if any) when the method on the server returns. If the method on the server throws an error, the `Promise` is rejected with the error message. Use `async` and `await` or the `Promise`'s `then` and `catch` methods to handle these cases.

JavaScript clients can also call public methods on hubs via the send method of the `HubConnection`. Unlike the `invoke` method, the `send` method doesn't wait for a response from the server. The `send` method returns a JavaScript `Promise`. The `Promise` is resolved when the message has been sent to the server. If there is an error sending the message, the `Promise` is rejected with the error message. Use `async` and `await` or the `Promise`'s `then` and `catch` methods to handle these cases.

Using `send` ***doesn't*** wait until the server has received the message. Consequently, it's not possible to return data or errors from the server.

Call client methods from the hub

To receive messages from the hub, define a method using the on method of the `HubConnection`.

- The name of the JavaScript client method.
- Arguments the hub passes to the method.

In the following example, the method name is `ReceiveMessage`. The argument names are `user` and `message`:

JavaScript

```
connection.on("ReceiveMessage", (user, message) => {
    const li = document.createElement("li");
    li.textContent = `${user}: ${message}`;
    document.getElementById("messageList").appendChild(li);
});
```

The preceding code in `connection.on` runs when server-side code calls it using the SendAsync method:

C#

```
using Microsoft.AspNetCore.SignalR;
namespace SignalRChat.Hubs;

public class ChatHub : Hub
{
    public async Task SendMessage(string user, string message)
    {
        await Clients.All.SendAsync("ReceiveMessage", user, message);
    }
}
```

SignalR determines which client method to call by matching the method name and arguments defined in `SendAsync` and `connection.on`.

A **best practice** is to call the start method on the `HubConnection` after `on`. Doing so ensures the handlers are registered before any messages are received.

Error handling and logging

Use `console.error` to output errors to the browser's console when the client can't connect or send a message:

JavaScript

```
try {
    await connection.invoke("SendMessage", user, message);
} catch (err) {
    console.error(err);
}
```

Set up client-side log tracing by passing a logger and type of event to log when the connection is made. Messages are logged with the specified log level and higher. Available log levels are as follows:

- `signalR.LogLevel.Error`: Error messages. Logs `Error` messages only.
- `signalR.LogLevel.Warning`: Warning messages about potential errors. Logs `Warning`, and `Error` messages.
- `signalR.LogLevel.Information`: Status messages without errors. Logs `Information`, `Warning`, and `Error` messages.
- `signalR.LogLevel.Trace`: Trace messages. Logs everything, including data transported between hub and client.

Use the configureLogging method on HubConnectionBuilder to configure the log level. Messages are logged to the browser console:

JavaScript

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging(signalR.LogLevel.Information)
    .build();
```

Reconnect clients

Automatically reconnect

The JavaScript client for SignalR can be configured to automatically reconnect using the WithAutomaticReconnect method on HubConnectionBuilder. It won't automatically reconnect by default.

JavaScript

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
```

```
    .withAutomaticReconnect()
    .build();
```

Without any parameters, WithAutomaticReconnect configures the client to wait 0, 2, 10, and 30 seconds respectively before trying each reconnect attempt. After four failed attempts, it stops trying to reconnect.

Before starting any reconnect attempts, the `HubConnection`:

- Transitions to the HubConnectionState.Reconnecting state and fires its `onreconnecting` callbacks.
- Doesn't transition to the `Disconnected` state and trigger its `onclose` callbacks like a `HubConnection` without automatic reconnect configured.

The reconnect approach provides an opportunity to:

- Warn users that the connection has been lost.
- Disable UI elements.

JavaScript

```
connection.onreconnecting(error => {
    console.assert(connection.state ===
signalR.HubConnectionState.Reconnecting);

    document.getElementById("messageInput").disabled = true;

    const li = document.createElement("li");
    li.textContent = `Connection lost due to error "${error}".
Reconnecting.`;
    document.getElementById("messageList").appendChild(li);
});
```

If the client successfully reconnects within its first four attempts, the `HubConnection` transitions back to the `Connected` state and fire its `onreconnected` callbacks. This provides an opportunity to inform users the connection has been reestablished.

Since the connection looks entirely new to the server, a new `connectionId` is provided to the `onreconnected` callback.

The `onreconnected` callback's `connectionId` parameter is ***undefined*** if the `HubConnection` is configured to skip negotiation.

JavaScript

```
connection.onreconnected(connectionId => {
    console.assert(connection.state ===
signalR.HubConnectionState.Connected);

    document.getElementById("messageInput").disabled = false;

    const li = document.createElement("li");
    li.textContent = `Connection reestablished. Connected with connectionId
"${connectionId}".`;
    document.getElementById("messageList").appendChild(li);
});
```

`withAutomaticReconnect` won't configure the `HubConnection` to retry initial start failures, so start failures need to be handled manually:

JavaScript

```
async function start() {
    try {
        await connection.start();
        console.assert(connection.state ===
signalR.HubConnectionState.Connected);
        console.log("SignalR Connected.");
    } catch (err) {
        console.assert(connection.state ===
signalR.HubConnectionState.Disconnected);
        console.log(err);
        setTimeout(() => start(), 5000);
    }
};
```

If the client doesn't successfully reconnect within its first four attempts, the `HubConnection` transitions to the `Disconnected` state and fires its onclose callbacks. This provides an opportunity to inform users:

- The connection has been permanently lost.
- Try refreshing the page:

JavaScript

```
connection.onclose(error => {
    console.assert(connection.state ===
signalR.HubConnectionState.Disconnected);

    document.getElementById("messageInput").disabled = true;

    const li = document.createElement("li");
    li.textContent = `Connection closed due to error "${error}". Try
refreshing this page to restart the connection.`;
```

```
    document.getElementById("messageList").appendChild(li);
});
```

In order to configure a custom number of reconnect attempts before disconnecting or change the reconnect timing, `withAutomaticReconnect` accepts an array of numbers representing the delay in milliseconds to wait before starting each reconnect attempt.

JavaScript

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withAutomaticReconnect([0, 0, 10000])
    .build();

    // .withAutomaticReconnect([0, 2000, 10000, 30000]) yields the default
behavior
```

The preceding example configures the `HubConnection` to start attempting reconnects immediately after the connection is lost. The default configuration also waits zero seconds to attempt reconnecting.

If the first reconnect attempt fails, the second reconnect attempt also starts immediately instead of waiting 2 seconds using the default configuration.

If the second reconnect attempt fails, the third reconnect attempt start in 10 seconds which is the same as the default configuration.

The configured reconnection timing differs from the default behavior by stopping after the third reconnect attempt failure instead of trying one more reconnect attempt in another 30 seconds.

For more control over the timing and number of automatic reconnect attempts, `withAutomaticReconnect` accepts an object implementing the `IRetryPolicy` interface, which has a single method named `nextRetryDelayInMilliseconds`.

`nextRetryDelayInMilliseconds` takes a single argument with the type `RetryContext`. The `RetryContext` has three properties: `previousRetryCount`, `elapsedMilliseconds` and `retryReason` which are a `number`, a `number` and an `Error` respectively. Before the first reconnect attempt, both `previousRetryCount` and `elapsedMilliseconds` will be zero, and the `retryReason` will be the Error that caused the connection to be lost. After each failed retry attempt, `previousRetryCount` will be incremented by one, `elapsedMilliseconds` will be updated to reflect the amount of time spent reconnecting so far in milliseconds, and the `retryReason` will be the Error that caused the last reconnect attempt to fail.

`nextRetryDelayInMilliseconds` must return either a number representing the number of milliseconds to wait before the next reconnect attempt or `null` if the `HubConnection` should stop reconnecting.

JavaScript

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withAutomaticReconnect({
        nextRetryDelayInMilliseconds: retryContext => {
            if (retryContext.elapsedMilliseconds < 60000) {
                // If we've been reconnecting for less than 60 seconds so
far,
                // wait between 0 and 10 seconds before the next reconnect
attempt.
                return Math.random() * 10000;
            } else {
                // If we've been reconnecting for more than 60 seconds so
far, stop reconnecting.
                return null;
            }
        }
    })
    .build();
```

Alternatively, code can be written that reconnects the client manually as demonstrated in the following section.

Manually reconnect

The following code demonstrates a typical manual reconnection approach:

1. A function (in this case, the `start` function) is created to start the connection.
2. Call the `start` function in the connection's `onclose` event handler.

JavaScript

```
async function start() {
    try {
        await connection.start();
        console.log("SignalR Connected.");
    } catch (err) {
        console.log(err);
        setTimeout(start, 5000);
    }
};

connection.onclose(async () => {
```

```
    await start();
});
```

Production implementations typically use an exponential back-off or retry a specified number of times.

Browser sleeping tab

Some browsers have a tab freezing or sleeping feature to reduce computer resource usage for inactive tabs. This can cause SignalR connections to close and may result in an unwanted user experience. Browsers use heuristics to figure out if a tab should be put to sleep, such as:

- Playing audio
- Holding a web lock
- Holding an `IndexedDB` lock
- Being connected to a USB device
- Capturing video or audio
- Being mirrored
- Capturing a window or display

Browser heuristics may change over time and can differ between browsers. Check the support matrix and figure out what method works best for your scenarios.

To avoid putting an app to sleep, the app should trigger one of the heuristics that the browser uses.

The following code example shows how to use a Web Lock to keep a tab awake and avoid an unexpected connection closure.

JavaScript

```
var lockResolver;
if (navigator && navigator.locks && navigator.locks.request) {
    const promise = new Promise((res) => {
        lockResolver = res;
    });

    navigator.locks.request('unique_lock_name', { mode: "shared" }, () => {
        return promise;
    });
}
```

For the preceding code example:

- Web Locks are experimental. The conditional check confirms that the browser supports Web Locks.
- The promise resolver, `lockResolver`, is stored so that the lock can be released when it's acceptable for the tab to sleep.
- When closing the connection, the lock is released by calling `lockResolver()`. When the lock is released, the tab is allowed to sleep.

@microsoft/signalr package

Reference

Classes

Expand table

DefaultHttpClient	Default implementation of HttpClient.
AbortError	Error thrown when an action is aborted.
HttpError	Error thrown when an HTTP request fails.
TimeoutError	Error thrown when a timeout elapses.
FetchHttpClient	
HeaderNames	
HttpClient	Abstraction over an HTTP client. This class provides an abstraction over an HTTP client so that a different implementation can be provided on different platforms.
HttpResponse	Represents an HTTP response.
HubConnection	Represents a connection to a SignalR Hub.
HubConnectionBuilder	A builder for configuring HubConnection instances.
JsonHubProtocol	Implements the JSON Hub Protocol.
NullLogger	A logger that does nothing when log messages are sent to it.
Subject	Stream implementation to stream items to the server.
XhrHttpClient	

Interfaces

Expand table

AbortSignal	Represents a signal that can be monitored to determine if a request has been aborted.

HttpRequest	Represents an HTTP request.
IHttpConnection Options	Options provided to the 'withUrl' method on HubConnectionBuilder to configure options for the HTTP-based transports.
CancelInvocation Message	A hub message sent to request that a streaming invocation be canceled.
CloseMessage	A hub message indicating that the sender is closing the connection. If error is defined, the sender is closing the connection due to an error.
Completion Message	A hub message representing the result of an invocation.
HubInvocation Message	Defines properties common to all Hub messages relating to a specific invocation.
HubMessageBase	Defines properties common to all Hub messages.
IHubProtocol	A protocol abstraction for communicating with SignalR Hubs.
Invocation Message	A hub message representing a non-streaming invocation.
MessageHeaders	Defines a dictionary of string keys and string values representing headers attached to a Hub message.
PingMessage	A hub message indicating that the sender is still active.
StreamInvocation Message	A hub message representing a streaming invocation.
StreamItem Message	A hub message representing a single item produced as part of a result stream.
ILogger	An abstraction that provides a sink for diagnostic messages.
IRetryPolicy	An abstraction that controls when the client attempts to reconnect and how many times it does so.
RetryContext	
ITransport	An abstraction over the behavior of transports. This is designed to support the framework and not intended for use by applications.
IStreamResult	Defines the result of a streaming hub method.
IStreamSubscriber	Defines the expected type for a receiver of results streamed by the server.
ISubscription	An interface that allows an IStreamSubscriber to be disconnected from a stream.

Type Aliases

Expand table

HubMessage	Union type of all known Hub messages.

Enums

Expand table

HubConnectionState	Describes the current state of the HubConnection to the server.
MessageType	Defines the type of a Hub Message.
LogLevel	Indicates the severity of a log message. Log Levels are ordered in increasing severity. So `Debug` is more severe than `Trace`, etc.
HttpTransportType	Specifies a specific HTTP transport type.
TransferFormat	Specifies the transfer format for a connection.

ASP.NET Core SignalR hosting and scaling

Article • 09/17/2024

By Andrew Stanton-Nurse, Brady Gaster, and Tom Dykstra

This article explains hosting and scaling considerations for high-traffic apps that use ASP.NET Core SignalR.

Sticky Sessions

SignalR requires that all HTTP requests for a specific connection be handled by the same server process. When SignalR is running on a server farm (multiple servers), "sticky sessions" must be used. "Sticky sessions" are also called session affinity. Azure App Service uses Application Request Routing (ARR) to route requests. Enabling the "Session affinity" (ARR Affinity) setting in your Azure App Service enables "sticky sessions." The only circumstances in which sticky sessions aren't required for the app are:

1. When hosting on a single server in a single process.
2. When using the Azure SignalR Service (sticky sessions are enabled for the service, not the app).
3. When all clients are configured to **only** use WebSockets, **and** the SkipNegotiation setting is enabled in the client configuration.

In all other circumstances (including when the Redis backplane is used), the server environment must be configured for sticky sessions.

For guidance on configuring Azure App Service for SignalR, see Publish an ASP.NET Core SignalR app to Azure App Service. For guidance on configuring sticky sessions for Blazor apps that use the Azure SignalR Service, see Host and deploy ASP.NET Core server-side Blazor apps.

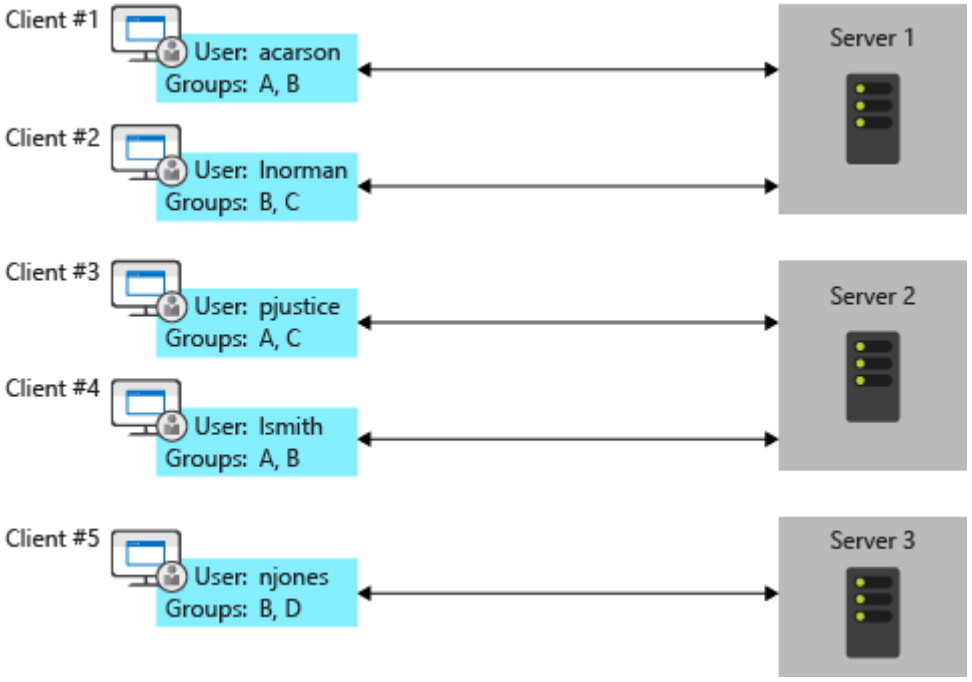
TCP connection resources

The number of concurrent TCP connections that a web server can support is limited. Standard HTTP clients use *ephemeral* connections. These connections can be closed when the client goes idle and reopened later. On the other hand, a SignalR connection is *persistent*. SignalR connections stay open even when the client goes idle. In a high-traffic app that serves many clients, these persistent connections can cause servers to hit their maximum number of connections.

Persistent connections also consume some additional memory, to track each connection.

The heavy use of connection-related resources by SignalR can affect other web apps that are hosted on the same server. When SignalR opens and holds the last available TCP connections, other web apps on the same server also have no more connections available to them.

If a server runs out of connections, you'll see random socket errors and connection reset errors. For example:

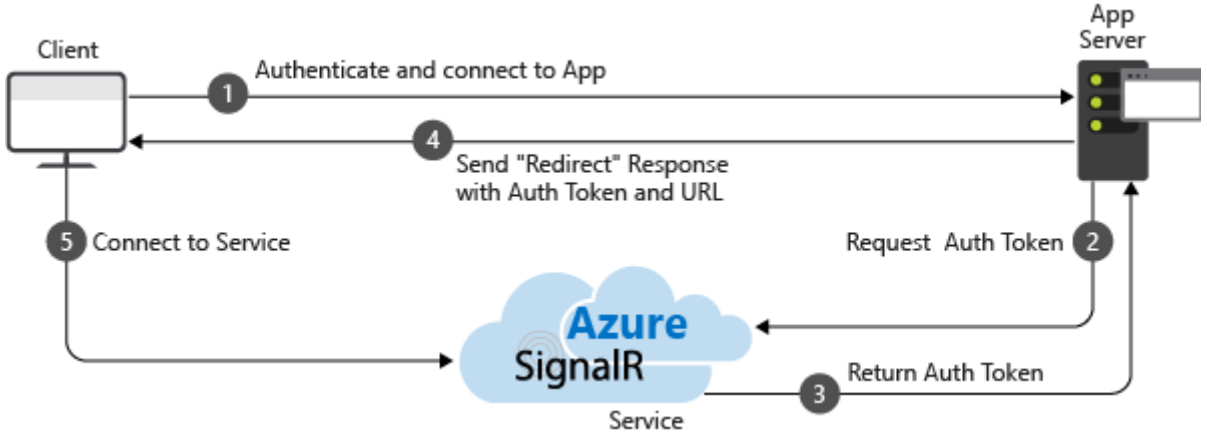


```
An attempt was made to access a socket in a way forbidden by its access permissions...
```

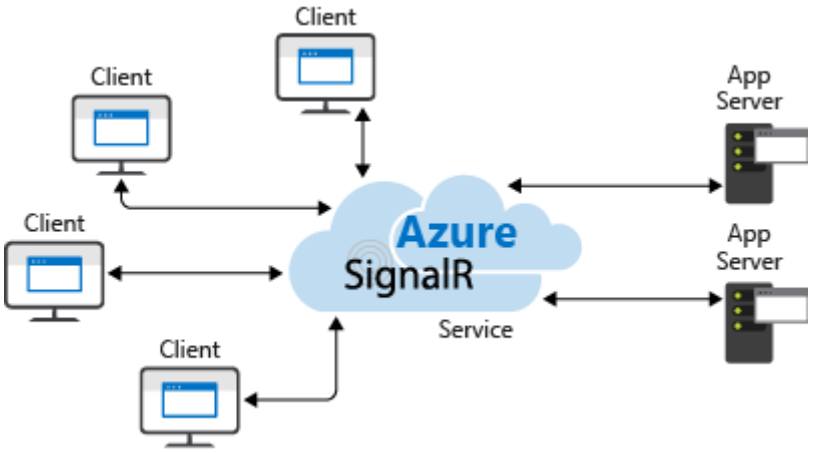
To keep SignalR resource usage from causing errors in other web apps, run SignalR on different servers than your other web apps.

To keep SignalR resource usage from causing errors in a SignalR app, scale out to limit the number of connections a server has to handle.

Scale out



An app that uses SignalR needs to keep track of all its connections, which creates problems for a server farm. Add a server, and it gets new connections that the other servers don't know about. For example, SignalR on each server in the following diagram is unaware of the connections on the other servers. When SignalR on one of the servers wants to send a message to all clients, the message only goes to the clients connected to that server.



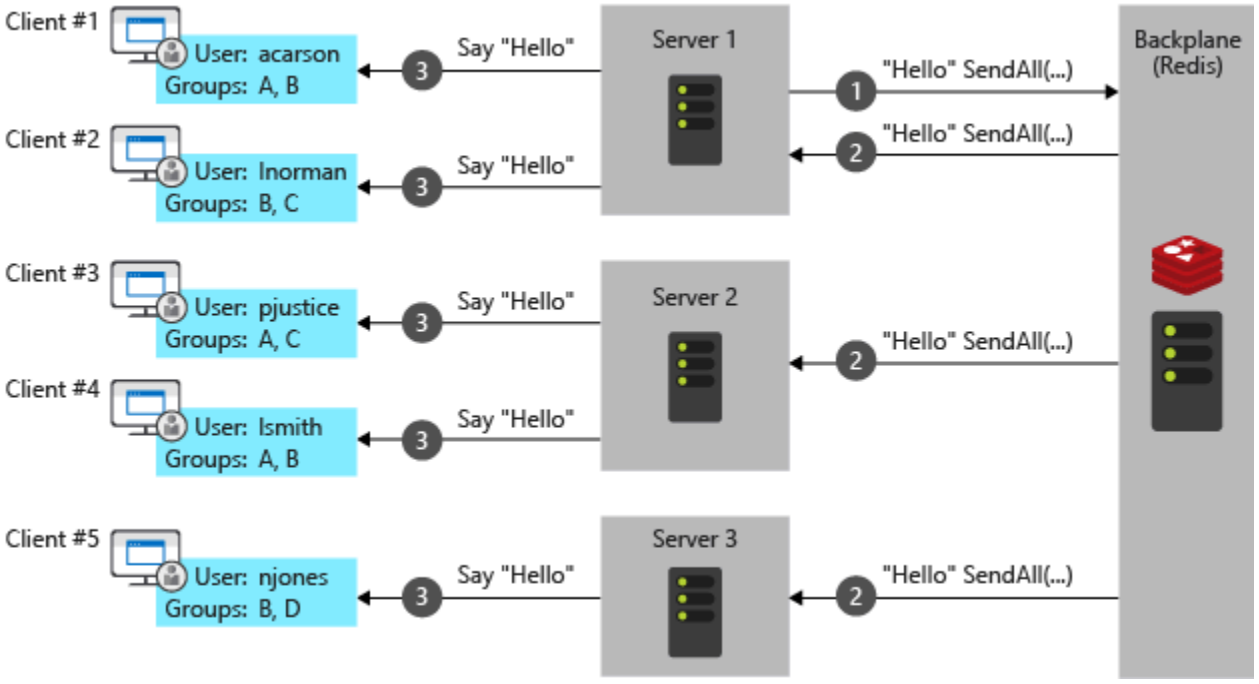
The options for solving this problem are the Azure SignalR Service and Redis backplane.

Azure SignalR Service

The Azure SignalR Service functions as a proxy for real-time traffic and doubles as a backplane when the app is scaled out across multiple servers. Each time a client initiates a connection to the server, the client is redirected to connect to the service. The process is illustrated by the following diagram:

The result is that the service manages all of the client connections, while each server needs only a small constant number of connections to the service, as shown in the following diagram:

This approach to scale-out has several advantages over the Redis backplane alternative:



- Sticky sessions, also known as client affinity, is not required, because clients are immediately redirected to the Azure SignalR Service when they connect.
- A SignalR app can scale out based on the number of messages sent, while the Azure SignalR Service scales to handle any number of connections. For example, there could be thousands of clients, but if only a few messages per second are sent, the SignalR app won't need to scale out to multiple servers just to handle the connections themselves.
- A SignalR app won't use significantly more connection resources than a web app without SignalR.

For these reasons, we recommend the Azure SignalR Service for all ASP.NET Core SignalR apps hosted on Azure, including App Service, VMs, and containers.

For more information see the Azure SignalR Service documentation.

Redis backplane

Redis is an in-memory key-value store that supports a messaging system with a publish/subscribe model. The SignalR Redis backplane uses the pub/sub feature to forward messages to other servers. When a client makes a connection, the connection information is passed to the backplane. When a server wants to send a message to all clients, it sends to the backplane. The backplane knows all connected clients and which servers they're on. It sends the message to all clients via their respective servers. This process is illustrated in the following diagram:

The Redis backplane is the recommended scale-out approach for apps hosted on your own infrastructure. If there is significant connection latency between your data center and an Azure data center, Azure SignalR Service may not be a practical option for on-premises apps with low latency or high throughput requirements.

The Azure SignalR Service advantages noted earlier are disadvantages for the Redis backplane:

- Sticky sessions, also known as client affinity, is required, except when **both** of the following are true:
  - All clients are configured to **only** use WebSockets.
  - The SkipNegotiation setting is enabled in the client configuration. Once a connection is initiated on a server, the connection has to stay on that server.
- A SignalR app must scale out based on number of clients even if few messages are being sent.
- A SignalR app uses significantly more connection resources than a web app without SignalR.

IIS limitations on Windows client OS

Windows 10 and Windows 8.x are client operating systems. IIS on client operating systems has a limit of 10 concurrent connections. SignalR's connections are:

- Transient and frequently re-established.
- **Not** disposed immediately when no longer used.

The preceding conditions make it likely to hit the 10 connection limit on a client OS. When a client OS is used for development, we recommend:

- Avoid IIS.
- Use Kestrel or IIS Express as deployment targets.

Linux with Nginx

The following contains the minimum required settings to enable WebSockets, ServerSentEvents, and LongPolling for SignalR:

nginx

```
http {
  map $http_connection $connection_upgrade {
    "~*Upgrade" $http_connection;
    default keep-alive;
  }

  server {
    listen 80;
    server_name example.com *.example.com;

    # Configure the SignalR Endpoint
    location /hubroute {
      # App server url
      proxy_pass http://localhost:5000;

      # Configuration for WebSockets
      proxy_set_header Upgrade $http_upgrade;
      proxy_set_header Connection $connection_upgrade;
      proxy_cache off;
      # WebSockets were implemented after http/1.0
      proxy_http_version 1.1;

      # Configuration for ServerSentEvents
      proxy_buffering off;

      # Configuration for LongPolling or if your KeepAliveInterval is longer
than 60 seconds
      proxy_read_timeout 100s;

      proxy_set_header Host $host;
      proxy_set_header X-Forwarded-For $proxy_add_x_forwarded_for;
      proxy_set_header X-Forwarded-Proto $scheme;
    }
  }
}
```

When multiple backend servers are used, sticky sessions must be added to prevent SignalR connections from switching servers when connecting. There are multiple ways to

add sticky sessions in Nginx. Two approaches are shown below depending on what you have available.

The following is added in addition to the previous configuration. In the following examples, `backend` is the name of the group of servers.

With Nginx Open Source, use `ip_hash` to route connections to a server based on the client's IP address:

nginx

```
http {
  upstream backend {
    # App server 1
    server localhost:5000;
    # App server 2
    server localhost:5002;

    ip_hash;
  }
}
```

With Nginx Plus, use `sticky` to add a cookie to requests and pin the user's requests to a server:

nginx

```
http {
  upstream backend {
    # App server 1
    server localhost:5000;
    # App server 2
    server localhost:5002;

    sticky cookie srv_id expires=max domain=.example.com path=/ httponly;
  }
}
```

Finally, change `proxy_pass http://localhost:5000` in the `server` section to `proxy_pass http://backend`.

For more information on WebSockets over Nginx, see NGINX as a WebSocket Proxy.

For more information on load balancing and sticky sessions, see NGINX load balancing.

Publish an ASP.NET Core SignalR app to Azure App Service

Article • 09/17/2024

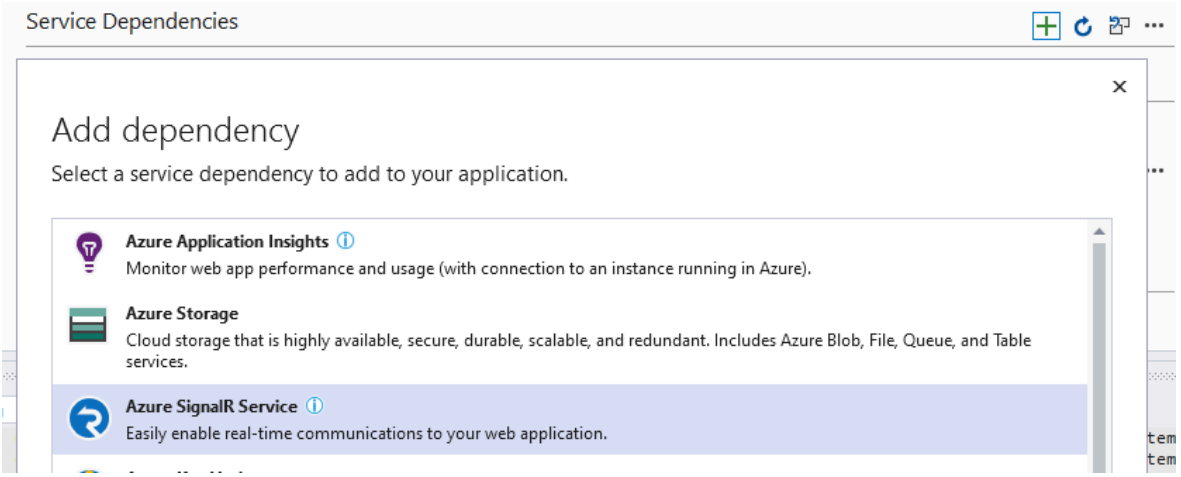
By Brady Gaster

Azure App Service is a Microsoft cloud computing platform service for hosting web apps, including ASP.NET Core.

> **Note**
>
> This article refers to publishing an ASP.NET Core SignalR app from Visual Studio. For more information, see SignalR service for Azure.

Publish the app

This article covers publishing using the tools in Visual Studio. Visual Studio Code users can use Azure CLI commands to publish apps to Azure. For more information, see Publish an ASP.NET Core app to Azure with command line tools.



1. Right-click on the project in **Solution Explorer** and select **Publish**.
2. Confirm that **App Service** and **Create new** are selected in the **Pick a publish target** dialog.
3. Select **Create Profile** from the **Publish** button drop down.

   Enter the information described in the following table in the **Create App Service** dialog and select **Create**.

Expand table

Item	Description
Name	Unique name of the app.
Subscription	Azure subscription that the app uses.
Resource Group	Group of related resources to which the app belongs.
Hosting Plan	Pricing plan for the web app.

4. Select **Azure SignalR Service** in the **Service Dependencies** section. Select the + button:

5. In the **Azure SignalR Service** dialog, select **Create a new Azure SignalR Service instance**.

6. Provide a **Name**, **Resource Group**, and **Location**. Return to the **Azure SignalR Service** dialog and select **Add**.

Visual Studio completes the following tasks:

- Creates a Publish Profile containing publish settings.
- Creates an *Azure Web App* with the provided details.
- Publishes the app.
- Launches a browser, which loads the web app.

The format of the app's URL is `{APP SERVICE NAME}.azurewebsites.net`. For example, an app named `SignalRChatApp` has a URL of `https://signalrchatapp.azurewebsites.net`.

If an HTTP *502.2 - Bad Gateway* error occurs when deploying an app that targets a preview .NET Core release, see Deploy ASP.NET Core preview release to Azure App Service to resolve it.

Configure the app in Azure App Service

> **Note**
>
> *This section only applies to apps not using the Azure SignalR Service.*
>
> If the app uses the Azure SignalR Service, the App Service doesn't require the configuration of WebSockets and session affinity, also called Application Request

Routing (ARR) affinity, described in this section. Clients connect their WebSockets to the Azure SignalR Service, not directly to the app.

For apps hosted without the Azure SignalR Service, enable:

- WebSockets to allow the WebSockets transport to function. The default setting is **Off**.
- Session affinity (ARR affinity) to route requests from a user back to the same App Service instance. The default setting is **On**.

1. In the Azure portal, navigate to the web app in **App Services**.
2. Open **Settings** > **Configuration**.
3. Set **Web sockets** to **On**.
4. Verify that **Session affinity** is set to **On**.

App Service Plan limits

WebSockets and other transports are limited based on the App Service Plan selected. For more information, see the *Azure Cloud Services limits* and *App Service limits* sections of the Azure subscription and service limits, quotas, and constraints article.

Set up a Redis backplane for ASP.NET Core SignalR scale-out

Article • 11/04/2024

By Andrew Stanton-Nurse, Brady Gaster, and Tom Dykstra.

This article explains SignalR-specific aspects of setting up a Redis server to use for scaling out an ASP.NET Core SignalR app.

> ⚠ **Warning**
>
> This article shows the use of connection strings. With a local database the user doesn't have to be authenticated, but in production, connection strings sometimes include a password to authenticate. A resource owner password credential (ROPC) is a security risk that should be avoided in production databases. Production apps should use the most secure authentication flow available. For more information on authentication for apps deployed to test or production environments, see Secure authentication flows.

Set up a Redis backplane

- Deploy a Redis server.

  > ⓘ **Important**
  >
  > For production use, a Redis backplane is recommended only when it runs in the same data center as the SignalR app. Otherwise, network latency degrades performance. If your SignalR app is running in the Azure cloud, we recommend Azure SignalR Service instead of a Redis backplane.

  For more information, see the following resources:
  - ASP.NET Core SignalR production hosting and scaling
  - Redis documentation
  - Azure Redis Cache documentation

- In the SignalR app, install the following NuGet package:
  - `Microsoft.AspNetCore.SignalR.StackExchangeRedis`

- Call AddStackExchangeRedis by adding the following line before the line that calls `builder.Build()`) in the `Program.cs` file.

  ```
  C#

  builder.Services.AddSignalR().AddStackExchangeRedis("
  <your_Redis_connection_string>");
  ```

- Configure options as needed:

  Most options can be set in the connection string or in the ConfigurationOptions object. Options specified in `ConfigurationOptions` override the ones set in the connection string.

  The following example shows how to set options in the `ConfigurationOptions` object. This example adds a channel prefix so that multiple apps can share the same Redis instance, as explained in the following step.

  ```
  C#

  builder.Services.AddSignalR()
    .AddStackExchangeRedis(connectionString, options => {
        options.Configuration.ChannelPrefix =
  RedisChannel.Literal("MyApp");
    });
  ```

  In the preceding code, `options.Configuration` is initialized with whatever was specified in the connection string.

  For information about Redis options, see the StackExchange Redis documentation.

- If you're using one Redis server for multiple SignalR apps, use a different channel prefix for each SignalR app.

  Setting a channel prefix isolates one SignalR app from others that use different channel prefixes. If you don't assign different prefixes, a message sent from one app to all of its own clients will go to all clients of all apps that use the Redis server as a backplane.

- Configure your server farm load balancing software for sticky sessions. Here are some examples of documentation on how to do that:
  - IIS
  - HAProxy
  - Nginx

Redis server errors

When a Redis server goes down, SignalR throws exceptions that indicate messages won't be delivered. Some typical exception messages:

- *Failed writing message*
- *Failed to invoke hub method 'MethodName'*
- *Connection to Redis failed*

SignalR doesn't buffer messages to send them when the server comes back up. Any messages sent while the Redis server is down are lost.

SignalR automatically reconnects when the Redis server is available again.

Custom behavior for connection failures

Here's an example that shows how to handle Redis connection failure events.

C#

```
services.AddSignalR()
        .AddMessagePackProtocol()
        .AddStackExchangeRedis(o =>
        {
            o.ConnectionFactory = async writer =>
            {
                var config = new ConfigurationOptions
                {
                    AbortOnConnectFail = false
                };
                config.EndPoints.Add(IPAddress.Loopback, 0);
                config.SetDefaultPorts();
                var connection = await
ConnectionMultiplexer.ConnectAsync(config, writer);
                connection.ConnectionFailed += (_, e) =>
                {
                    Console.WriteLine("Connection to Redis failed.");
                };

                if (!connection.IsConnected)
                {
                    Console.WriteLine("Did not connect to Redis.");
                }

                return connection;
            };
        });
```

Redis Cluster

Redis Cluster utilizes multiple simultaneously active Redis servers to achieve high availability. When Redis Cluster is used as the backplane for SignalR, messages are delivered to all of the nodes of the cluster without code modifications to the app.

There's a tradeoff between the number of nodes in the cluster and the throughput of the backplane. Increasing the number of nodes increases the availability of the cluster but decreases the throughput because messages must be transmitted to all of the nodes in the cluster.

In the SignalR app, include all of the possible Redis nodes using either of the following approaches:

- List the nodes in the connection string delimited with commas.
- If using custom behavior for connection failures, add the nodes to ConfigurationOptions.Endpoints.

Host ASP.NET Core SignalR in background services

Article • 06/18/2024

By Dave Pringle and Brady Gaster

This article provides guidance for:

- Hosting SignalR Hubs using a background worker process hosted with ASP.NET Core.
- Sending messages to connected clients from within a .NET Core BackgroundService.

View or download sample code (how to download)

Enable SignalR at app startup

Hosting ASP.NET Core SignalR Hubs in the context of a background worker process is identical to hosting a Hub in an ASP.NET Core web app. In `Program.cs`, calling `builder.Services.AddSignalR` adds the required services to the ASP.NET Core Dependency Injection (DI) layer to support SignalR. The `MapHub` method is called on the `WebApplication` `app` to connect the Hub endpoints in the ASP.NET Core request pipeline.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddSignalR();
builder.Services.AddHostedService<Worker>();

var app = builder.Build();

app.MapHub<ClockHub>("/hubs/clock");

app.Run();
```

In the preceding example, the `ClockHub` class implements the `Hub<T>` class to create a strongly typed Hub. The `ClockHub` has been configured in `Program.cs` to respond to requests at the endpoint `/hubs/clock`.

For more information on strongly typed Hubs, see Use hubs in SignalR for ASP.NET Core.

> **Note**
>
> This functionality isn't limited to the Hub<T> class. Any class that inherits from Hub, such as DynamicHub, works.

C#

```
public class ClockHub : Hub<IClock>
{
    public async Task SendTimeToClients(DateTime dateTime)
    {
        await Clients.All.ShowTime(dateTime);
    }
}
```

The interface used by the strongly typed `ClockHub` is the `IClock` interface.

C#

```
public interface IClock
{
    Task ShowTime(DateTime currentTime);
}
```

Call a SignalR Hub from a background service

During startup, the `Worker` class, a `BackgroundService`, is enabled using `AddHostedService`.

C#

```
builder.Services.AddHostedService<Worker>();
```

Since SignalR is also enabled up during the startup phase, in which each Hub is attached to an individual endpoint in ASP.NET Core's HTTP request pipeline, each Hub is represented by an `IHubContext<T>` on the server. Using ASP.NET Core's DI features, other classes instantiated by the hosting layer, like `BackgroundService` classes, MVC Controller classes, or Razor page models, can get references to server-side Hubs by accepting instances of `IHubContext<ClockHub, IClock>` during construction.

C#

```
public class Worker : BackgroundService
{
    private readonly ILogger<Worker> _logger;
    private readonly IHubContext<ClockHub, IClock> _clockHub;

    public Worker(ILogger<Worker> logger, IHubContext<ClockHub, IClock>
clockHub)
    {
        _logger = logger;
        _clockHub = clockHub;
    }

    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        while (!stoppingToken.IsCancellationRequested)
        {
            _logger.LogInformation("Worker running at: {Time}",
DateTime.Now);
            await _clockHub.Clients.All.ShowTime(DateTime.Now);
            await Task.Delay(1000, stoppingToken);
        }
    }
}
```

As the `ExecuteAsync` method is called iteratively in the background service, the server's current date and time are sent to the connected clients using the `ClockHub`.

React to SignalR events with background services

Like a Single Page App using the JavaScript client for SignalR, or a .NET desktop app using the ASP.NET Core SignalR .NET Client, a `BackgroundService` or `IHostedService` implementation can also be used to connect to SignalR Hubs and respond to events.

The `ClockHubClient` class implements both the `IClock` interface and the `IHostedService` interface. This way it can be enabled during startup to run continuously and respond to Hub events from the server.

C#

```
public partial class ClockHubClient : IClock, IHostedService
{
}
```

During initialization, the `ClockHubClient` creates an instance of a `HubConnection` and enables the `IClock.ShowTime` method as the handler for the Hub's `ShowTime` event.

C#

```
private readonly ILogger<ClockHubClient> _logger;
private HubConnection _connection;

public ClockHubClient(ILogger<ClockHubClient> logger)
{
    _logger = logger;

    _connection = new HubConnectionBuilder()
        .WithUrl(Strings.HubUrl)
        .Build();

    _connection.On<DateTime>(Strings.Events.TimeSent, ShowTime);
}

public Task ShowTime(DateTime currentTime)
{
    _logger.LogInformation("{CurrentTime}",
currentTime.ToShortTimeString());

    return Task.CompletedTask;
}
```

In the `IHostedService.StartAsync` implementation, the `HubConnection` is started asynchronously.

C#

```
public async Task StartAsync(CancellationToken cancellationToken)
{
    // Loop is here to wait until the server is running
    while (true)
    {
        try
        {
            await _connection.StartAsync(cancellationToken);

            break;
        }
        catch
        {
            await Task.Delay(1000, cancellationToken);
        }
    }
}
```

During the `IHostedService.StopAsync` method, the `HubConnection` is disposed of asynchronously.

C#

```
public async Task StopAsync(CancellationToken cancellationToken)
{
    await _connection.DisposeAsync();
}
```

ASP.NET Core SignalR configuration

Article • 09/18/2024

This article covers ASP.NET Core SignalR configuration.

For Blazor SignalR guidance, which adds to or supersedes the guidance in this article, see ASP.NET Core Blazor SignalR guidance.

JSON/MessagePack serialization options

ASP.NET Core SignalR supports two protocols for encoding messages: JSON and MessagePack. Each protocol has serialization configuration options.

JSON serialization can be configured on the server using the AddJsonProtocol extension method. `AddJsonProtocol` can be added after AddSignalR in `Startup.ConfigureServices`. The `AddJsonProtocol` method takes a delegate that receives an `options` object. The PayloadSerializerOptions property on that object is a `System.Text.Json` JsonSerializerOptions object that can be used to configure serialization of arguments and return values. For more information, see the System.Text.Json documentation.

For example, to configure the serializer to not change the casing of property names, rather than the default camel case names, use the following code in `Program.cs`:

C#

```
builder.Services.AddSignalR()
    .AddJsonProtocol(options => {
        options.PayloadSerializerOptions.PropertyNamingPolicy = null;
    });
```

In the .NET client, the same `AddJsonProtocol` extension method exists on HubConnectionBuilder. The `Microsoft.Extensions.DependencyInjection` namespace must be imported to resolve the extension method:

C#

```
// At the top of the file:
using Microsoft.Extensions.DependencyInjection;

// When constructing your connection:
var connection = new HubConnectionBuilder()
    .AddJsonProtocol(options => {
        options.PayloadSerializerOptions.PropertyNamingPolicy = null;
```

```
    })
    .Build();
```

> **Note**
>
> It's not possible to configure JSON serialization in the JavaScript client at this time.

Switch to Newtonsoft.Json

If you need features of `Newtonsoft.Json` that aren't supported in `System.Text.Json`, see Switch to Newtonsoft.Json.

MessagePack serialization options

MessagePack serialization can be configured by providing a delegate to the AddMessagePackProtocol call. See MessagePack in SignalR for more details.

> **Note**
>
> It's not possible to configure MessagePack serialization in the JavaScript client at this time.

Configure server options

The following table describes options for configuring SignalR hubs:

Expand table

Option	Default Value	Description
`ClientTimeoutInterval`	30 seconds	The server considers the client disconnected if it hasn't received a message (including keep-alive) in this interval. It could take longer than this timeout interval for the client to be marked disconnected due to how this is implemented. The recommended value is double the `KeepAliveInterval` value.

Option	Default Value	Description
`HandshakeTimeout`	15 seconds	If the client doesn't send an initial handshake message within this time interval, the connection is closed. This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification.
`KeepAliveInterval`	15 seconds	If the server hasn't sent a message within this interval, a ping message is sent automatically to keep the connection open. When changing `KeepAliveInterval`, change the `ServerTimeout` or `serverTimeoutInMilliseconds` setting on the client. The recommended `ServerTimeout` or `serverTimeoutInMilliseconds` value is double the `KeepAliveInterval` value.
`SupportedProtocols`	All installed protocols	Protocols supported by this hub. By default, all protocols registered on the server are allowed. Protocols can be removed from this list to disable specific protocols for individual hubs.
`EnableDetailedErrors`	`false`	If `true`, detailed exception messages are returned to clients when an exception is thrown in a Hub method. The default is `false` because these exception messages can contain sensitive information.
`StreamBufferCapacity`	`10`	The maximum number of items that can be buffered for client upload streams. If this limit is reached, the processing of invocations is blocked until the server processes stream items.
`MaximumReceiveMessageSize`	32 KB	Maximum size of a single incoming hub message. Increasing the value might increase the risk of Denial of service (DoS) attacks.
`MaximumParallelInvocationsPerClient`	1	The maximum number of hub methods that each client can call in parallel before queueing.

Option	Default Value	Description
`DisableImplicitFromServicesParameters`	`false`	Hub method arguments are resolved from DI if possible.

Options can be configured for all hubs by providing an options delegate to the `AddSignalR` call in `Program.cs`.

C#

```
builder.Services.AddSignalR(hubOptions =>
{
    hubOptions.EnableDetailedErrors = true;
    hubOptions.KeepAliveInterval = TimeSpan.FromMinutes(1);
});
```

Options for a single hub override the global options provided in `AddSignalR` and can be configured using AddHubOptions:

C#

```
builder.Services.AddSignalR().AddHubOptions<ChatHub>(options =>
{
    options.EnableDetailedErrors = true;
});
```

Advanced HTTP configuration options

Use `HttpConnectionDispatcherOptions` to configure advanced settings related to transports and memory buffer management. These options are configured by passing a delegate to MapHub in `Program.cs`.

C#

```
using Microsoft.AspNetCore.Http.Connections;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddSignalR();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
```

```
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();
app.MapHub<ChatHub>("/chathub", options =>
{
    options.Transports =
        HttpTransportType.WebSockets |
        HttpTransportType.LongPolling;
}
);
app.Run();
```

The following table describes options for configuring ASP.NET Core SignalR's advanced HTTP options:

Expand table

Option	Default Value	Description
`ApplicationMaxBufferSize`	64 KB	The maximum number of bytes received from the client that the server buffers before applying backpressure. Increasing this value allows the server to receive larger messages faster without applying backpressure, but can increase memory consumption.
`TransportMaxBufferSize`	64 KB	The maximum number of bytes sent by the app that the server buffers before observing backpressure. Increasing this value allows the server to buffer larger messages faster without awaiting backpressure, but can increase memory consumption.
`AuthorizationData`	Data automatically gathered from the `Authorize` attributes applied to the Hub class.	A list of IAuthorizeData objects used to determine if a client is authorized to connect to the hub.

Option	Default Value	Description
`Transports`	All Transports are enabled.	A bit flags enum of `HttpTransportType` values that can restrict the transports a client can use to connect.
`LongPolling`	See below.	Additional options specific to the Long Polling transport.
`WebSockets`	See below.	Additional options specific to the WebSockets transport.
`MinimumProtocolVersion`	0	Specify the minimum version of the negotiate protocol. This is used to limit clients to newer versions.
`CloseOnAuthenticationExpiration`	false	Set this option to enable authentication expiration tracking, which will close connections when a token expires.

The Long Polling transport has additional options that can be configured using the `LongPolling` property:

Expand table

Option	Default Value	Description
`PollTimeout`	90 seconds	The maximum amount of time the server waits for a message to send to the client before terminating a single poll request. Decreasing this value causes the client to issue new poll requests more frequently.

The WebSocket transport has additional options that can be configured using the `WebSockets` property:

Expand table

Option	Default Value	Description
`CloseTimeout`	5 seconds	After the server closes, if the client fails to close within this time interval, the connection is terminated.
`SubProtocolSelector`	`null`	A delegate that can be used to set the `Sec-WebSocket-Protocol` header to a custom value. The delegate receives the values requested by the client as input and is expected to return the desired value.

Configure client options

Client options can be configured on the `HubConnectionBuilder` type (available in the .NET and JavaScript clients). It's also available in the Java client, but the `HttpHubConnectionBuilder` subclass is what contains the builder configuration options, as well as on the `HubConnection` itself.

Configure logging

Logging is configured in the .NET Client using the `ConfigureLogging` method. Logging providers and filters can be registered in the same way as they are on the server. See the Logging in ASP.NET Core documentation for more information.

> **Note**
>
> In order to register Logging providers, you must install the necessary packages. See the Built-in logging providers section of the docs for a full list.

For example, to enable Console logging, install the `Microsoft.Extensions.Logging.Console` NuGet package. Call the `AddConsole` extension method:

C#

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub")
    .ConfigureLogging(logging => {
        logging.SetMinimumLevel(LogLevel.Information);
        logging.AddConsole();
    })
    .Build();
```

In the JavaScript client, a similar `configureLogging` method exists. Provide a `LogLevel` value indicating the minimum level of log messages to produce. Logs are written to the browser console window.

JavaScript

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging(signalR.LogLevel.Information)
    .build();
```

Instead of a `LogLevel` value, you can also provide a `string` value representing a log level name. This is useful when configuring SignalR logging in environments where you don't have access to the `LogLevel` constants.

JavaScript

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .configureLogging("warn")
    .build();
```

The following table lists the available log levels. The value you provide to `configureLogging` sets the **minimum** log level that will be logged. Messages logged at this level, **or the levels listed after it in the table**, will be logged.

Expand table

String	LogLevel
`trace`	`LogLevel.Trace`
`debug`	`LogLevel.Debug`
`info` or `information`	`LogLevel.Information`
`warn` or `warning`	`LogLevel.Warning`
`error`	`LogLevel.Error`
`critical`	`LogLevel.Critical`
`none`	`LogLevel.None`

> **Note**
>
> To disable logging entirely, specify `signalR.LogLevel.None` in the `configureLogging` method.

For more information on logging, see the SignalR Diagnostics documentation.

The SignalR Java client uses the SLF4J library for logging. It's a high-level logging API that allows users of the library to choose their own specific logging implementation by bringing in a specific logging dependency. The following code snippet shows how to use `java.util.logging` with the SignalR Java client.

Gradle

```
implementation 'org.slf4j:slf4j-jdk14:1.7.25'
```

If you don't configure logging in your dependencies, SLF4J loads a default no-operation logger with the following warning message:

```
SLF4J: Failed to load class "org.slf4j.impl.StaticLoggerBinder".
SLF4J: Defaulting to no-operation (NOP) logger implementation
SLF4J: See http://www.slf4j.org/codes.html#StaticLoggerBinder for further
details.
```

This can safely be ignored.

Configure allowed transports

The transports used by SignalR can be configured in the `WithUrl` call (`withUrl` in JavaScript). A bitwise-OR of the values of `HttpTransportType` can be used to restrict the client to only use the specified transports. All transports are enabled by default.

For example, to disable the Server-Sent Events transport, but allow WebSockets and Long Polling connections:

C#

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", HttpTransportType.WebSockets |
HttpTransportType.LongPolling)
    .Build();
```

In the JavaScript client, transports are configured by setting the `transport` field on the options object provided to `withUrl`:

JavaScript

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", { transport: signalR.HttpTransportType.WebSockets |
signalR.HttpTransportType.LongPolling })
    .build();
```

In this version of the Java client WebSockets is the only available transport.

In the Java client, the transport is selected with the `withTransport` method on the `HttpHubConnectionBuilder`. The Java client defaults to using the WebSockets transport.

Java

```
HubConnection hubConnection =
HubConnectionBuilder.create("https://example.com/chathub")
    .withTransport(TransportEnum.WEBSOCKETS)
    .build();
```

> **Note**
>
> The SignalR Java client doesn't support transport fallback yet.

Configure bearer authentication

To provide authentication data along with SignalR requests, use the `AccessTokenProvider` option (`accessTokenFactory` in JavaScript) to specify a function that returns the desired access token. In the .NET Client, this access token is passed in as an HTTP "Bearer Authentication" token (Using the `Authorization` header with a type of `Bearer`). In the JavaScript client, the access token is used as a Bearer token, **except** in a few cases where browser APIs restrict the ability to apply headers (specifically, in Server-Sent Events and WebSockets requests). In these cases, the access token is provided as a query string value `access_token`.

In the .NET client, the `AccessTokenProvider` option can be specified using the options delegate in `WithUrl`:

C#

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.AccessTokenProvider = async () => {
            // Get and return the access token.
        };
    })
    .Build();
```

In the JavaScript client, the access token is configured by setting the `accessTokenFactory` field on the options object in `withUrl`:

JavaScript

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        accessTokenFactory: () => {
            // Get and return the access token.
            // This function can return a JavaScript Promise if asynchronous
            // logic is required to retrieve the access token.
        }
    })
    .build();
```

In the SignalR Java client, you can configure a bearer token to use for authentication by providing an access token factory to the HttpHubConnectionBuilder. Use withAccessTokenFactory to provide an RxJava Single<String>. With a call to Single.defer, you can write logic to produce access tokens for your client.

Java

```
HubConnection hubConnection =
HubConnectionBuilder.create("https://example.com/chathub")
    .withAccessTokenProvider(Single.defer(() -> {
        // Your logic here.
        return Single.just("An Access Token");
    })).build();
```

Configure timeout and keep-alive options

Additional options for configuring timeout and keep-alive behavior:

.NET

Expand table

Option	Default value	Description
`WithServerTimeout`	30 seconds (30,000 milliseconds)	Timeout for server activity and is set directly on HubConnectionBuilder. If the server hasn't sent a message in this interval, the client considers the server disconnected and triggers the `Closed` event (`onclose` in JavaScript). This value must be large enough for a ping message to be sent from the server **and** received by the client within the timeout interval. The recommended value is a number at least double the server's keep-alive

Option	Default value	Description
		interval (`WithKeepAliveInterval`) value to allow time for pings to arrive.
`HandshakeTimeout`	15 seconds	Timeout for initial server handshake and is available on the `HubConnection` object itself. If the server doesn't send a handshake response in this interval, the client cancels the handshake and triggers the `Closed` event (`onclose` in JavaScript). This is an advanced setting that should only be modified if handshake timeout errors are occurring due to severe network latency. For more detail on the handshake process, see the SignalR Hub Protocol Specification .
`WithKeepAliveInterval`	15 seconds	Determines the interval at which the client sends ping messages and is set directly on HubConnectionBuilder. This setting allows the server to detect hard disconnects, such as when a client unplugs their computer from the network. Sending any message from the client resets the timer to the start of the interval. If the client hasn't sent a message in the `ClientTimeoutInterval` set on the server, the server considers the client disconnected.

In the .NET Client, timeout values are specified as `TimeSpan` values.

The following example shows values that are double the default values:

C#

```
var builder = new HubConnectionBuilder()
    .WithUrl(Navigation.ToAbsoluteUri("/chathub"))
    .WithServerTimeout(TimeSpan.FromSeconds(60))
    .WithKeepAliveInterval(TimeSpan.FromSeconds(30))
    .Build();

builder.On<string, string>("ReceiveMessage", (user, message) => ...

await builder.StartAsync();
```

Configure stateful reconnect

SignalR stateful reconnect reduces the perceived downtime of clients that have a temporary disconnect in their network connection, such as when switching network connections or a short temporary loss in access.

Stateful reconnect achieves this by:

- Temporarily buffering data on the server and client.
- Acknowledging messages received (ACK-ing) by both the server and client.
- Recognizing when a connection is up and replaying messages that might have been sent while the connection was down.

Stateful reconnect is available in ASP.NET Core 8.0 and later.

Opt in to stateful reconnect at both the server hub endpoint and the client:

- Update the server hub endpoint configuration to enable the `AllowStatefulReconnects` option:

  C#

  ```
  app.MapHub<MyHub>("/hubName", options =>
  {
      options.AllowStatefulReconnects = true;
  });
  ```

  Optionally, the maximum buffer size in bytes allowed by the server can be set globally or for a specific hub with the `StatefulReconnectBufferSize` option:

  The `StatefulReconnectBufferSize` option set globally:

  C#

  ```
  builder.AddSignalR(o => o.StatefulReconnectBufferSize = 1000);
  ```

  The `StatefulReconnectBufferSize` option set for a specific hub:

  C#

  ```
  builder.AddSignalR().AddHubOptions<MyHub>(o =>
  o.StatefulReconnectBufferSize = 1000);
  ```

  The `StatefulReconnectBufferSize` option is optional with a default of 100,000 bytes.

- Update JavaScript or TypeScript client code to enable the `withStatefulReconnect` option:

  JavaScript

  ```
  const builder = new signalR.HubConnectionBuilder()
    .withUrl("/hubname")
    .withStatefulReconnect({ bufferSize: 1000 });  // Optional, defaults
  to 100,000
  const connection = builder.build();
  ```

  The `bufferSize` option is optional with a default of 100,000 bytes.

- Update .NET client code to enable the `WithStatefulReconnect` option:

  C#

  ```
    var builder = new HubConnectionBuilder()
        .WithUrl("<hub url>")
        .WithStatefulReconnect();
    builder.Services.Configure<HubConnectionOptions>(o =>
  o.StatefulReconnectBufferSize = 1000);
    var hubConnection = builder.Build();
  ```

  The `StatefulReconnectBufferSize` option is optional with a default of 100,000 bytes.

Configure additional options

Additional options can be configured in the `WithUrl` (`withUrl` in JavaScript) method on `HubConnectionBuilder` or on the various configuration APIs on the `HttpHubConnectionBuilder` in the Java client:

.NET

Expand table

.NET Option	Default value	Description
`AccessTokenProvider`	`null`	A function returning a string that is provided as a Bearer authentication token in HTTP requests.

.NET Option	Default value	Description
`SkipNegotiation`	`false`	Set this to `true` to skip the negotiation step. **Only supported when the WebSockets transport is the only enabled transport**. This setting can't be enabled when using the Azure SignalR Service.
`ClientCertificates`	Empty	A collection of TLS certificates to send to authenticate requests.
`Cookies`	Empty	A collection of HTTP cookies to send with every HTTP request.
`Credentials`	Empty	Credentials to send with every HTTP request.
`CloseTimeout`	5 seconds	WebSockets only. The maximum amount of time the client waits after closing for the server to acknowledge the close request. If the server doesn't acknowledge the close within this time, the client disconnects.
`Headers`	Empty	A Map of additional HTTP headers to send with every HTTP request.
`HttpMessageHandlerFactory`	`null`	A delegate that can be used to configure or replace the `HttpMessageHandler` used to send HTTP requests. Not used for WebSocket connections. This delegate must return a non-null value, and it receives the default value as a parameter. Either modify settings on that default value and return it, or return a new `HttpMessageHandler` instance. **When replacing the handler make sure to copy the settings you want to keep from the provided handler, otherwise, the configured options (such as Cookies and Headers) won't apply to the new handler.**
`Proxy`	`null`	An HTTP proxy to use when sending HTTP requests.
`UseDefaultCredentials`	`false`	Set this boolean to send the default credentials for HTTP and WebSockets requests. This enables the use of Windows authentication.
`WebSocketConfiguration`	`null`	A delegate that can be used to configure additional WebSocket options. Receives an instance of ClientWebSocketOptions that can be used to configure the options.
`ApplicationMaxBufferSize`	1 MB	The maximum number of bytes received from the server that the client buffers before applying

.NET Option	Default value	Description
		backpressure. Increasing this value allows the client to receive larger messages faster without applying backpressure, but can increase memory consumption.
`TransportMaxBufferSize`	1 MB	The maximum number of bytes sent by the user application that the client buffers before observing backpressure. Increasing this value allows the client to buffer larger messages faster without awaiting backpressure, but can increase memory consumption.

In the .NET Client, these options can be modified by the options delegate provided to `WithUrl`:

C#

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options => {
        options.Headers["Foo"] = "Bar";
        options.SkipNegotiation = true;
        options.Transports = HttpTransportType.WebSockets;
        options.Cookies.Add(new Cookie(/* ... */);
        options.ClientCertificates.Add(/* ... */);
    })
    .Build();
```

In the JavaScript Client, these options can be provided in a JavaScript object provided to `withUrl`:

JavaScript

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub", {
        // "Foo: Bar" will not be sent with WebSockets or Server-Sent Events
requests
        headers: { "Foo": "Bar" },
        transport: signalR.HttpTransportType.LongPolling
    })
    .build();
```

In the Java client, these options can be configured with the methods on the `HttpHubConnectionBuilder` returned from the `HubConnectionBuilder.create("HUB URL")`

Java

```
HubConnection hubConnection =
HubConnectionBuilder.create("https://example.com/chathub")
        .withHeader("Foo", "Bar")
        .shouldSkipNegotiate(true)
        .withHandshakeResponseTimeout(30*1000)
        .build();
```

Authentication and authorization in ASP.NET Core SignalR

Article • 06/18/2024

Authenticate users connecting to a SignalR hub

SignalR can be used with ASP.NET Core authentication to associate a user with each connection. In a hub, authentication data can be accessed from the HubConnectionContext.User property. Authentication allows the hub to call methods on all connections associated with a user. For more information, see Manage users and groups in SignalR. Multiple connections may be associated with a single user.

The following code is an example that uses SignalR and ASP.NET Core authentication:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using SignalRAuthenticationSample.Data;
using SignalRAuthenticationSample.Hubs;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
builder.Services.AddRazorPages();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
```

```
app.UseStaticFiles();

app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();
app.MapHub<ChatHub>("/chat");

app.Run();
```

> **Note**
>
> If a token expires during the lifetime of a connection, by default the connection continues to work. `LongPolling` and `ServerSentEvent` connections fail on subsequent requests if they don't send new access tokens. For connections to close when the authentication token expires, set CloseOnAuthenticationExpiration.

Cookie authentication

In a browser-based app, cookie authentication allows existing user credentials to automatically flow to SignalR connections. When using the browser client, no extra configuration is needed. If the user is logged in to an app, the SignalR connection automatically inherits this authentication.

Cookies are a browser-specific way to send access tokens, but non-browser clients can send them. When using the .NET Client, the `Cookies` property can be configured in the `.WithUrl` call to provide a cookie. However, using cookie authentication from the .NET client requires the app to provide an API to exchange authentication data for a cookie.

Bearer token authentication

The client can provide an access token instead of using a cookie. The server validates the token and uses it to identify the user. This validation is done only when the connection is established. During the life of the connection, the server doesn't automatically revalidate to check for token revocation.

In the JavaScript client, the token can be provided using the accessTokenFactory option.

TypeScript

```
// Connect, using the token we got.
this.connection = new signalR.HubConnectionBuilder()
    .withUrl("/hubs/chat", { accessTokenFactory: () => this.loginToken })
    .build();
```

In the .NET client, there's a similar AccessTokenProvider property that can be used to configure the token:

C#

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options =>
    {
        options.AccessTokenProvider = () => Task.FromResult(_myAccessToken);
    })
    .Build();
```

> **Note**
>
> The access token function provided is called before **every** HTTP request made by SignalR. If the token needs to be renewed in order to keep the connection active, do so from within this function and return the updated token. The token may need to be renewed so it doesn't expire during the connection.

In standard web APIs, bearer tokens are sent in an HTTP header. However, SignalR is unable to set these headers in browsers when using some transports. When using WebSockets and Server-Sent Events, the token is transmitted as a query string parameter.

Built-in JWT authentication

On the server, bearer token authentication is configured using the JWT Bearer middleware:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.SignalR;
using Microsoft.EntityFrameworkCore;
using SignalRAuthenticationSample.Data;
using SignalRAuthenticationSample.Hubs;
using Microsoft.AspNetCore.Authentication.JwtBearer;
using SignalRAuthenticationSample;
```

```
var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();

builder.Services.AddAuthentication(options =>
{
    // Identity made Cookie authentication the default.
    // However, we want JWT Bearer Auth to be the default.
    options.DefaultAuthenticateScheme =
JwtBearerDefaults.AuthenticationScheme;
    options.DefaultChallengeScheme = JwtBearerDefaults.AuthenticationScheme;
```

```
}).AddJwtBearer(options =>
  {
      // Configure the Authority to the expected value for
      // the authentication provider. This ensures the token
      // is appropriately validated.
      options.Authority = "Authority URL"; // TODO: Update URL

      // We have to hook the OnMessageReceived event in order to
      // allow the JWT authentication handler to read the access
      // token from the query string when a WebSocket or
      // Server-Sent Events request comes in.

      // Sending the access token in the query string is required when using
WebSockets or ServerSentEvents
      // due to a limitation in Browser APIs. We restrict it to only calls
to the
      // SignalR hub in this code.
      // See https://docs.microsoft.com/aspnet/core/signalr/security#access-
token-logging
      // for more information about security considerations when using
      // the query string to transmit the access token.
      options.Events = new JwtBearerEvents
      {
          OnMessageReceived = context =>
          {
              var accessToken = context.Request.Query["access_token"];

              // If the request is for our hub...
              var path = context.HttpContext.Request.Path;
              if (!string.IsNullOrEmpty(accessToken) &&
                  (path.StartsWithSegments("/hubs/chat")))
              {
                  // Read the token out of the query string
                  context.Token = accessToken;
              }
              return Task.CompletedTask;
          }
      };
  });
```

```
builder.Services.AddRazorPages();
builder.Services.AddSignalR();

// Change to use Name as the user identifier for SignalR
// WARNING: This requires that the source of your JWT token
// ensures that the Name claim is unique!
// If the Name claim isn't unique, users could receive messages
// intended for a different user!
builder.Services.AddSingleton<IUserIdProvider, NameUserIdProvider>();

// Change to use email as the user identifier for SignalR
// builder.Services.AddSingleton<IUserIdProvider, EmailBasedUserIdProvider>
();

// WARNING: use *either* the NameUserIdProvider *or* the
```

```
// EmailBasedUserIdProvider, but do not use both.

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();
app.MapHub<ChatHub>("/chatHub");

app.Run();
```

> ⓘ Note
>
> The query string is used on browsers when connecting with WebSockets and Server-Sent Events due to browser API limitations. When using HTTPS, query string values are secured by the TLS connection. However, many servers log query string values. For more information, see Security considerations in ASP.NET Core SignalR. SignalR uses headers to transmit tokens in environments which support them (such as the .NET and Java clients).

Identity Server JWT authentication

When using Duende IdentityServer add a PostConfigureOptions<TOptions> service to the project:

C#

```
using Microsoft.AspNetCore.Authentication.JwtBearer;
using Microsoft.Extensions.Options;
public class ConfigureJwtBearerOptions :
IPostConfigureOptions<JwtBearerOptions>
{
```

```
    public void PostConfigure(string name, JwtBearerOptions options)
    {
        var originalOnMessageReceived = options.Events.OnMessageReceived;
        options.Events.OnMessageReceived = async context =>
        {
            await originalOnMessageReceived(context);

            if (string.IsNullOrEmpty(context.Token))
            {
                var accessToken = context.Request.Query["access_token"];
                var path = context.HttpContext.Request.Path;

                if (!string.IsNullOrEmpty(accessToken) &&
                    path.StartsWithSegments("/hubs"))
                {
                    context.Token = accessToken;
                }
            }
        };
    }
}
```

Register the service after adding services for authentication (AddAuthentication) and the authentication handler for Identity Server (AddIdentityServerJwt):

C#

```
using Microsoft.AspNetCore.Authentication.JwtBearer;
using Microsoft.Extensions.DependencyInjection.Extensions;
using SignalRAuthenticationSample.Hubs;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication()
    .AddIdentityServerJwt();
builder.Services.TryAddEnumerable(
    ServiceDescriptor.Singleton<IPostConfigureOptions<JwtBearerOptions>,
        ConfigureJwtBearerOptions>());

builder.Services.AddRazorPages();

var app = builder.Build();

// Code removed for brevity.
```

Cookies vs. bearer tokens

Cookies are specific to browsers. Sending them from other kinds of clients adds complexity compared to sending bearer tokens. Cookie authentication isn't recommended unless the app only needs to authenticate users from the browser client.

Bearer token authentication is the recommended approach when using clients other than the browser client.

Windows authentication

If Windows authentication is configured in the app, SignalR can use that identity to secure hubs. However, to send messages to individual users, add a custom User ID provider. The Windows authentication system doesn't provide the "Name Identifier" claim. SignalR uses the claim to determine the user name.

Add a new class that implements `IUserIdProvider` and retrieve one of the claims from the user to use as the identifier. For example, to use the "Name" claim (which is the Windows username in the form `[Domain]/[Username]`), create the following class:

C#

```
public class NameUserIdProvider : IUserIdProvider
{
    public string GetUserId(HubConnectionContext connection)
    {
        return connection.User?.Identity?.Name;
    }
}
```

Rather than `ClaimTypes.Name`, use any value from the `User`, such as the Windows SID identifier, etc.

> **Note**
>
> The value chosen must be unique among all the users in the system. Otherwise, a message intended for one user could end up going to a different user.

Register this component in `Program.cs`:

C#

```
using Microsoft.AspNetCore.Authentication.Negotiate;
using Microsoft.AspNetCore.SignalR;
using SignalRAuthenticationSample;

var builder = WebApplication.CreateBuilder(args);
var services = builder.Services;

services.AddAuthentication(NegotiateDefaults.AuthenticationScheme)
   .AddNegotiate();
```

```
services.AddAuthorization(options =>
{
    options.FallbackPolicy = options.DefaultPolicy;
});
services.AddRazorPages();

services.AddSignalR();
services.AddSingleton<IUserIdProvider, NameUserIdProvider>();

var app = builder.Build();

// Code removed for brevity.
```

In the .NET Client, Windows Authentication must be enabled by setting the UseDefaultCredentials property:

C#

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/chathub", options =>
    {
        options.UseDefaultCredentials = true;
    })
    .Build();
```

Windows authentication is supported in Microsoft Edge, but not in all browsers. For example, in Chrome and Safari, attempting to use Windows authentication and WebSockets fails. When Windows authentication fails, the client attempts to fall back to other transports which might work.

Use claims to customize identity handling

An app that authenticates users can derive SignalR user IDs from user claims. To specify how SignalR creates user IDs, implement `IUserIdProvider` and register the implementation.

The sample code demonstrates how to use claims to select the user's email address as the identifying property.

> **Note**
>
> The value chosen must be unique among all the users in the system. Otherwise, a message intended for one user could end up going to a different user.

C#

```
public class EmailBasedUserIdProvider : IUserIdProvider
{
    public virtual string GetUserId(HubConnectionContext connection)
    {
        return connection.User?.FindFirst(ClaimTypes.Email)?.Value!;
    }
}
```

The account registration adds a claim with type `ClaimsTypes.Email` to the ASP.NET identity database.

C#

```
public async Task<IActionResult> OnPostAsync(string returnUrl = null)
{
    returnUrl ??= Url.Content("~/");
    ExternalLogins = (await
_signInManager.GetExternalAuthenticationSchemesAsync())

.ToList();
    if (ModelState.IsValid)
    {
        var user = CreateUser();

        await _userStore.SetUserNameAsync(user, Input.Email,
CancellationToken.None);
        await _emailStore.SetEmailAsync(user, Input.Email,
CancellationToken.None);
        var result = await _userManager.CreateAsync(user, Input.Password);

        // Add the email claim and value for this user.
        await _userManager.AddClaimAsync(user, new Claim(ClaimTypes.Email,
Input.Email));

        // Remaining code removed for brevity.
```

Register this component in `Program.cs`:

C#

```
builder.Services.AddSingleton<IUserIdProvider, EmailBasedUserIdProvider>();
```

Authorize users to access hubs and hub methods

By default, all methods in a hub can be called by an unauthenticated user. To require authentication, apply the AuthorizeAttribute attribute to the hub:

C#

```
[Authorize]
public class ChatHub: Hub
{
}
```

The constructor arguments and properties of the `[Authorize]` attribute can be used to restrict access to only users matching specific authorization policies. For example, with the custom authorization policy called `MyAuthorizationPolicy`, only users matching that policy can access the hub using the following code:

C#

```
[Authorize("MyAuthorizationPolicy")]
public class ChatPolicyHub : Hub
{
    public override async Task OnConnectedAsync()
    {
        await Clients.All.SendAsync("ReceiveSystemMessage",
                                    $"{Context.UserIdentifier} joined.");
        await base.OnConnectedAsync();
    }
    // Code removed for brevity.
```

The `[Authorize]` attribute can be applied to individual hub methods. If the current user doesn't match the policy applied to the method, an error is returned to the caller:

C#

```
[Authorize]
public class ChatHub : Hub
{
    public async Task Send(string message)
    {
        // ... send a message to all users ...
    }

    [Authorize("Administrators")]
    public void BanUser(string userName)
    {
        // ... ban a user from the chat room (something only Administrators
can do) ...
    }
}
```

Use authorization handlers to customize hub method authorization

SignalR provides a custom resource to authorization handlers when a hub method requires authorization. The resource is an instance of HubInvocationContext. The `HubInvocationContext` includes the HubCallerContext, the name of the hub method being invoked, and the arguments to the hub method.

Consider the example of a chat room allowing multiple organization sign-in via Microsoft Entra ID. Anyone with a Microsoft account can sign in to chat, but only members of the owning organization should be able to ban users or view users' chat histories. Furthermore, we might want to restrict some functionality from specific users. Note how the `DomainRestrictedRequirement` serves as a custom IAuthorizationRequirement. Now that the `HubInvocationContext` resource parameter is being passed in, the internal logic can inspect the context in which the Hub is being called and make decisions on allowing the user to execute individual Hub methods:

C#

```
[Authorize]
public class ChatHub : Hub
{
    public void SendMessage(string message)
    {
    }

    [Authorize("DomainRestricted")]
    public void BanUser(string username)
    {
    }

    [Authorize("DomainRestricted")]
    public void ViewUserHistory(string username)
    {
    }
}
```

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.SignalR;

namespace SignalRAuthenticationSample;

public class DomainRestrictedRequirement :
    AuthorizationHandler<DomainRestrictedRequirement, HubInvocationContext>,
```

```
    IAuthorizationRequirement
{
    protected override Task
HandleRequirementAsync(AuthorizationHandlerContext context,
        DomainRestrictedRequirement requirement,
        HubInvocationContext resource)
    {
        if (context.User.Identity != null &&
          !string.IsNullOrEmpty(context.User.Identity.Name) &&
          IsUserAllowedToDoThis(resource.HubMethodName,
                                context.User.Identity.Name) &&
          context.User.Identity.Name.EndsWith("@microsoft.com"))
        {
                context.Succeed(requirement);

        }
        return Task.CompletedTask;
    }

    private bool IsUserAllowedToDoThis(string hubMethodName,
        string currentUsername)
    {
        return !(currentUsername.Equals("asdf42@microsoft.com") &&
            hubMethodName.Equals("banUser",
StringComparison.OrdinalIgnoreCase));
    }
}
```

In `Program.cs`, add the new policy, providing the custom `DomainRestrictedRequirement` requirement as a parameter to create the `DomainRestricted` policy:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using SignalRAuthenticationSample;
using SignalRAuthenticationSample.Data;
using SignalRAuthenticationSample.Hubs;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
var services = builder.Services;

services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
services.AddDatabaseDeveloperPageExceptionFilter();

services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();
```

```
services.AddAuthorization(options =>
    {
        options.AddPolicy("DomainRestricted", policy =>
        {
            policy.Requirements.Add(new DomainRestrictedRequirement());
        });
    });

services.AddRazorPages();

var app = builder.Build();

// Code removed for brevity.
```

In the preceding example, the `DomainRestrictedRequirement` class is both an `IAuthorizationRequirement` and its own `AuthorizationHandler` for that requirement. It's acceptable to split these two components into separate classes to separate concerns. A benefit of the example's approach is there's no need to inject the `AuthorizationHandler` during startup, as the requirement and the handler are the same thing.

Security considerations in ASP.NET Core SignalR

Article • 06/18/2024

By Andrew Stanton-Nurse

This article provides information on securing SignalR.

Cross-Origin Resource Sharing

Cross-Origin Resource Sharing (CORS) can be used to allow cross-origin SignalR connections in the browser. If JavaScript code is hosted on a different domain from the SignalR app, CORS middleware must be enabled to allow the JavaScript to connect to the SignalR app. Allow cross-origin requests only from domains you trust or control. For example:

- Your site is hosted on `http://www.example.com`
- Your SignalR app is hosted on `http://signalr.example.com`

CORS should be configured in the SignalR app to only allow the origin `www.example.com`.

For more information on configuring CORS, see Enable Cross-Origin Requests (CORS). SignalR **requires** the following CORS policies:

- Allow the specific expected origins. Allowing any origin is possible but is **not** secure or recommended.
- HTTP methods `GET` and `POST` must be allowed.
- Credentials must be allowed in order for cookie-based sticky sessions to work correctly. They must be enabled even when authentication isn't used.

However, in 5.0 we have provided an option in the TypeScript client to not use credentials. The option to not use credentials should only be used when you know 100% that credentials like Cookies are not needed in your app (cookies are used by azure app service when using multiple servers for sticky sessions).

For example, the following highlighted CORS policy allows a SignalR browser client hosted on `https://example.com` to access the SignalR app hosted on `https://signalr.example.com`:

C#

```
using SignalRChat.Hubs;

var MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(name: MyAllowSpecificOrigins,
                      policy =>
                      {
                          policy.WithOrigins("http://example.com");
                          policy.WithMethods("GET", "POST");
                          policy.AllowCredentials();
                      });
});

// Add services to the container.
builder.Services.AddRazorPages();
builder.Services.AddSignalR();

var app = builder.Build();

app.MapHub<ChatHub>("/chatHub");
```

In the previous example, the CORS policy is customized to allow specific origins, methods, and credentials. For more information on customizing CORS policies and middleware in ASP.NET Core, see CORS middleware: CORS with named policy and middleware.

WebSocket Origin Restriction

The protections provided by CORS don't apply to WebSockets. For origin restriction on WebSockets, read WebSockets origin restriction.

ConnectionId

Exposing `ConnectionId` can lead to malicious impersonation if the SignalR server or client version is ASP.NET Core 2.2 or earlier. If the SignalR server and client version are ASP.NET Core 3.0 or later, the `ConnectionToken` rather than the `ConnectionId` must be kept secret. The `ConnectionToken` is purposely not exposed in any API. It can be difficult to ensure that older SignalR clients aren't connecting to the server, so even if your SignalR server version is ASP.NET Core 3.0 or later, the `ConnectionId` shouldn't be exposed.

Access token logging

When using WebSockets or Server-Sent Events, the browser client sends the access token in the query string. Receiving the access token via query string is generally as secure as using the standard `Authorization` header. Always use HTTPS to ensure a secure end-to-end connection between the client and the server. Many web servers log the URL for each request, including the query string. Logging the URLs may log the access token. ASP.NET Core logs the URL for each request by default, which includes the query string. For example:

Output

```
info: Microsoft.AspNetCore.Hosting.Internal.WebHost[1]
      Request starting HTTP/1.1 GET http://localhost:5000/chathub?
access_token=1234
```

If you have concerns about logging this data with your server logs, you can disable this logging entirely by configuring the `Microsoft.AspNetCore.Hosting` logger to the `Warning` level or above (these messages are written at `Info` level). For more information, see Apply log filter rules in code for more information. If you still want to log certain request information, you can write middleware to log the data that you require and filter out the `access_token` query string value (if present).

Exceptions

Exception messages are generally considered sensitive data that shouldn't be revealed to a client. By default, SignalR doesn't send the details of an exception thrown by a hub method to the client. Instead, the client receives a generic message indicating an error occurred. Exception message delivery to the client can be overridden (for example in development or test) with EnableDetailedErrors. Exception messages should not be exposed to the client in production apps.

Buffer management

SignalR uses per-connection buffers to manage incoming and outgoing messages. By default, SignalR limits these buffers to 32 KB. The largest message a client or server can send is 32 KB. The maximum memory consumed by a connection for messages is 32 KB. If your messages are always smaller than 32 KB, you can reduce the limit, which:

- Prevents a client from being able to send a larger message.
- The server will never need to allocate large buffers to accept messages.

If your messages are larger than 32 KB, you can increase the limit. Increasing this limit means:

- The client can cause the server to allocate large memory buffers.
- Server allocation of large buffers may reduce the number of concurrent connections.

There are limits for incoming and outgoing messages, both can be configured on the HttpConnectionDispatcherOptions object configured in `MapHub`:

- `ApplicationMaxBufferSize` represents the maximum number of bytes from the client that the server buffers. If the client attempts to send a message larger than this limit, the connection may be closed.
- `TransportMaxBufferSize` represents the maximum number of bytes the server can send. If the server attempts to send a message (including return values from hub methods) larger than this limit, an exception will be thrown.

Setting the limit to `0` disables the limit. Removing the limit allows a client to send a message of any size. Malicious clients sending large messages can cause excess memory to be allocated. Excess memory usage can significantly reduce the number of concurrent connections.

Use MessagePack Hub Protocol in SignalR for ASP.NET Core

Article • 06/18/2024

This article assumes the reader is familiar with the topics covered in Get started with ASP.NET Core SignalR.

What is MessagePack?

MessagePack is a fast and compact binary serialization format. It's useful when performance and bandwidth are a concern because it creates smaller messages than JSON. The binary messages are unreadable when looking at network traces and logs unless the bytes are passed through a MessagePack parser. SignalR has built-in support for the MessagePack format and provides APIs for the client and server to use.

Configure MessagePack on the server

To enable the MessagePack Hub Protocol on the server, install the `Microsoft.AspNetCore.SignalR.Protocols.MessagePack` package in your app. In the `Startup.ConfigureServices` method, add `AddMessagePackProtocol` to the `AddSignalR` call to enable MessagePack support on the server.

C#

```
services.AddSignalR()
    .AddMessagePackProtocol();
```

> **Note**
>
> JSON is enabled by default. Adding MessagePack enables support for both JSON and MessagePack clients.

To customize how MessagePack formats data, `AddMessagePackProtocol` takes a delegate for configuring options. In that delegate, the `SerializerOptions` property is used to configure MessagePack serialization options. For more information on how the resolvers work, visit the MessagePack library at MessagePack-CSharp. Attributes can be used on the objects you want to serialize to define how they should be handled.

C#

```
services.AddSignalR()
    .AddMessagePackProtocol(options =>
    {
        options.SerializerOptions = MessagePackSerializerOptions.Standard
            .WithResolver(new CustomResolver())
            .WithSecurity(MessagePackSecurity.UntrustedData);
    });
```

> ⚠ **Warning**
>
> We strongly recommend reviewing CVE-2020-5234 and applying the recommended patches. For example, calling `.WithSecurity(MessagePackSecurity.UntrustedData)` when replacing the `SerializerOptions`.

Configure MessagePack on the client

> ⓘ **Note**
>
> JSON is enabled by default for the supported clients. Clients can only support a single protocol. Adding MessagePack support replaces any previously configured protocols.

.NET client

To enable MessagePack in the .NET Client, install the `Microsoft.AspNetCore.SignalR.Protocols.MessagePack` package and call `AddMessagePackProtocol` on `HubConnectionBuilder`.

C#

```
using Microsoft.AspNetCore.SignalR.Client;
using Microsoft.Extensions.DependencyInjection;

var hubConnection = new HubConnectionBuilder()
                        .WithUrl("/chathub")
                        .AddMessagePackProtocol()
                        .Build();
```

> **Note**
>
> This `AddMessagePackProtocol` call takes a delegate for configuring options just like the server.

JavaScript client

MessagePack support for the JavaScript client is provided by the @microsoft/signalr-protocol-msgpack npm package. Install the package by executing the following command in a command shell:

Bash

```
npm install @microsoft/signalr-protocol-msgpack
```

After installing the npm package, the module can be used directly via a JavaScript module loader or imported into the browser by referencing the following file:

node_modules\@microsoft\signalr-protocol-msgpack\dist\browser\signalr-protocol-msgpack.js

The following required javaScript files must be referenced in the order shown below:

HTML

```
<script src="~/lib/signalr/signalr.js"></script>
<script src="~/lib/signalr/signalr-protocol-msgpack.js"></script>
```

Adding `.withHubProtocol(new signalR.protocols.msgpack.MessagePackHubProtocol())` to the `HubConnectionBuilder` configures the client to use the MessagePack protocol when connecting to a server.

JavaScript

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withHubProtocol(new signalR.protocols.msgpack.MessagePackHubProtocol())
    .build();
```

At this time, there are no configuration options for the MessagePack protocol on the JavaScript client.

Java client

To enable MessagePack with Java, install the `com.microsoft.signalr.messagepack` package. When using Gradle, add the following line to the `dependencies` section of the *build.gradle* file:

Gradle

```
implementation 'com.microsoft.signalr.messagepack:signalr-messagepack:5.0.0'
```

When using Maven, add the following lines inside the `<dependencies>` element of the `pom.xml` file:

XML

```
<dependency>
    <groupId>com.microsoft.signalr.messagepack</groupId>
    <artifactId>signalr</artifactId>
    <version>5.0.0</version>
</dependency>
```

Call `withHubProtocol(new MessagePackHubProtocol())` on `HubConnectionBuilder`.

Java

```
HubConnection messagePackConnection = HubConnectionBuilder.create("YOUR HUB
URL HERE")
    .withHubProtocol(new MessagePackHubProtocol())
    .build();
```

MessagePack considerations

There are a few issues to be aware of when using the MessagePack Hub Protocol.

MessagePack is case-sensitive

The MessagePack protocol is case-sensitive. For example, consider the following C# class:

C#

```
public class ChatMessage
{
    public string Sender { get; }
```

```
    public string Message { get; }
}
```

When sending from the JavaScript client, you must use `PascalCased` property names, since the casing must match the C# class exactly. For example:

JavaScript

```
connection.invoke("SomeMethod", { Sender: "Sally", Message: "Hello!" });
```

Using `camelCased` names won't properly bind to the C# class. You can work around this by using the `Key` attribute to specify a different name for the MessagePack property. For more information, see the MessagePack-CSharp documentation.

DateTime.Kind is not preserved when serializing/deserializing

The MessagePack protocol doesn't provide a way to encode the `Kind` value of a `DateTime`. As a result, when deserializing a date, the MessagePack Hub Protocol will convert to the UTC format if the `DateTime.Kind` is `DateTimeKind.Local` otherwise it will not touch the time and pass it as is. If you're working with `DateTime` values, we recommend converting to UTC before sending them. Convert them from UTC to local time when you receive them.

MessagePack support in "ahead-of-time" compilation environment

The MessagePack-CSharp library used by the .NET client and server uses code generation to optimize serialization. As a result, it isn't supported by default on environments that use "ahead-of-time" compilation (such as Xamarin iOS or Unity). It's possible to use MessagePack in these environments by "pre-generating" the serializer/deserializer code. For more information, see the MessagePack-CSharp documentation. Once you have pre-generated the serializers, you can register them using the configuration delegate passed to `AddMessagePackProtocol`:

C#

```
services.AddSignalR()
    .AddMessagePackProtocol(options =>
    {
        StaticCompositeResolver.Instance.Register(
            MessagePack.Resolvers.GeneratedResolver.Instance,
```

```
            MessagePack.Resolvers.StandardResolver.Instance
        );
        options.SerializerOptions = MessagePackSerializerOptions.Standard
            .WithResolver(StaticCompositeResolver.Instance)
            .WithSecurity(MessagePackSecurity.UntrustedData);
    });
```

Type checks are more strict in MessagePack

The JSON Hub Protocol will perform type conversions during deserialization. For example, if the incoming object has a property value that is a number (`{ foo: 42 }`) but the property on the .NET class is of type `string`, the value will be converted. However, MessagePack doesn't perform this conversion and will throw an exception that can be seen in server-side logs (and in the console):

```
InvalidDataException: Error binding arguments. Make sure that the types of
the provided values match the types of the hub method being invoked.
```

For more information on this limitation, see GitHub issue aspnet/SignalR#2937.

Chars and Strings in Java

In the java client, `char` objects will be serialized as one-character `String` objects. This is in contrast with the C# and JavaScript client, which serialize them as `short` objects. The MessagePack spec itself does not define behavior for `char` objects, so it is up to the library author to determine how to serialize them. The difference in behavior between our clients is a result of the libraries we used for our implementations.

Use streaming in ASP.NET Core SignalR

Article • 06/18/2024

By Brennan Conroy

ASP.NET Core SignalR supports streaming from client to server and from server to client. This is useful for scenarios where fragments of data arrive over time. When streaming, each fragment is sent to the client or server as soon as it becomes available, rather than waiting for all of the data to become available.

View or download sample code (how to download)

Set up a hub for streaming

A hub method automatically becomes a streaming hub method when it returns IAsyncEnumerable<T>, ChannelReader<T>, `Task<IAsyncEnumerable<T>>`, or `Task<ChannelReader<T>>`.

Server-to-client streaming

Streaming hub methods can return `IAsyncEnumerable<T>` in addition to `ChannelReader<T>`. The simplest way to return `IAsyncEnumerable<T>` is by making the hub method an async iterator method as the following sample demonstrates. Hub async iterator methods can accept a `CancellationToken` parameter that's triggered when the client unsubscribes from the stream. Async iterator methods avoid problems common with Channels, such as not returning the `ChannelReader` early enough or exiting the method without completing the ChannelWriter<T>.

> **Note**
>
> The following sample requires C# 8.0 or later.

C#

```
public class AsyncEnumerableHub : Hub
{
    public async IAsyncEnumerable<int> Counter(
        int count,
        int delay,
        [EnumeratorCancellation]
        CancellationToken cancellationToken)
```

```
    {
        for (var i = 0; i < count; i++)
        {
            // Check the cancellation token regularly so that the server
will stop
            // producing items if the client disconnects.
            cancellationToken.ThrowIfCancellationRequested();

            yield return i;

            // Use the cancellationToken in other APIs that accept
cancellation
            // tokens so the cancellation can flow down to them.
            await Task.Delay(delay, cancellationToken);
        }
    }
}
```

The following sample shows the basics of streaming data to the client using Channels. Whenever an object is written to the ChannelWriter<T>, the object is immediately sent to the client. At the end, the `ChannelWriter` is completed to tell the client the stream is closed.

> **Note**
>
> Write to the `ChannelWriter<T>` on a background thread and return the `ChannelReader` as soon as possible. Other hub invocations are blocked until a `ChannelReader` is returned.
>
> Wrap logic in a try ... catch statement. Complete the `Channel` in a finally block. If you want to flow an error, capture it inside the `catch` block and write it in the `finally` block.

C#

```
public ChannelReader<int> Counter(
    int count,
    int delay,
    CancellationToken cancellationToken)
{
    var channel = Channel.CreateUnbounded<int>();

    // We don't want to await WriteItemsAsync, otherwise we'd end up waiting
    // for all the items to be written before returning the channel back to
    // the client.
    _ = WriteItemsAsync(channel.Writer, count, delay, cancellationToken);

    return channel.Reader;
```

```
}

private async Task WriteItemsAsync(
    ChannelWriter<int> writer,
    int count,
    int delay,
    CancellationToken cancellationToken)
{
    Exception localException = null;
    try
    {
        for (var i = 0; i < count; i++)
        {
            await writer.WriteAsync(i, cancellationToken);

            // Use the cancellationToken in other APIs that accept
cancellation
            // tokens so the cancellation can flow down to them.
            await Task.Delay(delay, cancellationToken);
        }
    }
    catch (Exception ex)
    {
        localException = ex;
    }
    finally
    {
        writer.Complete(localException);
    }
}
```

Server-to-client streaming hub methods can accept a `CancellationToken` parameter that's triggered when the client unsubscribes from the stream. Use this token to stop the server operation and release any resources if the client disconnects before the end of the stream.

Client-to-server streaming

A hub method automatically becomes a client-to-server streaming hub method when it accepts one or more objects of type ChannelReader<T> or IAsyncEnumerable<T>. The following sample shows the basics of reading streaming data sent from the client. Whenever the client writes to the ChannelWriter<T>, the data is written into the `ChannelReader` on the server from which the hub method is reading.

C#

```
public async Task UploadStream(ChannelReader<string> stream)
{
    while (await stream.WaitToReadAsync())
```

```
    {
        while (stream.TryRead(out var item))
        {
            // do something with the stream item
            Console.WriteLine(item);
        }
    }
}
```

An IAsyncEnumerable<T> version of the method follows.

> ⓘ Note
>
> The following sample requires C# 8.0 or later.

C#

```
public async Task UploadStream(IAsyncEnumerable<string> stream)
{
    await foreach (var item in stream)
    {
        Console.WriteLine(item);
    }
}
```

.NET client

Server-to-client streaming

The `StreamAsync` and `StreamAsChannelAsync` methods on `HubConnection` are used to invoke server-to-client streaming methods. Pass the hub method name and arguments defined in the hub method to `StreamAsync` or `StreamAsChannelAsync`. The generic parameter on `StreamAsync<T>` and `StreamAsChannelAsync<T>` specifies the type of objects returned by the streaming method. An object of type `IAsyncEnumerable<T>` or `ChannelReader<T>` is returned from the stream invocation and represents the stream on the client.

A `StreamAsync` example that returns `IAsyncEnumerable<int>`:

C#

```
// Call "Cancel" on this CancellationTokenSource to send a cancellation
message to
// the server, which will trigger the corresponding token in the hub method.
```

```
var cancellationTokenSource = new CancellationTokenSource();
var stream = hubConnection.StreamAsync<int>(
    "Counter", 10, 500, cancellationTokenSource.Token);

await foreach (var count in stream)
{
    Console.WriteLine($"{count}");
}

Console.WriteLine("Streaming completed");
```

A corresponding `StreamAsChannelAsync` example that returns `ChannelReader<int>`:

C#

```
// Call "Cancel" on this CancellationTokenSource to send a cancellation
message to
// the server, which will trigger the corresponding token in the hub method.
var cancellationTokenSource = new CancellationTokenSource();
var channel = await hubConnection.StreamAsChannelAsync<int>(
    "Counter", 10, 500, cancellationTokenSource.Token);

// Wait asynchronously for data to become available
while (await channel.WaitToReadAsync())
{
    // Read all currently available data synchronously, before waiting for
more data
    while (channel.TryRead(out var count))
    {
        Console.WriteLine($"{count}");
    }
}

Console.WriteLine("Streaming completed");
```

In the previous code:

- The `StreamAsChannelAsync` method on `HubConnection` is used to invoke a server-to-client streaming method. Pass the hub method name and arguments defined in the hub method to `StreamAsChannelAsync`.
- The generic parameter on `StreamAsChannelAsync<T>` specifies the type of objects returned by the streaming method.
- A `ChannelReader<T>` is returned from the stream invocation and represents the stream on the client.

Client-to-server streaming

There are two ways to invoke a client-to-server streaming hub method from the .NET client. You can either pass in an `IAsyncEnumerable<T>` or a `ChannelReader` as an argument to `SendAsync`, `InvokeAsync`, or `StreamAsChannelAsync`, depending on the hub method invoked.

Whenever data is written to the `IAsyncEnumerable` or `ChannelWriter` object, the hub method on the server receives a new item with the data from the client.

If using an `IAsyncEnumerable` object, the stream ends after the method returning stream items exits.

> ⓘ **Note**
>
> The following sample requires C# 8.0 or later.

C#

```
async IAsyncEnumerable<string> clientStreamData()
{
    for (var i = 0; i < 5; i++)
    {
        var data = await FetchSomeData();
        yield return data;
    }
    //After the for loop has completed and the local function exits the
stream completion will be sent.
}

await connection.SendAsync("UploadStream", clientStreamData());
```

Or if you're using a `ChannelWriter`, you complete the channel with `channel.Writer.Complete()`:

C#

```
var channel = Channel.CreateBounded<string>(10);
await connection.SendAsync("UploadStream", channel.Reader);
await channel.Writer.WriteAsync("some data");
await channel.Writer.WriteAsync("some more data");
channel.Writer.Complete();
```

JavaScript client

Server-to-client streaming

JavaScript clients call server-to-client streaming methods on hubs with `connection.stream`. The `stream` method accepts two arguments:

- The name of the hub method. In the following example, the hub method name is `Counter`.
- Arguments defined in the hub method. In the following example, the arguments are a count for the number of stream items to receive and the delay between stream items.

`connection.stream` returns an `IStreamResult`, which contains a `subscribe` method. Pass an `IStreamSubscriber` to `subscribe` and set the `next`, `error`, and `complete` callbacks to receive notifications from the `stream` invocation.

JavaScript

```
connection.stream("Counter", 10, 500)
    .subscribe({
        next: (item) => {
            var li = document.createElement("li");
            li.textContent = item;
            document.getElementById("messagesList").appendChild(li);
        },
        complete: () => {
            var li = document.createElement("li");
            li.textContent = "Stream completed";
            document.getElementById("messagesList").appendChild(li);
        },
        error: (err) => {
            var li = document.createElement("li");
            li.textContent = err;
            document.getElementById("messagesList").appendChild(li);
        },
});
```

To end the stream from the client, call the `dispose` method on the `ISubscription` that's returned from the `subscribe` method. Calling this method causes cancellation of the `CancellationToken` parameter of the Hub method, if you provided one.

Client-to-server streaming

JavaScript clients call client-to-server streaming methods on hubs by passing in a `Subject` as an argument to `send`, `invoke`, or `stream`, depending on the hub method

invoked. The `Subject` is a class that looks like a `Subject`. For example in RxJS, you can use the Subject class from that library.

JavaScript

```
const subject = new signalR.Subject();
yield connection.send("UploadStream", subject);
var iteration = 0;
const intervalHandle = setInterval(() => {
    iteration++;
    subject.next(iteration.toString());
    if (iteration === 10) {
        clearInterval(intervalHandle);
        subject.complete();
    }
}, 500);
```

Calling `subject.next(item)` with an item writes the item to the stream, and the hub method receives the item on the server.

To end the stream, call `subject.complete()`.

Java client

Server-to-client streaming

The SignalR Java client uses the `stream` method to invoke streaming methods. `stream` accepts three or more arguments:

- The expected type of the stream items.
- The name of the hub method.
- Arguments defined in the hub method.

Java

```
hubConnection.stream(String.class, "ExampleStreamingHubMethod", "Arg1")
    .subscribe(
        (item) -> {/* Define your onNext handler here. */ },
        (error) -> {/* Define your onError handler here. */},
        () -> {/* Define your onCompleted handler here. */});
```

The `stream` method on `HubConnection` returns an Observable of the stream item type. The Observable type's `subscribe` method is where `onNext`, `onError` and `onCompleted` handlers are defined.

Client-to-server streaming

The SignalR Java client can call client-to-server streaming methods on hubs by passing in an Observable as an argument to `send`, `invoke`, or `stream`, depending on the hub method invoked.

Java

```
ReplaySubject<String> stream = ReplaySubject.create();
hubConnection.send("UploadStream", stream);
stream.onNext("FirstItem");
stream.onNext("SecondItem");
stream.onComplete();
```

Calling `stream.onNext(item)` with an item writes the item to the stream, and the hub method receives the item on the server.

To end the stream, call `stream.onComplete()`.

Differences between ASP.NET SignalR and ASP.NET Core SignalR

Article • 06/18/2024

ASP.NET Core SignalR isn't compatible with clients or servers for ASP.NET SignalR. This article details features which have been removed or changed in ASP.NET Core SignalR.

How to identify the SignalR version

Expand table

	ASP.NET SignalR	ASP.NET Core SignalR
Server NuGet package	Microsoft.AspNet.SignalR	None. Included in the Microsoft.AspNetCore.App shared framework.
Client NuGet packages	Microsoft.AspNet.SignalR.Client Microsoft.AspNet.SignalR.JS	Microsoft.AspNetCore.SignalR.Client
JavaScript client npm package	signalr	@microsoft/signalr
Java client	GitHub Repository (deprecated)	Maven package com.microsoft.signalr
Server app type	ASP.NET (System.Web) or OWIN Self-Host	ASP.NET Core
Supported server platforms	.NET Framework 4.5 or later	.NET Core 3.0 or later

Feature differences

Automatic reconnects

In ASP.NET SignalR:

- By default, SignalR attempts to reconnect to the server if the connection is dropped.

In ASP.NET Core SignalR:

- Automatic reconnects are opt-in with both the .NET client and the JavaScript client:

C#

```
HubConnection connection = new HubConnectionBuilder()
    .WithUrl(new Uri("http://127.0.0.1:5000/chathub"))
    .WithAutomaticReconnect()
    .Build();
```

JavaScript

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/chathub")
    .withAutomaticReconnect()
    .build();
```

Protocol support

ASP.NET Core SignalR supports JSON, as well as a new binary protocol based on MessagePack. Additionally, custom protocols can be created.

Transports

The Forever Frame transport isn't supported in ASP.NET Core SignalR.

Differences on the server

The ASP.NET Core SignalR server-side libraries are included in Microsoft.AspNetCore.App, which is used in the **ASP.NET Core Web Application** template for both Razor and MVC projects.

ASP.NET Core SignalR is an ASP.NET Core middleware. It must be configured by calling AddSignalR in `Startup.ConfigureServices`.

C#

```
services.AddSignalR()
```

To configure routing, map routes to hubs inside the UseEndpoints method call in the `Startup.Configure` method.

C#

```
app.UseRouting();

app.UseEndpoints(endpoints =>
{
    endpoints.MapHub<ChatHub>("/hub");
});
```

Sticky sessions

The scaleout model for ASP.NET SignalR allows clients to reconnect and send messages to any server in the farm. In ASP.NET Core SignalR, the client must interact with the same server for the duration of the connection. For scaleout using Redis, that means sticky sessions are required. For scaleout using Azure SignalR Service, sticky sessions aren't required because the service handles connections to clients.

Single hub per connection

In ASP.NET Core SignalR, the connection model has been simplified. Connections are made directly to a single hub, rather than a single connection being used to share access to multiple hubs.

Streaming

ASP.NET Core SignalR now supports streaming data from the hub to the client.

State

The ability to pass arbitrary state between clients and the hub (often called `HubState`) has been removed, as well as support for progress messages. There is no counterpart of hub proxies at the moment.

PersistentConnection removal

In ASP.NET Core SignalR, the PersistentConnection class has been removed.

GlobalHost

ASP.NET Core has dependency injection (DI) built into the framework. Services can use DI to access the HubContext. The `GlobalHost` object that is used in ASP.NET SignalR to get a `HubContext` doesn't exist in ASP.NET Core SignalR.

HubPipeline

ASP.NET Core SignalR doesn't have support for `HubPipeline` modules.

Differences on the client

TypeScript

The ASP.NET Core SignalR client is written in TypeScript. You can write in JavaScript or TypeScript when using the JavaScript client.

The JavaScript client is hosted at npm

In ASP.NET versions, the JavaScript client was obtained through a NuGet package in Visual Studio. In the ASP.NET Core versions, the @microsoft/signalr npm package contains the JavaScript libraries. This package isn't included in the **ASP.NET Core Web Application** template. Use npm to obtain and install the `@microsoft/signalr` npm package.

Console

```
npm init -y
npm install @microsoft/signalr
```

jQuery

The dependency on jQuery has been removed, however projects can still use jQuery.

Internet Explorer support

ASP.NET Core SignalR doesn't support Microsoft Internet Explorer, whereas ASP.NET SignalR supports Microsoft Internet Explorer 8 or later. For more information, see ASP.NET Core SignalR supported platforms.

JavaScript client method syntax

The JavaScript syntax has changed from the ASP.NET version of SignalR. Rather than using the `$connection` object, create a connection using the HubConnectionBuilder API.

JavaScript

```
const connection = new signalR.HubConnectionBuilder()
    .withUrl("/hub")
    .build();
```

Use the on method to specify client methods that the hub can call.

JavaScript

```
connection.on("ReceiveMessage", (user, message) => {
    const msg = message.replace(/&/g, "&amp;").replace(/</g,
"&lt;").replace(/>/g, "&gt;");
    const encodedMsg = `${user} says ${msg}`;
    console.log(encodedMsg);
});
```

After creating the client method, start the hub connection. Chain a catch method to log or handle errors.

JavaScript

```
connection.start().catch(err => console.error(err));
```

Hub proxies

Hub proxies are no longer automatically generated. Instead, the method name is passed into the invoke API as a string.

.NET and other clients

The Microsoft.AspNetCore.SignalR.Client NuGet package contains the .NET client libraries for ASP.NET Core SignalR.

Use the HubConnectionBuilder to create and build an instance of a connection to a hub.

C#

```
connection = new HubConnectionBuilder()
    .WithUrl("url")
    .Build();
```

Scaleout differences

ASP.NET SignalR supports SQL Server and Redis. ASP.NET Core SignalR supports Azure SignalR Service and Redis.

ASP.NET

- SignalR scaleout with Azure Service Bus
- SignalR scaleout with Redis
- SignalR scaleout with SQL Server

ASP.NET Core

- Azure SignalR Service
- Redis Backplane

Additional resources

- Hubs
- JavaScript client
- .NET client
- Supported platforms

WebSockets support in ASP.NET Core

Article • 09/17/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to get started with WebSockets in ASP.NET Core. WebSocket (RFC 6455) is a protocol that enables two-way persistent communication channels over TCP connections. It's used in apps that benefit from fast, real-time communication, such as chat, dashboard, and game apps.

View or download sample code (how to download, how to run).

Http/2 WebSockets support

Using WebSockets over HTTP/2 takes advantage of new features such as:

- Header compression.
- Multiplexing, which reduces the time and resources needed when making multiple requests to the server.

These supported features are available in Kestrel on all HTTP/2 enabled platforms. The version negotiation is automatic in browsers and Kestrel, so no new APIs are needed.

.NET 7 introduced WebSockets over HTTP/2 support for Kestrel, the SignalR JavaScript client, and SignalR with Blazor WebAssembly.

> **Note**
>
> HTTP/2 WebSockets use CONNECT requests rather than GET, so your own routes and controllers may need updating. For more information, see **Add HTTP/2 WebSockets support for existing controllers** in this article.

Chrome and Edge have HTTP/2 WebSockets enabled by default, and you can enable it in FireFox on the `about:config` page with the `network.http.spdy.websockets` flag.

WebSockets were originally designed for HTTP/1.1 but have since been adapted to work over HTTP/2. (RFC 8441)

SignalR

ASP.NET Core SignalR is a library that simplifies adding real-time web functionality to apps. It uses WebSockets whenever possible.

For most applications, we recommend SignalR rather than raw WebSockets. SignalR:

- Provides transport fallback for environments where WebSockets isn't available.
- Provides a basic remote procedure call app model.
- Has no significant performance disadvantage compared to using raw WebSockets in most scenarios.

WebSockets over HTTP/2 is supported for:

- ASP.NET Core SignalR JavaScript client
- ASP.NET Core SignalR with Blazor WebAssembly

For some apps, gRPC on .NET provides an alternative to WebSockets.

Prerequisites

- Any OS that supports ASP.NET Core:
  - Windows 7 / Windows Server 2008 or later
  - Linux
  - macOS
- If the app runs on Windows with IIS:
  - Windows 8 / Windows Server 2012 or later
  - IIS 8 / IIS 8 Express
  - WebSockets must be enabled. See the IIS/IIS Express support section.
- If the app runs on HTTP.sys:
  - Windows 8 / Windows Server 2012 or later
- For supported browsers, see Can I use.

Configure the middleware

Add the WebSockets middleware in `Program.cs`:

```
C#

app.UseWebSockets();
```

The following settings can be configured:

- KeepAliveInterval - How frequently to send "ping" frames to the client to ensure proxies keep the connection open. The default is two minutes.
- AllowedOrigins - A list of allowed Origin header values for WebSocket requests. By default, all origins are allowed. For more information, see WebSocket origin restriction in this article.

```
C#

var webSocketOptions = new WebSocketOptions
{
    KeepAliveInterval = TimeSpan.FromMinutes(2)
};

app.UseWebSockets(webSocketOptions);
```

Accept WebSocket requests

Somewhere later in the request life cycle (later in `Program.cs` or in an action method, for example) check if it's a WebSocket request and accept the WebSocket request.

The following example is from later in `Program.cs`:

```
C#

app.Use(async (context, next) =>
{
    if (context.Request.Path == "/ws")
    {
        if (context.WebSockets.IsWebSocketRequest)
        {
            using var webSocket = await
context.WebSockets.AcceptWebSocketAsync();
            await Echo(webSocket);
        }
        else
        {
            context.Response.StatusCode = StatusCodes.Status400BadRequest;
        }
    }
```

```
    else
    {
        await next(context);
    }

});
```

A WebSocket request could come in on any URL, but this sample code only accepts requests for `/ws`.

A similar approach can be taken in a controller method:

C#

```
public class WebSocketController : ControllerBase
{
    [Route("/ws")]
    public async Task Get()
    {
        if (HttpContext.WebSockets.IsWebSocketRequest)
        {
            using var webSocket = await
HttpContext.WebSockets.AcceptWebSocketAsync();
            await Echo(webSocket);
        }
        else
        {
            HttpContext.Response.StatusCode =
StatusCodes.Status400BadRequest;
        }
    }
```

When using a WebSocket, you **must** keep the middleware pipeline running for the duration of the connection. If you attempt to send or receive a WebSocket message after the middleware pipeline ends, you may get an exception like the following:

```
System.Net.WebSockets.WebSocketException (0x80004005): The remote party
closed the WebSocket connection without completing the close handshake. --->
System.ObjectDisposedException: Cannot write to the response body, the
response has completed.
Object name: 'HttpResponseStream'.
```

If you're using a background service to write data to a WebSocket, make sure you keep the middleware pipeline running. Do this by using a TaskCompletionSource<TResult>. Pass the `TaskCompletionSource` to your background service and have it call TrySetResult

when you finish with the WebSocket. Then `await` the Task property during the request, as shown in the following example:

C#

```
app.Run(async (context) =>
{
    using var webSocket = await context.WebSockets.AcceptWebSocketAsync();
    var socketFinishedTcs = new TaskCompletionSource<object>();

    BackgroundSocketProcessor.AddSocket(webSocket, socketFinishedTcs);

    await socketFinishedTcs.Task;
});
```

The WebSocket closed exception can also happen when returning too soon from an action method. When accepting a socket in an action method, wait for the code that uses the socket to complete before returning from the action method.

Never use `Task.Wait`, `Task.Result`, or similar blocking calls to wait for the socket to complete, as that can cause serious threading issues. Always use `await`.

Add HTTP/2 WebSockets support for existing controllers

.NET 7 introduced WebSockets over HTTP/2 support for Kestrel, the SignalR JavaScript client, and SignalR with Blazor WebAssembly. HTTP/2 WebSockets use CONNECT requests rather than GET. If you previously used `[HttpGet("/path")]` on your controller action method for Websocket requests, update it to use `[Route("/path")]` instead.

C#

```
public class WebSocketController : ControllerBase
{
    [Route("/ws")]
    public async Task Get()
    {
        if (HttpContext.WebSockets.IsWebSocketRequest)
        {
            using var webSocket = await
HttpContext.WebSockets.AcceptWebSocketAsync();
            await Echo(webSocket);
        }
        else
        {
            HttpContext.Response.StatusCode =
```

```
StatusCodes.Status400BadRequest;
        }
    }
```

Compression

> **⚠ Warning**
>
> Enabling compression over encrypted connections can make an app subject to CRIME/BREACH attacks. If sending sensitive information, avoid enabling compression or use `WebSocketMessageFlags.DisableCompression` when calling `WebSocket.SendAsync`. This applies to both sides of the WebSocket. Note that the WebSockets API in the browser doesn't have configuration for disabling compression per send.

If compression of messages over WebSockets is desired, then the accept code must specify that it allows compression as follows:

C#

```
using (var webSocket = await context.WebSockets.AcceptWebSocketAsync(
    new WebSocketAcceptContext { DangerousEnableCompression = true }))
{

}
```

`WebSocketAcceptContext.ServerMaxWindowBits` and `WebSocketAcceptContext.DisableServerContextTakeover` are advanced options that control how the compression works.

Compression is negotiated between the client and server when first establishing a connection. You can read more about the negotiation in the Compression Extensions for WebSocket RFC.

> **ⓘ Note**
>
> If the compression negotiation isn't accepted by either the server or client, the connection is still established. However, the connection doesn't use compression when sending and receiving messages.

Send and receive messages

The `AcceptWebSocketAsync` method upgrades the TCP connection to a WebSocket connection and provides a WebSocket object. Use the `WebSocket` object to send and receive messages.

The code shown earlier that accepts the WebSocket request passes the `WebSocket` object to an `Echo` method. The code receives a message and immediately sends back the same message. Messages are sent and received in a loop until the client closes the connection:

C#

```
private static async Task Echo(WebSocket webSocket)
{
    var buffer = new byte[1024 * 4];
    var receiveResult = await webSocket.ReceiveAsync(
        new ArraySegment<byte>(buffer), CancellationToken.None);

    while (!receiveResult.CloseStatus.HasValue)
    {
        await webSocket.SendAsync(
            new ArraySegment<byte>(buffer, 0, receiveResult.Count),
            receiveResult.MessageType,
            receiveResult.EndOfMessage,
            CancellationToken.None);

        receiveResult = await webSocket.ReceiveAsync(
            new ArraySegment<byte>(buffer), CancellationToken.None);
    }

    await webSocket.CloseAsync(
        receiveResult.CloseStatus.Value,
        receiveResult.CloseStatusDescription,
        CancellationToken.None);
}
```

When accepting the WebSocket connection before beginning the loop, the middleware pipeline ends. Upon closing the socket, the pipeline unwinds. That is, the request stops moving forward in the pipeline when the WebSocket is accepted. When the loop is finished and the socket is closed, the request proceeds back up the pipeline.

Handle client disconnects

The server isn't automatically informed when the client disconnects due to loss of connectivity. The server receives a disconnect message only if the client sends it, which

can't be done if the internet connection is lost. If you want to take some action when that happens, set a timeout after nothing is received from the client within a certain time window.

If the client isn't always sending messages and you don't want to time out just because the connection goes idle, have the client use a timer to send a ping message every X seconds. On the server, if a message hasn't arrived within 2*X seconds after the previous one, terminate the connection and report that the client disconnected. Wait for twice the expected time interval to leave extra time for network delays that might hold up the ping message.

WebSocket origin restriction

The protections provided by CORS don't apply to WebSockets. Browsers do **not**:

- Perform CORS pre-flight requests.
- Respect the restrictions specified in `Access-Control` headers when making WebSocket requests.

However, browsers do send the `Origin` header when issuing WebSocket requests. Applications should be configured to validate these headers to ensure that only WebSockets coming from the expected origins are allowed.

If you're hosting your server on "https://server.com" and hosting your client on "https://client.com", add "https://client.com" to the AllowedOrigins list for WebSockets to verify.

C#

```
var webSocketOptions = new WebSocketOptions
{
    KeepAliveInterval = TimeSpan.FromMinutes(2)
};

webSocketOptions.AllowedOrigins.Add("https://client.com");
webSocketOptions.AllowedOrigins.Add("https://www.client.com");

app.UseWebSockets(webSocketOptions);
```

> ⓘ **Note**
>
> The `Origin` header is controlled by the client and, like the `Referer` header, can be faked. Do **not** use these headers as an authentication mechanism.

IIS/IIS Express support

Windows Server 2012 or later and Windows 8 or later with IIS/IIS Express 8 or later has support for the WebSocket protocol, but not for WebSockets over HTTP/2.

> ⓘ **Note**
>
> WebSockets are always enabled when using IIS Express.

Enabling WebSockets on IIS

To enable support for the WebSocket protocol on Windows Server 2012 or later:

> ⓘ **Note**
>
> These steps are not required when using IIS Express

1. Use the **Add Roles and Features** wizard from the **Manage** menu or the link in **Server Manager**.
2. Select **Role-based or Feature-based Installation**. Select **Next**.
3. Select the appropriate server (the local server is selected by default). Select **Next**.
4. Expand **Web Server (IIS)** in the **Roles** tree, expand **Web Server**, and then expand **Application Development**.
5. Select **WebSocket Protocol**. Select **Next**.
6. If additional features aren't needed, select **Next**.
7. Select **Install**.
8. When the installation completes, select **Close** to exit the wizard.

To enable support for the WebSocket protocol on Windows 8 or later:

> ⓘ **Note**
>
> These steps are not required when using IIS Express

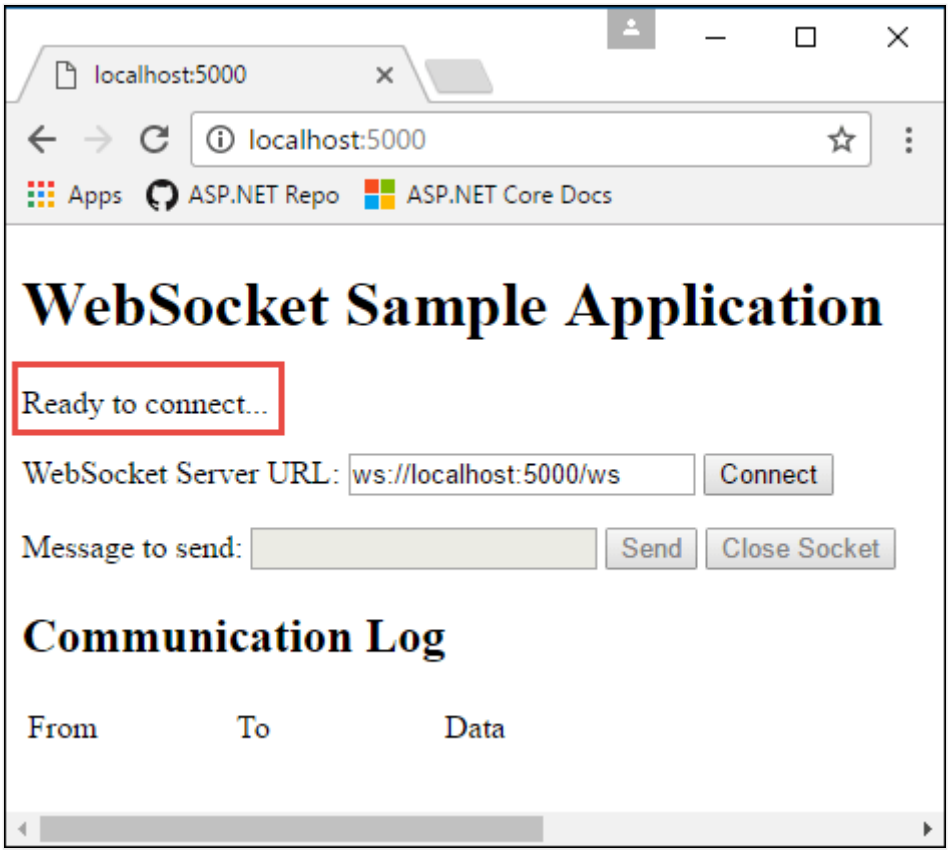
1. Navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Open the following nodes: **Internet Information Services** > **World Wide Web Services** > **Application Development Features**.
3. Select the **WebSocket Protocol** feature. Select **OK**.

Disable WebSocket when using socket.io on Node.js

If using the WebSocket support in socket.io on Node.js, disable the default IIS WebSocket module using the `webSocket` element in *web.config* or *applicationHost.config*. If this step isn't performed, the IIS WebSocket module attempts to handle the WebSocket communication rather than Node.js and the app.

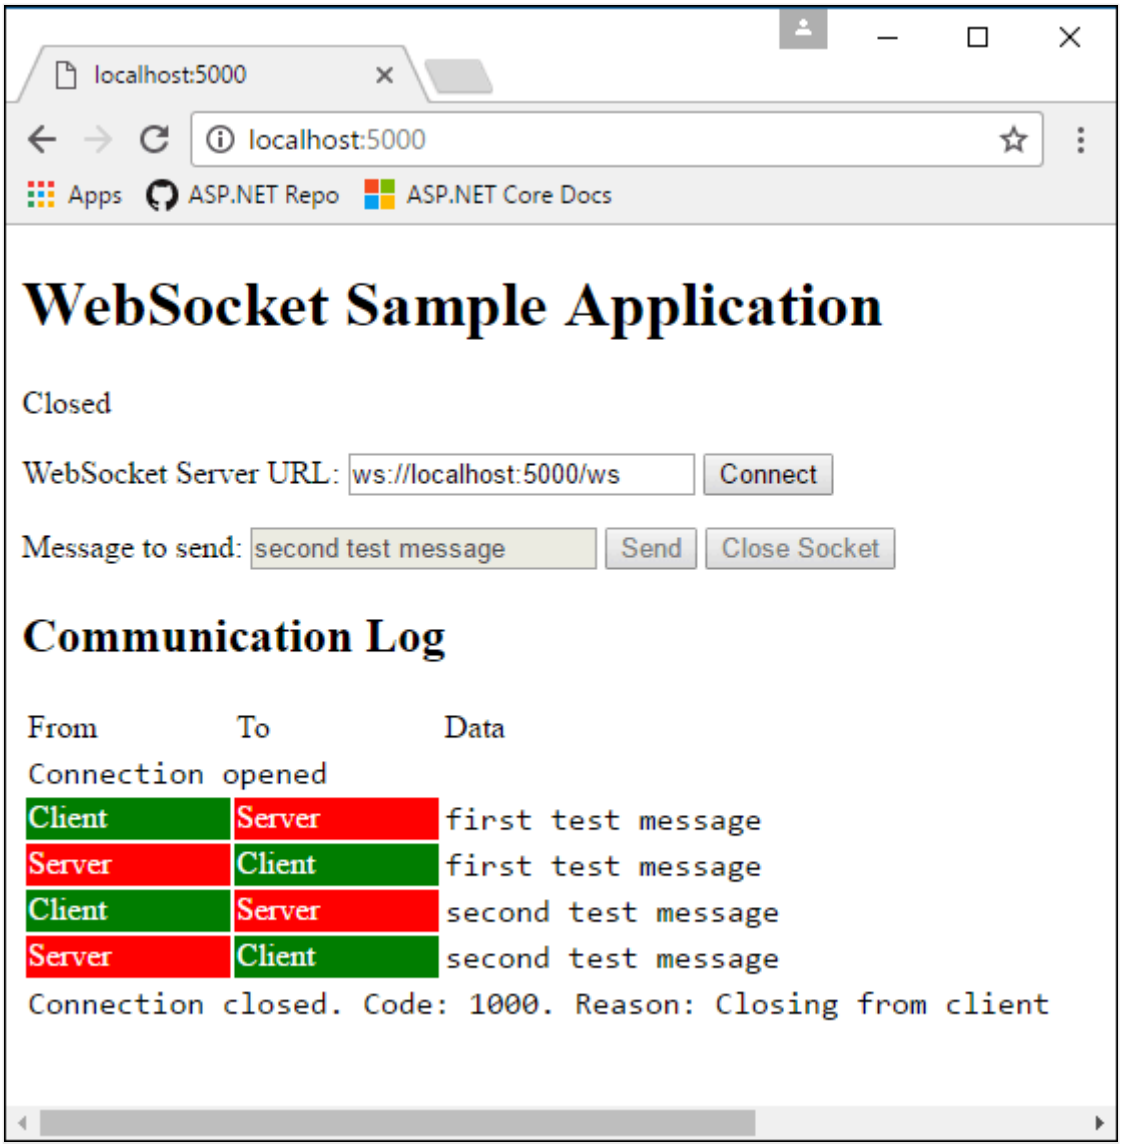
XML

```
<system.webServer>
  <webSocket enabled="false" />
</system.webServer>
```



Sample app

The sample app that accompanies this article is an echo app. It has a webpage that makes WebSocket connections, and the server resends any messages it receives back to the client. The sample app supports WebSockets over HTTP/2 when using a targeted framework of .NET 7 or later.



Run the app:

- To run app in Visual Studio: Open the sample project in Visual Studio, and press Ctrl+F5 to run without the debugger.
- To run the app in a command shell: Run the command dotnet run and navigate in a browser to `http://localhost:<port>`.

The webpage shows the connection status:

Select **Connect** to send a WebSocket request to the URL shown. Enter a test message and select **Send**. When done, select **Close Socket**. The **Communication Log** section reports each open, send, and close action as it happens.

Logging and diagnostics in ASP.NET Core SignalR

Article • 06/18/2024

By Andrew Stanton-Nurse

This article provides guidance for gathering diagnostics from your ASP.NET Core SignalR app to help troubleshoot issues.

Server-side logging

> ⚠ **Warning**
>
> Server-side logs may contain sensitive information from your app. **Never** post raw logs from production apps to public forums like GitHub.

Since SignalR is part of ASP.NET Core, it uses the ASP.NET Core logging system. In the default configuration, SignalR logs very little information, but this can configured. See the documentation on ASP.NET Core logging for details on configuring ASP.NET Core logging.

SignalR uses two logger categories:

- `Microsoft.AspNetCore.SignalR`: For logs related to Hub Protocols, activating Hubs, invoking methods, and other Hub-related activities.
- `Microsoft.AspNetCore.Http.Connections`: For logs related to transports, such as WebSockets, Long Polling, Server-Sent Events, and low-level SignalR infrastructure.

To enable detailed logs from SignalR, configure both of the preceding prefixes to the `Debug` level in your `appsettings.json` file by adding the following items to the `LogLevel` sub-section in `Logging`:

JSON

```
{
    "Logging": {
        "LogLevel": {
            "Default": "Debug",
            "System": "Information",
            "Microsoft": "Information",
            "Microsoft.AspNetCore.SignalR": "Debug",
            "Microsoft.AspNetCore.Http.Connections": "Debug"
```

```
        }
    }
}
```

You can also configure this in code in your `CreateWebHostBuilder` method:

C#

```
public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
    WebHost.CreateDefaultBuilder(args)
        .ConfigureLogging(logging =>
        {
            logging.AddFilter("Microsoft.AspNetCore.SignalR",
LogLevel.Debug);
            logging.AddFilter("Microsoft.AspNetCore.Http.Connections",
LogLevel.Debug);
        })
        .UseStartup<Startup>();
```

If you aren't using JSON-based configuration, set the following configuration values in your configuration system:

- `Logging:LogLevel:Microsoft.AspNetCore.SignalR` = `Debug`
- `Logging:LogLevel:Microsoft.AspNetCore.Http.Connections` = `Debug`

Check the documentation for your configuration system to determine how to specify nested configuration values. For example, when using environment variables, two `_` characters are used instead of the `:` (for example, `Logging__LogLevel__Microsoft.AspNetCore.SignalR`).

We recommend using the `Debug` level when gathering more detailed diagnostics for your app. The `Trace` level produces very low-level diagnostics and is rarely needed to diagnose issues in your app.

Access server-side logs

How you access server-side logs depends on the environment in which you're running.

As a console app outside IIS

If you're running in a console app, the Console logger should be enabled by default. SignalR logs will appear in the console.

Within IIS Express from Visual Studio

Visual Studio displays the log output in the **Output** window. Select the **ASP.NET Core Web Server** drop down option.

Azure App Service

Enable the **Application Logging (Filesystem)** option in the **Diagnostics logs** section of the Azure App Service portal and configure the **Level** to `Verbose`. Logs should be available from the **Log streaming** service and in logs on the file system of the App Service. For more information, see Azure log streaming.

Other environments

If the app is deployed to another environment (for example, Docker, Kubernetes, or Windows Service), see Logging in .NET Core and ASP.NET Core for more information on how to configure logging providers suitable for the environment.

JavaScript client logging

> ⚠ **Warning**
>
> Client-side logs may contain sensitive information from your app. **Never** post raw logs from production apps to public forums like GitHub.

When using the JavaScript client, you can configure logging options using the `configureLogging` method on `HubConnectionBuilder`:

JavaScript

```
let connection = new signalR.HubConnectionBuilder()
    .withUrl("/my/hub/url")
    .configureLogging(signalR.LogLevel.Debug)
    .build();
```

To disable framework logging, specify `signalR.LogLevel.None` in the `configureLogging` method. Note that some logging is emitted directly by the browser and can't be disabled via setting the log level.

The following table shows log levels available to the JavaScript client. Setting the log level to one of these values enables logging at that level and all levels above it in the

table.

Expand table

Level	Description
`None`	No messages are logged.
`Critical`	Messages that indicate a failure in the entire app.
`Error`	Messages that indicate a failure in the current operation.
`Warning`	Messages that indicate a non-fatal problem.
`Information`	Informational messages.
`Debug`	Diagnostic messages useful for debugging.
`Trace`	Very detailed diagnostic messages designed for diagnosing specific issues.

Once you've configured the verbosity, the logs will be written to the Browser Console (or Standard Output in a NodeJS app).

If you want to send logs to a custom logging system, you can provide a JavaScript object implementing the `ILogger` interface. The only method that needs to be implemented is `log`, which takes the level of the event and the message associated with the event. For example:

TypeScript

```
import { ILogger, LogLevel, HubConnectionBuilder } from
"@microsoft/signalr";

export class MyLogger implements ILogger {
    log(logLevel: LogLevel, message: string) {
        // Use `message` and `logLevel` to record the log message to your
own system
    }
}

// later on, when configuring your connection...

let connection = new HubConnectionBuilder()
    .withUrl("/my/hub/url")
    .configureLogging(new MyLogger())
    .build();
```

.NET client logging

> ⚠ **Warning**
>
> Client-side logs may contain sensitive information from your app. **Never** post raw logs from production apps to public forums like GitHub.

To get logs from the .NET client, you can use the `ConfigureLogging` method on `HubConnectionBuilder`. This works the same way as the `ConfigureLogging` method on `WebHostBuilder` and `HostBuilder`. You can configure the same logging providers you use in ASP.NET Core. However, you have to manually install and enable the NuGet packages for the individual logging providers.

To add .NET client logging to a Blazor WebAssembly app, see ASP.NET Core Blazor logging.

Console logging

In order to enable Console logging, add the Microsoft.Extensions.Logging.Console package. Then, use the `AddConsole` method to configure the console logger:

C#

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/my/hub/url")
    .ConfigureLogging(logging =>
    {
        // Log to the Console
        logging.AddConsole();

        // This will set ALL logging to Debug level
        logging.SetMinimumLevel(LogLevel.Debug);
    })
    .Build();
```

Debug output window logging

You can also configure logs to go to the **Output** window in Visual Studio. Install the Microsoft.Extensions.Logging.Debug package and use the `AddDebug` method:

C#

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/my/hub/url")
    .ConfigureLogging(logging =>
    {
```

```
        // Log to the Output Window
        logging.AddDebug();

        // This will set ALL logging to Debug level
        logging.SetMinimumLevel(LogLevel.Debug)
    })
    .Build();
```

Other logging providers

SignalR supports other logging providers such as Serilog, Seq, NLog, or any other logging system that integrates with `Microsoft.Extensions.Logging`. If your logging system provides an `ILoggerProvider`, you can register it with `AddProvider`:

C#

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/my/hub/url")
    .ConfigureLogging(logging =>
    {
        // Log to your custom provider
        logging.AddProvider(new MyCustomLoggingProvider());

        // This will set ALL logging to Debug level
        logging.SetMinimumLevel(LogLevel.Debug)
    })
    .Build();
```

Control verbosity

If you are logging from other places in your app, changing the default level to `Debug` may be too verbose. You can use a Filter to configure the logging level for SignalR logs. This can be done in code, in much the same way as on the server:

C#

```
var connection = new HubConnectionBuilder()
    .WithUrl("https://example.com/my/hub/url")
    .ConfigureLogging(logging =>
    {
        // Register your providers

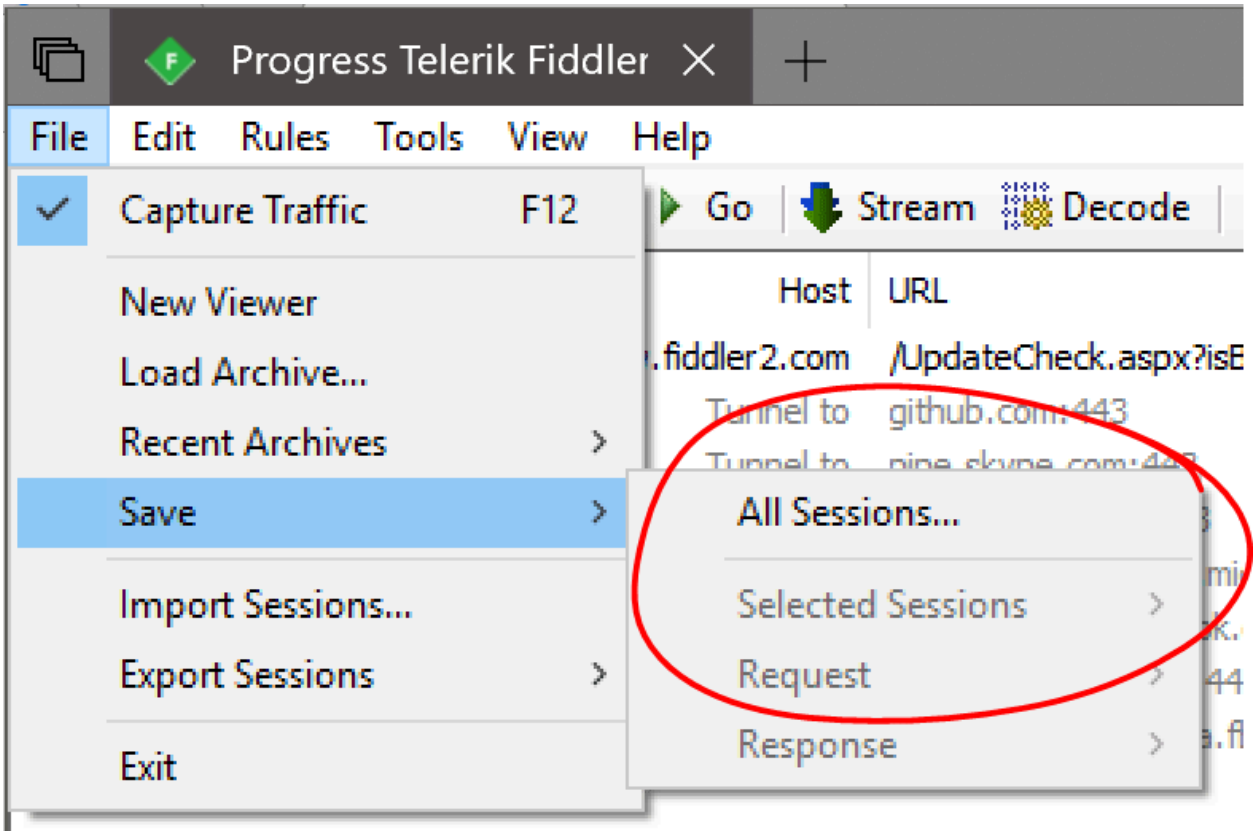
        // Set the default log level to Information, but to Debug for
SignalR-related loggers.
        logging.SetMinimumLevel(LogLevel.Information);
```

```
        logging.AddFilter("Microsoft.AspNetCore.SignalR", LogLevel.Debug);
        logging.AddFilter("Microsoft.AspNetCore.Http.Connections",
LogLevel.Debug);
    })
    .Build();
```

Network traces

> ⚠ **Warning**
>
> A network trace contains the full contents of every message sent by your app. **Never** post raw network traces from production apps to public forums like GitHub.

If you encounter an issue, a network trace can sometimes provide a lot of helpful information. This is particularly useful if you're going to file an issue on our issue tracker.



Collect a network trace with Fiddler (preferred option)

This method works for all apps.

Fiddler is a very powerful tool for collecting HTTP traces. Install it from telerik.com/fiddler, launch it, and then run your app and reproduce the issue. Fiddler is available for Windows, and there are beta versions for macOS and Linux.

If you connect using HTTPS, there are some extra steps to ensure Fiddler can decrypt the HTTPS traffic. For more details, see the Fiddler documentation.

Once you've collected the trace, you can export the trace by choosing **File** > **Save** > **All Sessions** from the menu bar.

Collect a network trace with tcpdump (macOS and Linux only)

This method works for all apps.

You can collect raw TCP traces using tcpdump by running the following command from a command shell. You may need to be `root` or prefix the command with `sudo` if you get a permissions error:

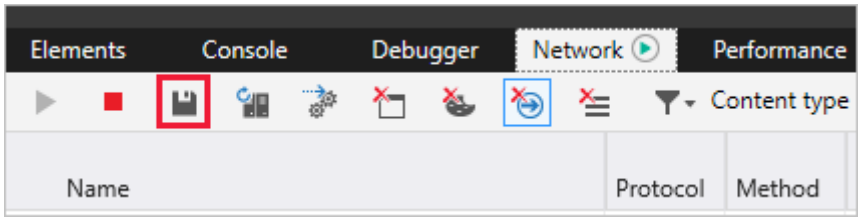
Console

```
tcpdump -i [interface] -w trace.pcap
```

Replace `[interface]` with the network interface you wish to capture on. Usually, this is something like `/dev/eth0` (for your standard Ethernet interface) or `/dev/lo0` (for localhost traffic). For more information, see the `tcpdump` man page on your host system.

Collect a network trace in the browser

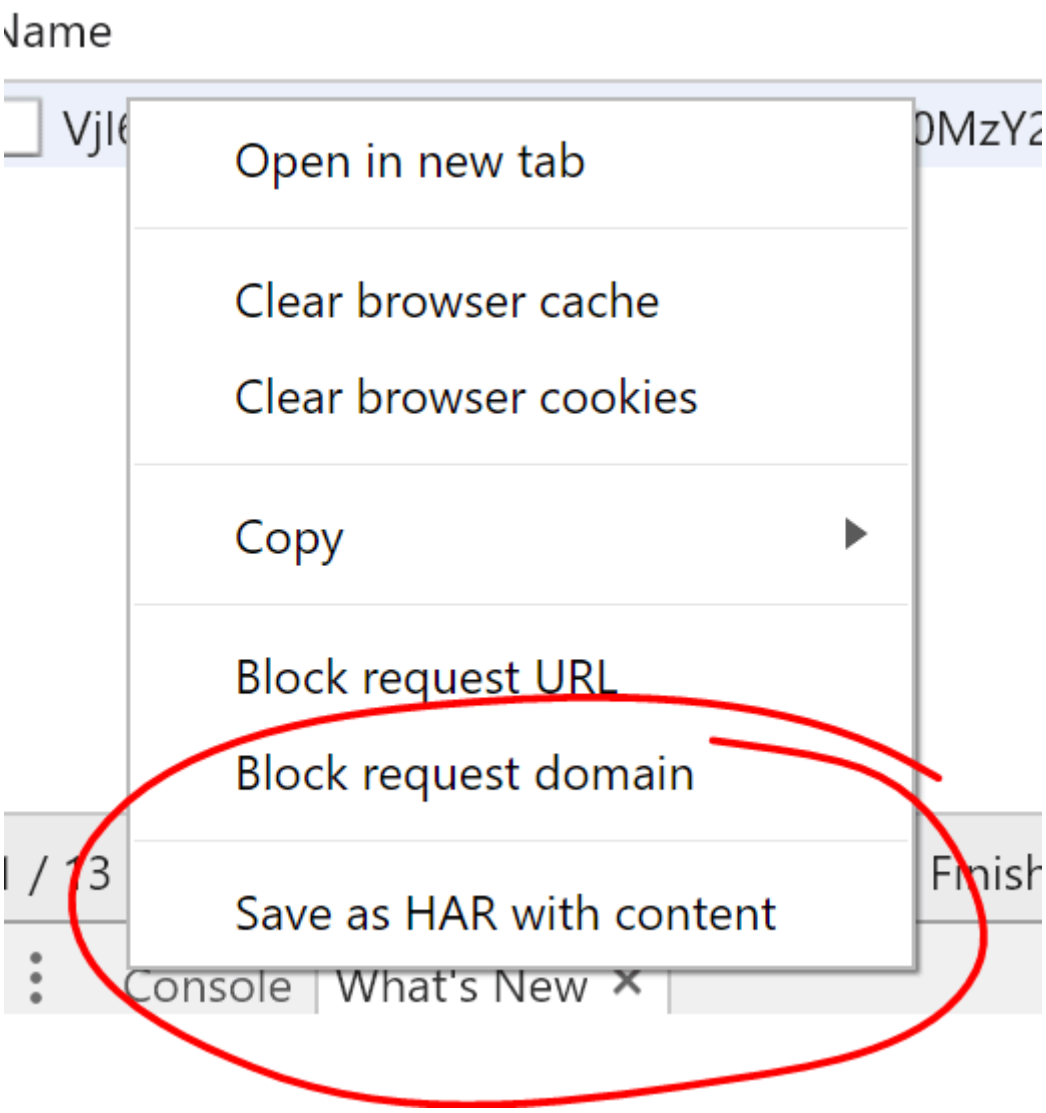
This method only works for browser-based apps.



Most browser developer tools consoles have a "Network" tab that allows you to capture network activity between the browser and the server. However, these traces don't

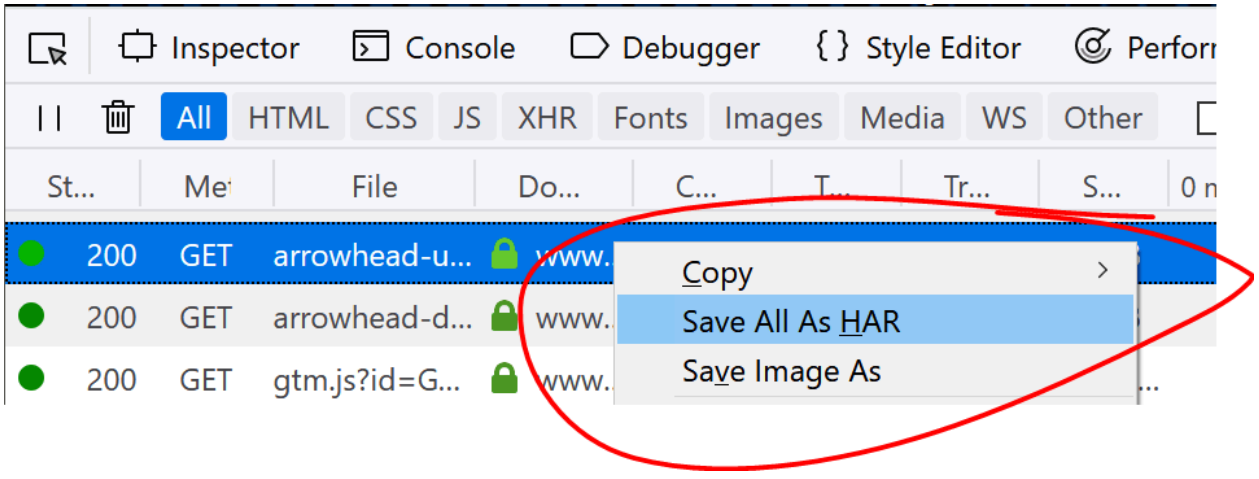
include WebSocket and Server-Sent Event messages. If you are using those transports, using a tool like Fiddler or TcpDump (described below) is a better approach.

Microsoft Edge and Internet Explorer



(The instructions are the same for both Edge and Internet Explorer)

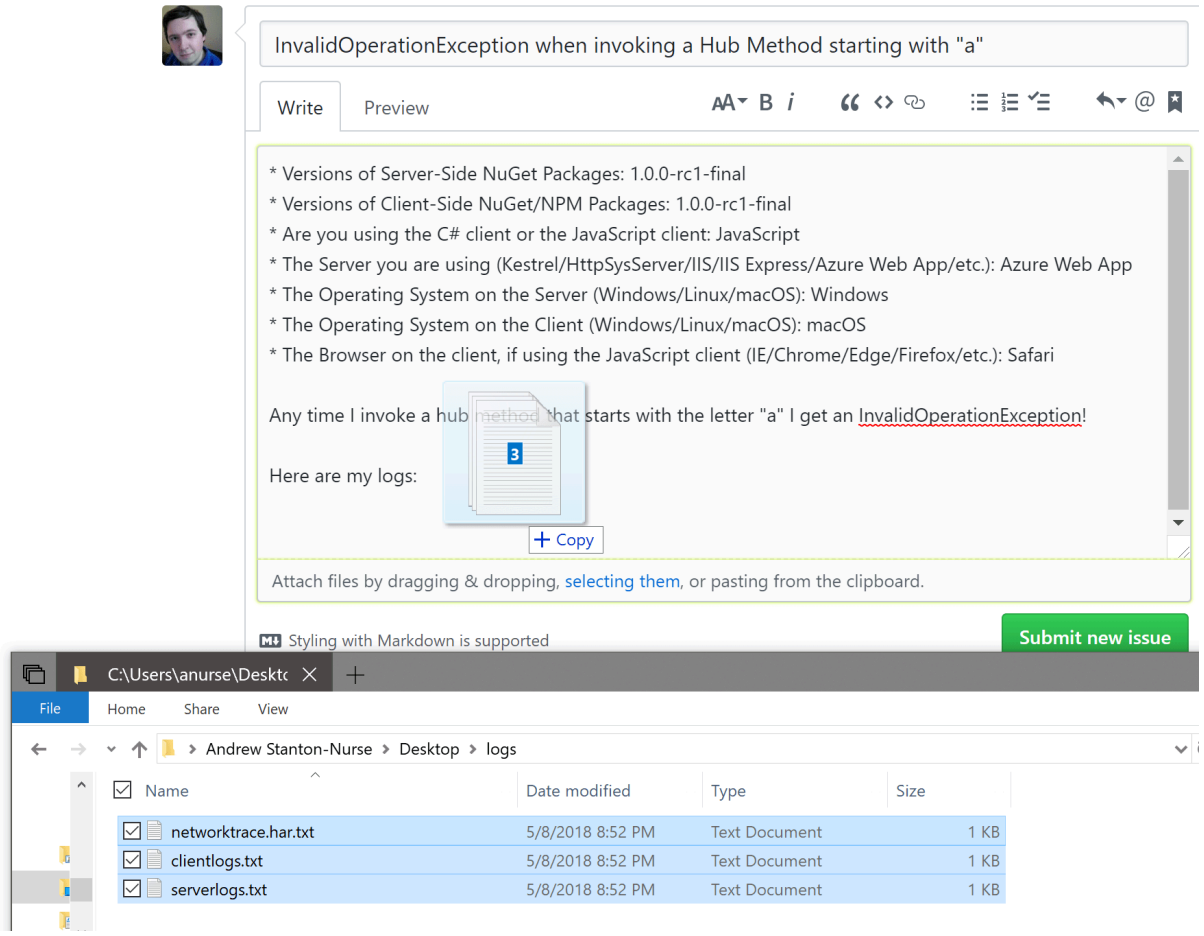
1. Press F12 to open the Dev Tools
2. Click the Network Tab
3. Refresh the page (if needed) and reproduce the problem
4. Click the Save icon in the toolbar to export the trace as a "HAR" file:



Google Chrome

1. Press F12 to open the Dev Tools
2. Click the Network Tab
3. Refresh the page (if needed) and reproduce the problem
4. Right click anywhere in the list of requests and choose "Save as HAR with content":

Mozilla Firefox



1. Press F12 to open the Dev Tools
2. Click the Network Tab
3. Refresh the page (if needed) and reproduce the problem
4. Right click anywhere in the list of requests and choose "Save All As HAR"

Attach diagnostics files to GitHub issues

You can attach Diagnostics files to GitHub issues by renaming them so they have a `.txt` extension and then dragging and dropping them on to the issue.

> **Note**
>
> Please don't paste the content of log files or network traces into a GitHub issue. These logs and traces can be quite large, and GitHub usually truncates them.

Metrics

Metrics is a representation of data measures over intervals of time. For example, requests per second. Metrics data allows observation of the state of an app at a high level. .NET gRPC metrics are emitted using EventCounter.

SignalR server metrics

SignalR server metrics are reported on the Microsoft.AspNetCore.Http.Connections event source.

Expand table

Name	Description
`connections-started`	Total connections started
`connections-stopped`	Total connections stopped
`connections-timed-out`	Total connections timed out
`current-connections`	Current connections
`connections-duration`	Average connection duration

Observe metrics

dotnet-counters is a performance monitoring tool for ad-hoc health monitoring and first-level performance investigation. Monitor a .NET app with `Microsoft.AspNetCore.Http.Connections` as the provider name. For example:

Console

```
> dotnet-counters monitor --process-id 37016
Microsoft.AspNetCore.Http.Connections

Press p to pause, r to resume, q to quit.
    Status: Running
[Microsoft.AspNetCore.Http.Connections]
    Average Connection Duration (ms)       16,040.56
    Current Connections                            1
    Total Connections Started                      8
    Total Connections Stopped                      7
    Total Connections Timed Out                    0
```

Troubleshoot connection errors

Article • 06/18/2024

This section provides help with errors that can occur when trying to establish a connection to an ASP.NET Core SignalR hub.

Response code 404

When using WebSockets and `skipNegotiation = true`

log

```
WebSocket connection to 'wss://xxx/HubName' failed: Error during WebSocket
handshake: Unexpected response code: 404
```

- When using multiple servers without sticky sessions, the connection can start on one server and then switch to another server. The other server is not aware of the previous connection.
- Verify the client is connecting to the correct endpoint. For example, the server is hosted at `http://127.0.0.1:5000/hub/myHub` and client is trying to connect to `http://127.0.0.1:5000/myHub`.
- If the connection uses the ID and takes too long to send a request to the server after the negotiate, the server:
  - Deletes the ID.
  - Returns a 404.

Response code 400 or 503

For the following error:

log

```
WebSocket connection to 'wss://xxx/HubName' failed: Error during WebSocket
handshake: Unexpected response code: 400

Error: Failed to start the connection: Error: There was an error with the
transport.
```

This error is usually caused by a client using only the WebSockets transport but the WebSocket protocol isn't enabled on the server.

Response code 307

When using WebSockets and `skipNegotiation = true`

log

```
WebSocket connection to 'ws://xxx/HubName' failed: Error during WebSocket
handshake: Unexpected response code: 307
```

This error can also happen during the negotiate request.

Common cause:

- App is configured to enforce HTTPS by calling `UseHttpsRedirection` in `Startup`, or enforces HTTPS via URL rewrite rule.

Possible solution:

- Change the URL on the client side from "http" to "https".
  `.withUrl("https://xxx/HubName")`

Response code 405

Http status code 405 - Method Not Allowed

- The app doesn't have CORS enabled

Response code 0

Http status code 0 - Usually a CORS issue, no status code is given

log

```
Cross-Origin Request Blocked: The Same Origin Policy disallows reading the
remote resource at http://localhost:5000/default/negotiate?
negotiateVersion=1. (Reason: CORS header 'Access-Control-Allow-Origin'
missing).
```

- Add the expected origins to `.WithOrigins(...)`

log

```
Cross-Origin Request Blocked: The Same Origin Policy disallows reading the
remote resource at http://localhost:5000/default/negotiate?
```

```
negotiateVersion=1. (Reason: expected 'true' in CORS header 'Access-Control-
Allow-Credentials').
```

- Add `.AllowCredentials()` to your CORS policy. Cannot use `.AllowAnyOrigin()` or `.WithOrigins("*")` with this option

Response code 413

Http status code 413 - Payload Too Large

This is often caused by having an access token that is over 4k.

- If using the Azure SignalR Service, reduce the token size by customizing the claims being sent through the Service with:

C#

```
.AddAzureSignalR(options =>
{
    options.ClaimsProvider = context => context.User.Claims;
});
```

Transient network failures

Transient network failures may close the SignalR connection. The server may interpret the closed connection as a graceful client disconnect. To get more info on why a client disconnected in those cases gather logs from the client and server.

Overview for gRPC on .NET

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

gRPC is a language agnostic, high-performance Remote Procedure Call (RPC) framework.

The main benefits of gRPC are:

- Modern, high-performance, lightweight RPC framework.
- Contract-first API development, using Protocol Buffers by default, allowing for language agnostic implementations.
- Tooling available for many languages to generate strongly-typed servers and clients.
- Supports client, server, and bi-directional streaming calls.
- Reduced network usage with Protobuf binary serialization.

These benefits make gRPC ideal for:

- Lightweight microservices where efficiency is critical.
- Polyglot systems where multiple languages are required for development.
- Point-to-point real-time services that need to handle streaming requests or responses.

C# Tooling support for `.proto` files

gRPC uses a contract-first approach to API development. Services and messages are defined in `.proto` files:

ProtoBuf

```
syntax = "proto3";
```

```
service Greeter {
  rpc SayHello (HelloRequest) returns (HelloReply);
}

message HelloRequest {
  string name = 1;
}

message HelloReply {
  string message = 1;
}
```

.NET types for services, clients, and messages are automatically generated by including `.proto` files in a project:

- Add a package reference to Grpc.Tools package.
- Add `.proto` files to the `<Protobuf>` item group.

XML

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" />
</ItemGroup>
```

For more information on gRPC tooling support, see gRPC services with C#.

gRPC services on ASP.NET Core

gRPC services can be hosted on ASP.NET Core. Services have full integration with ASP.NET Core features such as logging, dependency injection (DI), authentication, and authorization.

Add gRPC services to an ASP.NET Core app

gRPC requires the Grpc.AspNetCore package. For information on configuring gRPC in a .NET app, see Configure gRPC.

The gRPC service project template

The **ASP.NET Core gRPC Service** project template provides a starter service:

C#

```
public class GreeterService : Greeter.GreeterBase
{
```

```
    private readonly ILogger<GreeterService> _logger;

    public GreeterService(ILogger<GreeterService> logger)
    {
        _logger = logger;
    }

    public override Task<HelloReply> SayHello(HelloRequest request,
        ServerCallContext context)
    {
        _logger.LogInformation("Saying hello to {Name}", request.Name);
        return Task.FromResult(new HelloReply
        {
            Message = "Hello " + request.Name
        });
    }
}
```

`GreeterService` inherits from the `GreeterBase` type, which is generated from the `Greeter` service in the `.proto` file. The service is made accessible to clients in `Program.cs`:

C#

```
app.MapGrpcService<GreeterService>();
```

To learn more about gRPC services on ASP.NET Core, see gRPC services with ASP.NET Core.

Call gRPC services with a .NET client

gRPC clients are concrete client types that are generated from .proto files. The concrete gRPC client has methods that translate to the gRPC service in the `.proto` file.

C#

```
var channel = GrpcChannel.ForAddress("https://localhost:5001");
var client = new Greeter.GreeterClient(channel);

var response = await client.SayHelloAsync(
    new HelloRequest { Name = "World" });

Console.WriteLine(response.Message);
```

A gRPC client is created using a channel, which represents a long-lived connection to a gRPC service. A channel can be created using `GrpcChannel.ForAddress`.

For more information on creating clients, and calling different service methods, see Call gRPC services with the .NET client.

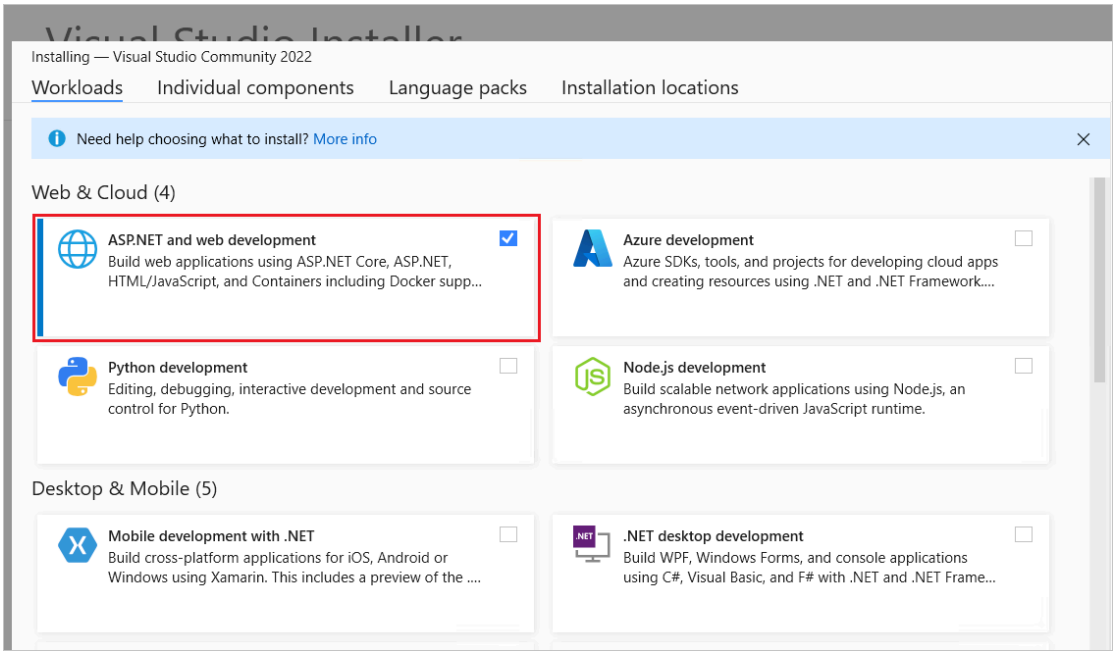
Tutorial: Create a gRPC client and server in ASP.NET Core

Article • 06/18/2024

This tutorial shows how to create a .NET Core gRPC client and an ASP.NET Core gRPC Server. At the end, you'll have a gRPC client that communicates with the gRPC Greeter service.



In this tutorial, you:

- ✓ Create a gRPC Server.
- ✓ Create a gRPC client.
- ✓ Test the gRPC client with the gRPC Greeter service.

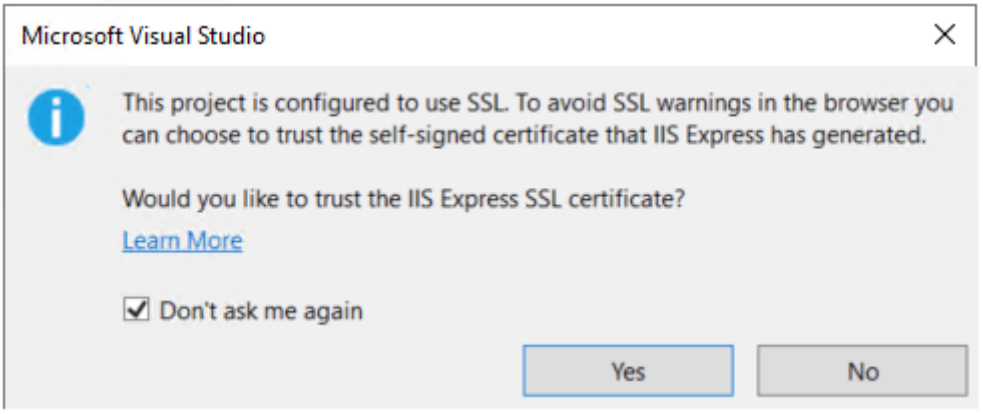
Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.

Create a gRPC service

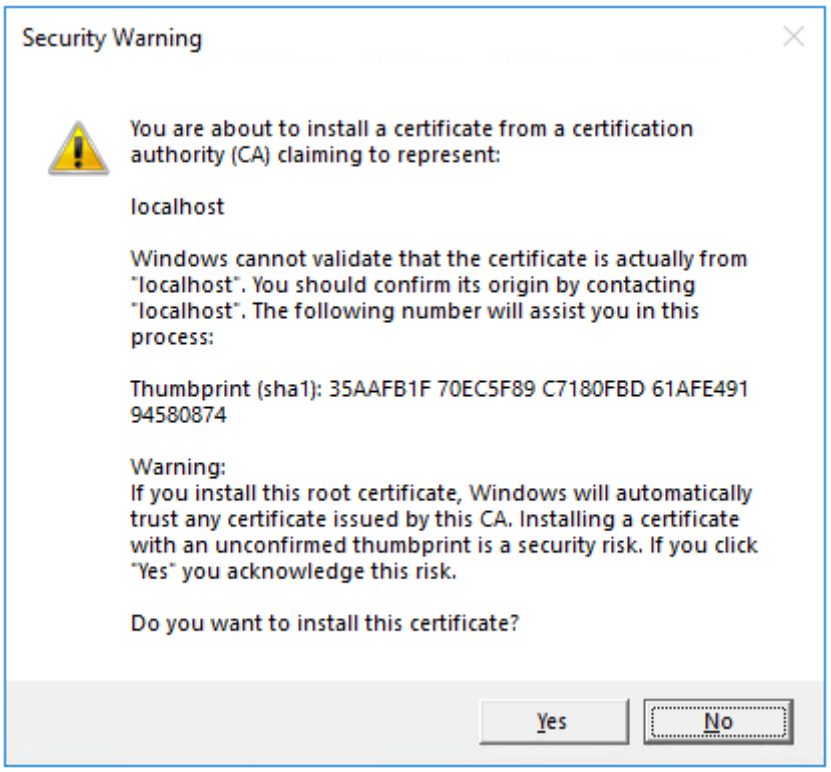
Visual Studio



- Start Visual Studio 2022 and select **New Project**.
- In the **Create a new project** dialog, search for `gRPC`. Select **ASP.NET Core gRPC Service** and select **Next**.
- In the **Configure your new project** dialog, enter `GrpcGreeter` for **Project name**. It's important to name the project *GrpcGreeter* so the namespaces match when you copy and paste code.
- Select **Next**.
- In the **Additional information** dialog, select **.NET 8.0 (Long Term Support)** and then select **Create**.

Run the service

Visual Studio



- Press Ctrl+F5 to run without the debugger.

  Visual Studio displays the following dialog when a project is not yet configured to use SSL:

  Select **Yes** if you trust the IIS Express SSL certificate.

  The following dialog is displayed:

Select **Yes** if you agree to trust the development certificate.

For information on trusting the Firefox browser, see Firefox SEC_ERROR_INADEQUATE_KEY_USAGE certificate error.

Visual Studio:

- Starts Kestrel server.
- Launches a browser.
- Navigates to `http://localhost:port`, such as `http://localhost:7042`.
  - *port*: A randomly assigned port number for the app.
  - `localhost`: The standard hostname for the local computer. Localhost only serves web requests from the local computer.

The logs show the service listening on `https://localhost:<port>`, where `<port>` is the localhost port number randomly assigned when the project is created and set in `Properties/launchSettings.json`.

Console

```
info: Microsoft.Hosting.Lifetime[0]
      Now listening on: https://localhost:<port>
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
```

> **Note**
>
> The gRPC template is configured to use Transport Layer Security (TLS). gRPC clients need to use HTTPS to call the server. The gRPC service localhost port number is randomly assigned when the project is created and set in the *Properties\launchSettings.json* file of the gRPC service project.

Examine the project files

GrpcGreeter project files:

- `Protos/greet.proto`: defines the `Greeter` gRPC and is used to generate the gRPC server assets. For more information, see Introduction to gRPC.
- `Services` folder: Contains the implementation of the `Greeter` service.
- `appSettings.json`: Contains configuration data such as the protocol used by Kestrel. For more information, see Configuration in ASP.NET Core.
- `Program.cs`, which contains:
  - The entry point for the gRPC service. For more information, see .NET Generic Host in ASP.NET Core.
  - Code that configures app behavior. For more information, see App startup.

Create the gRPC client in a .NET console app

Visual Studio

- Open a second instance of Visual Studio and select **New Project**.
- In the **Create a new project** dialog, select **Console App**, and select **Next**.
- In the **Project name** text box, enter **GrpcGreeterClient** and select **Next**.
- In the **Additional information** dialog, select **.NET 8.0 (Long Term Support)** and then select **Create**.

Add required NuGet packages

The gRPC client project requires the following NuGet packages:

- Grpc.Net.Client, which contains the .NET Core client.
- Google.Protobuf, which contains protobuf message APIs for C#.

- Grpc.Tools, which contain C# tooling support for protobuf files. The tooling package isn't required at runtime, so the dependency is marked with `PrivateAssets="All"`.

Visual Studio

Install the packages using either the Package Manager Console (PMC) or Manage NuGet Packages.

PMC option to install packages

- From Visual Studio, select **Tools** > **NuGet Package Manager** > **Package Manager Console**
- From the **Package Manager Console** window, run `cd GrpcGreeterClient` to change directories to the folder containing the `GrpcGreeterClient.csproj` files.
- Run the following commands:

PowerShell

```
Install-Package Grpc.Net.Client
Install-Package Google.Protobuf
Install-Package Grpc.Tools
```

Manage NuGet Packages option to install packages

- Right-click the project in **Solution Explorer** > **Manage NuGet Packages**.
- Select the **Browse** tab.
- Enter **Grpc.Net.Client** in the search box.
- Select the **Grpc.Net.Client** package from the **Browse** tab and select **Install**.
- Repeat for `Google.Protobuf` and `Grpc.Tools`.

Add greet.proto

- Create a *Protos* folder in the gRPC client project.
- Copy the *Protos\greet.proto* file from the gRPC Greeter service to the *Protos* folder in the gRPC client project.
- Update the namespace inside the `greet.proto` file to the project's namespace:

JSON

```
option csharp_namespace = "GrpcGreeterClient";
```

- Edit the `GrpcGreeterClient.csproj` project file:

Visual Studio

Right-click the project and select **Edit Project File**.

- Add an item group with a `<Protobuf>` element that refers to the *greet.proto* file:

XML

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" GrpcServices="Client" />
</ItemGroup>
```

Create the Greeter client

- Build the client project to create the types in the `GrpcGreeterClient` namespace.

> **Note**
>
> The `GrpcGreeterClient` types are generated automatically by the build process. The tooling package Grpc.Tools generates the following files based on the *greet.proto* file:
>
> - `GrpcGreeterClient\obj\Debug\[TARGET_FRAMEWORK]\Protos\Greet.cs`: The protocol buffer code which populates, serializes and retrieves the request and response message types.
> - `GrpcGreeterClient\obj\Debug\[TARGET_FRAMEWORK]\Protos\GreetGrpc.cs`: Contains the generated client classes.
>
> For more information on the C# assets automatically generated by Grpc.Tools, see gRPC services with C#: Generated C# assets.

- Update the gRPC client `Program.cs` file with the following code.

C#

```
using System.Threading.Tasks;
using Grpc.Net.Client;
using GrpcGreeterClient;

// The port number must match the port of the gRPC server.
using var channel = GrpcChannel.ForAddress("https://localhost:7042");
var client = new Greeter.GreeterClient(channel);
var reply = await client.SayHelloAsync(
                  new HelloRequest { Name = "GreeterClient" });
Console.WriteLine("Greeting: " + reply.Message);
Console.WriteLine("Press any key to exit...");
Console.ReadKey();
```

- In the preceding highlighted code, replace the localhost port number `7042` with the `HTTPS` port number specified in `Properties/launchSettings.json` within the `GrpcGreeter` service project.

`Program.cs` contains the entry point and logic for the gRPC client.

The Greeter client is created by:

- Instantiating a `GrpcChannel` containing the information for creating the connection to the gRPC service.
- Using the `GrpcChannel` to construct the Greeter client:

C#

```
// The port number must match the port of the gRPC server.
using var channel = GrpcChannel.ForAddress("https://localhost:7042");
var client = new Greeter.GreeterClient(channel);
var reply = await client.SayHelloAsync(
                  new HelloRequest { Name = "GreeterClient" });
Console.WriteLine("Greeting: " + reply.Message);
Console.WriteLine("Press any key to exit...");
Console.ReadKey();
```

The Greeter client calls the asynchronous `SayHello` method. The result of the `SayHello` call is displayed:

C#

```
// The port number must match the port of the gRPC server.
using var channel = GrpcChannel.ForAddress("https://localhost:7042");
var client = new Greeter.GreeterClient(channel);
```

```
var reply = await client.SayHelloAsync(
                  new HelloRequest { Name = "GreeterClient" });
Console.WriteLine("Greeting: " + reply.Message);
Console.WriteLine("Press any key to exit...");
Console.ReadKey();
```

Test the gRPC client with the gRPC Greeter service

Update the `appsettings.Development.json` file by adding the following highlighted lines:

C#

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
      ,"Microsoft.AspNetCore.Hosting": "Information",
      "Microsoft.AspNetCore.Routing.EndpointMiddleware": "Information"
    }
  }
}
```

Visual Studio

- In the Greeter service, press `Ctrl+F5` to start the server without the debugger.
- In the `GrpcGreeterClient` project, press `Ctrl+F5` to start the client without the debugger.

The client sends a greeting to the service with a message containing its name, *GreeterClient*. The service sends the message "Hello GreeterClient" as a response. The "Hello GreeterClient" response is displayed in the command prompt:

Console

```
Greeting: Hello GreeterClient
Press any key to exit...
```

The gRPC service records the details of the successful call in the logs written to the command prompt:

Console

```
info: Microsoft.Hosting.Lifetime[0]
      Now listening on: https://localhost:<port>
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path:
C:\GH\aspnet\docs\4\Docs\aspnetcore\tutorials\grpc\grpc-
start\sample\GrpcGreeter
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/2 POST https://localhost:
<port>/Greet.Greeter/SayHello application/grpc
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint 'gRPC - /Greet.Greeter/SayHello'
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint 'gRPC - /Greet.Greeter/SayHello'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 78.32260000000001ms 200 application/grpc
```

> **Note**
>
> The code in this article requires the ASP.NET Core HTTPS development certificate to secure the gRPC service. If the .NET gRPC client fails with the message `The remote certificate is invalid according to the validation procedure.` or `The SSL connection could not be established.`, the development certificate isn't trusted. To fix this issue, see Call a gRPC service with an untrusted/invalid certificate.

gRPC services with C#

Article • 07/31/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This document outlines the concepts needed to write gRPC apps in C#. The topics covered here apply to both C-core -based and ASP.NET Core-based gRPC apps.

proto file

gRPC uses a contract-first approach to API development. Protocol buffers (protobuf) are used as the Interface Definition Language (IDL) by default. The `.proto` file contains:

- The definition of the gRPC service.
- The messages sent between clients and servers.

For more information on the syntax of protobuf files, see Create Protobuf messages for .NET apps.

For example, consider the *greet.proto* file used in Get started with gRPC service:

- Defines a `Greeter` service.
- The `Greeter` service defines a `SayHello` call.
- `SayHello` sends a `HelloRequest` message and receives a `HelloReply` message:

ProtoBuf

```
syntax = "proto3";

option csharp_namespace = "GrpcGreeter";

package greet;

// The greeting service definition.
service Greeter {
  // Sends a greeting
  rpc SayHello (HelloRequest) returns (HelloReply);
```

```
}

// The request message containing the user's name.
message HelloRequest {
  string name = 1;
}

// The response message containing the greetings.
message HelloReply {
  string message = 1;
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

Add a `.proto` file to a C# app

The `.proto` file is included in a project by adding it to the `<Protobuf>` item group:

XML

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" GrpcServices="Server" />
</ItemGroup>
```

By default, a `<Protobuf>` reference generates a concrete client and a service base class. The reference element's `GrpcServices` attribute can be used to limit C# asset generation. Valid `GrpcServices` options are:

- `Both` (default when not present)
- `Server`
- `Client`
- `None`

C# Tooling support for `.proto` files

The tooling package Grpc.Tools is required to generate the C# assets from `.proto` files. The generated assets (files):

- Are generated on an as-needed basis each time the project is built.
- Aren't added to the project or checked into source control.
- Are a build artifact contained in the *obj* directory.

This package is required by both the server and client projects. The `Grpc.AspNetCore` metapackage includes a reference to `Grpc.Tools`. Server projects can add `Grpc.AspNetCore` using the Package Manager in Visual Studio or by adding a `<PackageReference>` to the project file:

XML

```xml
<PackageReference Include="Grpc.AspNetCore" Version="2.32.0" />
```

Client projects should directly reference `Grpc.Tools` alongside the other packages required to use the gRPC client. The tooling package isn't required at runtime, so the dependency is marked with `PrivateAssets="All"`:

XML

```xml
<PackageReference Include="Google.Protobuf" Version="3.18.0" />
<PackageReference Include="Grpc.Net.Client" Version="2.52.0" />
<PackageReference Include="Grpc.Tools" Version="2.40.0">
  <IncludeAssets>runtime; build; native; contentfiles; analyzers;
buildtransitive</IncludeAssets>
  <PrivateAssets>all</PrivateAssets>
</PackageReference>
```

Generated C# assets

The tooling package generates the C# types representing the messages defined in the included `.proto` files.

For server-side assets, an abstract service base type is generated. The base type contains the definitions of all the gRPC calls contained in the `.proto` file. Create a concrete service implementation that derives from this base type and implements the logic for the gRPC calls. For the `greet.proto`, the example described previously, an abstract `GreeterBase` type that contains a virtual `SayHello` method is generated. A concrete implementation `GreeterService` overrides the method and implements the logic handling the gRPC call.

C#

```csharp
public class GreeterService : Greeter.GreeterBase
{
    private readonly ILogger<GreeterService> _logger;
    public GreeterService(ILogger<GreeterService> logger)
    {
        _logger = logger;
```

```
    }

    public override Task<HelloReply> SayHello(HelloRequest request,
ServerCallContext context)
    {
        return Task.FromResult(new HelloReply
        {
            Message = "Hello " + request.Name
        });
    }
}
```

For client-side assets, a concrete client type is generated. The gRPC calls in the `.proto` file are translated into methods on the concrete type, which can be called. For the `greet.proto`, the example described previously, a concrete `GreeterClient` type is generated. Call `GreeterClient.SayHelloAsync` to initiate a gRPC call to the server.

C#

```
// The port number must match the port of the gRPC server.
using var channel = GrpcChannel.ForAddress("https://localhost:7042");
var client = new Greeter.GreeterClient(channel);
var reply = await client.SayHelloAsync(
                  new HelloRequest { Name = "GreeterClient" });
Console.WriteLine("Greeting: " + reply.Message);
Console.WriteLine("Press any key to exit...");
Console.ReadKey();
```

By default, server and client assets are generated for each `.proto` file included in the `<Protobuf>` item group. To ensure only the server assets are generated in a server project, the `GrpcServices` attribute is set to `Server`.

XML

```
<ItemGroup>
  <Protobuf Include="Protos\greet.proto" GrpcServices="Server" />
</ItemGroup>
```

Similarly, the attribute is set to `Client` in client projects.

Create gRPC services and methods

Article • 07/31/2024

> **Important**

By James Newton-King

This document explains how to create gRPC services and methods in C#. Topics include:

- How to define services and methods in `.proto` files.
- Generated code using gRPC C# tooling.
- Implementing gRPC services and methods.

Create new gRPC services

gRPC services with C# introduced gRPC's contract-first approach to API development. Services and messages are defined in `.proto` files. C# tooling then generates code from `.proto` files. For server-side assets, an abstract base type is generated for each service, along with classes for any messages.

The following `.proto` file:

- Defines a `Greeter` service.
- The `Greeter` service defines a `SayHello` call.
- `SayHello` sends a `HelloRequest` message and receives a `HelloReply` message

ProtoBuf

```
syntax = "proto3";

service Greeter {
  rpc SayHello (HelloRequest) returns (HelloReply);
}

message HelloRequest {
  string name = 1;
}
```

```
message HelloReply {
  string message = 1;
}
```

C# tooling generates the C# `GreeterBase` base type:

C#

```
public abstract partial class GreeterBase
{
    public virtual Task<HelloReply> SayHello(HelloRequest request,
ServerCallContext context)
    {
        throw new RpcException(new Status(StatusCode.Unimplemented, ""));
    }
}

public class HelloRequest
{
    public string Name { get; set; }
}

public class HelloReply
{
    public string Message { get; set; }
}
```

By default the generated `GreeterBase` doesn't do anything. Its virtual `SayHello` method will return an `UNIMPLEMENTED` error to any clients that call it. For the service to be useful an app must create a concrete implementation of `GreeterBase`:

C#

```
public class GreeterService : GreeterBase
{
    public override Task<HelloReply> SayHello(HelloRequest request,
ServerCallContext context)
    {
        return Task.FromResult(new HelloReply { Message = $"Hello
{request.Name}" });
    }
}
```

The `ServerCallContext` gives the context for a server-side call.

The service implementation is registered with the app. If the service is hosted by ASP.NET Core gRPC, it should be added to the routing pipeline with the `MapGrpcService`

method.

C#

```
app.MapGrpcService<GreeterService>();
```

See gRPC services with ASP.NET Core for more information.

Implement gRPC methods

A gRPC service can have different types of methods. How messages are sent and received by a service depends on the type of method defined. The gRPC method types are:

- Unary
- Server streaming
- Client streaming
- Bi-directional streaming

Streaming calls are specified with the `stream` keyword in the `.proto` file. `stream` can be placed on a call's request message, response message, or both.

ProtoBuf

```
syntax = "proto3";

service ExampleService {
  // Unary
  rpc UnaryCall (ExampleRequest) returns (ExampleResponse);

  // Server streaming
  rpc StreamingFromServer (ExampleRequest) returns (stream ExampleResponse);

  // Client streaming
  rpc StreamingFromClient (stream ExampleRequest) returns (ExampleResponse);

  // Bi-directional streaming
  rpc StreamingBothWays (stream ExampleRequest) returns (stream
ExampleResponse);
}
```

Each call type has a different method signature. Overriding generated methods from the abstract base service type in a concrete implementation ensures the correct arguments and return type are used.

Unary method

A unary method has the request message as a parameter, and returns the response. A unary call is complete when the response is returned.

C#

```
public override Task<ExampleResponse> UnaryCall(ExampleRequest request,
    ServerCallContext context)
{
    var response = new ExampleResponse();
    return Task.FromResult(response);
}
```

Unary calls are the most similar to actions on web API controllers. One important difference gRPC methods have from actions is gRPC methods are not able to bind parts of a request to different method arguments. gRPC methods always have one message argument for the incoming request data. Multiple values can still be sent to a gRPC service by adding fields to the request message:

ProtoBuf

```
message ExampleRequest {
    int32 pageIndex = 1;
    int32 pageSize = 2;
    bool isDescending = 3;
}
```

Server streaming method

A server streaming method has the request message as a parameter. Because multiple messages can be streamed back to the caller, `responseStream.WriteAsync` is used to send response messages. A server streaming call is complete when the method returns.

C#

```
public override async Task StreamingFromServer(ExampleRequest request,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext
context)
{
    for (var i = 0; i < 5; i++)
    {
        await responseStream.WriteAsync(new ExampleResponse());
        await Task.Delay(TimeSpan.FromSeconds(1));
    }
}
```

The client has no way to send additional messages or data once the server streaming method has started. Some streaming methods are designed to run forever. For continuous streaming methods, a client can cancel the call when it's no longer needed. When cancellation happens the client sends a signal to the server and the ServerCallContext.CancellationToken is raised. The `CancellationToken` token should be used on the server with async methods so that:

- Any asynchronous work is canceled together with the streaming call.
- The method exits quickly.

C#

```
public override async Task StreamingFromServer(ExampleRequest request,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext
context)
{
    while (!context.CancellationToken.IsCancellationRequested)
    {
        await responseStream.WriteAsync(new ExampleResponse());
        await Task.Delay(TimeSpan.FromSeconds(1),
context.CancellationToken);
    }
}
```

Client streaming method

A client streaming method starts *without* the method receiving a message. The `requestStream` parameter is used to read messages from the client. A client streaming call is complete when a response message is returned:

C#

```
public override async Task<ExampleResponse> StreamingFromClient(
    IAsyncStreamReader<ExampleRequest> requestStream, ServerCallContext
context)
{
    await foreach (var message in requestStream.ReadAllAsync())
    {
        // ...
    }
    return new ExampleResponse();
}
```

Bi-directional streaming method

A bi-directional streaming method starts *without* the method receiving a message. The `requestStream` parameter is used to read messages from the client. The method can choose to send messages with `responseStream.WriteAsync`. A bi-directional streaming call is complete when the method returns:

C#

```
public override async Task
StreamingBothWays(IAsyncStreamReader<ExampleRequest> requestStream,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext
context)
{
    await foreach (var message in requestStream.ReadAllAsync())
    {
        await responseStream.WriteAsync(new ExampleResponse());
    }
}
```

The preceding code:

- Sends a response for each request.
- Is a basic usage of bi-directional streaming.

It is possible to support more complex scenarios, such as reading requests and sending responses simultaneously:

C#

```
public override async Task
StreamingBothWays(IAsyncStreamReader<ExampleRequest> requestStream,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext
context)
{
    // Read requests in a background task.
    var readTask = Task.Run(async () =>
    {
        await foreach (var message in requestStream.ReadAllAsync())
        {
            // Process request.
        }
    });

    // Send responses until the client signals that it is complete.
    while (!readTask.IsCompleted)
    {
        await responseStream.WriteAsync(new ExampleResponse());
        await Task.Delay(TimeSpan.FromSeconds(1),
context.CancellationToken);
```

```
    }
}
```

In a bi-directional streaming method, the client and service can send messages to each other at any time. The best implementation of a bi-directional method varies depending upon requirements.

Access gRPC request headers

A request message is not the only way for a client to send data to a gRPC service. Header values are available in a service using `ServerCallContext.RequestHeaders`.

C#

```
public override Task<ExampleResponse> UnaryCall(ExampleRequest request,
    ServerCallContext context)
{
    var userAgent = context.RequestHeaders.GetValue("user-agent");
    // ...

    return Task.FromResult(new ExampleResponse());
}
```

Multi-threading with gRPC streaming methods

There are important considerations to implementing gRPC streaming methods that use multiple threads.

Reader and writer thread safety

`IAsyncStreamReader<TMessage>` and `IServerStreamWriter<TMessage>` can each be used by only one thread at a time. For a streaming gRPC method, multiple threads can't read new messages with `requestStream.MoveNext()` simultaneously. And multiple threads can't write new messages with `responseStream.WriteAsync(message)` simultaneously.

A safe way to enable multiple threads to interact with a gRPC method is to use the producer-consumer pattern with System.Threading.Channels.

C#

```
public override async Task DownloadResults(DataRequest request,
        IServerStreamWriter<DataResult> responseStream, ServerCallContext
context)
```

```
{
    var channel = Channel.CreateBounded<DataResult>(new
BoundedChannelOptions(capacity: 5));

    var consumerTask = Task.Run(async () =>
    {
        // Consume messages from channel and write to response stream.
        await foreach (var message in channel.Reader.ReadAllAsync())
        {
            await responseStream.WriteAsync(message);
        }
    });

    var dataChunks = request.Value.Chunk(size: 10);

    // Write messages to channel from multiple threads.
    await Task.WhenAll(dataChunks.Select(
        async c =>
        {
            var message = new DataResult { BytesProcessed = c.Length };
            await channel.Writer.WriteAsync(message);
        }));

    // Complete writing and wait for consumer to complete.
    channel.Writer.Complete();
    await consumerTask;
}
```

The preceding gRPC server streaming method:

- Creates a bounded channel for producing and consuming `DataResult` messages.
- Starts a task to read messages from the channel and write them to the response stream.
- Writes messages to the channel from multiple threads.

> ⓘ Note
>
> Bidirectional streaming methods take `IAsyncStreamReader<TMessage>` and `IServerStreamWriter<TMessage>` as arguments. It's safe to use these types on separate threads from each other.

Interacting with a gRPC method after a call ends

A gRPC call ends on the server once the gRPC method exits. The following arguments passed to gRPC methods aren't safe to use after the call has ended:

- `ServerCallContext`

- `IAsyncStreamReader<TMessage>`
- `IServerStreamWriter<TMessage>`

If a gRPC method starts background tasks that use these types, it must complete the tasks before the gRPC method exits. Continuing to use the context, stream reader, or stream writer after the gRPC method exists causes errors and unpredictable behavior.

In the following example, the server streaming method could write to the response stream after the call has finished:

C#

```
public override async Task StreamingFromServer(ExampleRequest request,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext
context)
{
    _ = Task.Run(async () =>
    {
        for (var i = 0; i < 5; i++)
        {
            await responseStream.WriteAsync(new ExampleResponse());
            await Task.Delay(TimeSpan.FromSeconds(1));
        }
    });

    await PerformLongRunningWorkAsync();
}
```

For the previous example, the solution is to await the write task before exiting the method:

C#

```
public override async Task StreamingFromServer(ExampleRequest request,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext
context)
{
    var writeTask = Task.Run(async () =>
    {
        for (var i = 0; i < 5; i++)
        {
            await responseStream.WriteAsync(new ExampleResponse());
            await Task.Delay(TimeSpan.FromSeconds(1));
        }
    });

    await PerformLongRunningWorkAsync();
```

```
    await writeTask;
}
```

Create Protobuf messages for .NET apps

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King and Mark Rendle

gRPC uses Protobuf as its Interface Definition Language (IDL). Protobuf IDL is a language neutral format for specifying the messages sent and received by gRPC services. Protobuf messages are defined in `.proto` files. This document explains how Protobuf concepts map to .NET.

Protobuf messages

Messages are the main data transfer object in Protobuf. They are conceptually similar to .NET classes.

ProtoBuf

```
syntax = "proto3";

option csharp_namespace = "Contoso.Messages";

message Person {
    int32 id = 1;
    string first_name = 2;
    string last_name = 3;
}
```

The preceding message definition specifies three fields as name-value pairs. Like properties on .NET types, each field has a name and a type. The field type can be a Protobuf scalar value type, for example `int32`, or another message.

The Protobuf style guide recommends using `underscore_separated_names` for field names. New Protobuf messages created for .NET apps should follow the Protobuf style guidelines. .NET tooling automatically generates .NET types that use .NET naming

standards. For example, a `first_name` Protobuf field generates a `FirstName` .NET property.

In addition to a name, each field in the message definition has a unique number. Field numbers are used to identify fields when the message is serialized to Protobuf. Serializing a small number is faster than serializing the entire field name. Because field numbers identify a field it is important to take care when changing them. For more information about changing Protobuf messages see Versioning gRPC services.

When an app is built the Protobuf tooling generates .NET types from `.proto` files. The `Person` message generates a .NET class:

C#

```
public class Person
{
    public int Id { get; set; }
    public string FirstName { get; set; }
    public string LastName { get; set; }
}
```

For more information about Protobuf messages see the Protobuf language guide.

Scalar Value Types

Protobuf supports a range of native scalar value types. The following table lists them all with their equivalent C# type:

Expand table

Protobuf type	C# type
`double`	`double`
`float`	`float`
`int32`	`int`
`int64`	`long`
`uint32`	`uint`
`uint64`	`ulong`
`sint32`	`int`

Protobuf type	C# type
`sint64`	`long`
`fixed32`	`uint`
`fixed64`	`ulong`
`sfixed32`	`int`
`sfixed64`	`long`
`bool`	`bool`
`string`	`string`
`bytes`	`ByteString`

Scalar values always have a default value and can't be set to `null`. This constraint includes `string` and `ByteString` which are C# classes. `string` defaults to an empty string value and `ByteString` defaults to an empty bytes value. Attempting to set them to `null` throws an error.

Nullable wrapper types can be used to support null values.

Dates and times

The native scalar types don't provide for date and time values, equivalent to .NET's DateTimeOffset, DateTime, and TimeSpan. These types can be specified by using some of Protobuf's *Well-Known Types* extensions. These extensions provide code generation and runtime support for complex field types across the supported platforms.

The following table shows the date and time types:

Expand table

.NET type	Protobuf Well-Known Type
`DateTimeOffset`	`google.protobuf.Timestamp`
`DateTime`	`google.protobuf.Timestamp`
`TimeSpan`	`google.protobuf.Duration`

```
syntax = "proto3";

import "google/protobuf/duration.proto";
import "google/protobuf/timestamp.proto";

message Meeting {
    string subject = 1;
    google.protobuf.Timestamp start = 2;
    google.protobuf.Duration duration = 3;
}
```

The generated properties in the C# class aren't the .NET date and time types. The properties use the `Timestamp` and `Duration` classes in the `Google.Protobuf.WellKnownTypes` namespace. These classes provide methods for converting to and from `DateTimeOffset`, `DateTime`, and `TimeSpan`.

C#

```
// Create Timestamp and Duration from .NET DateTimeOffset and TimeSpan.
var meeting = new Meeting
{
    Time = Timestamp.FromDateTimeOffset(meetingTime), // also FromDateTime()
    Duration = Duration.FromTimeSpan(meetingLength)
};

// Convert Timestamp and Duration to .NET DateTimeOffset and TimeSpan.
var time = meeting.Time.ToDateTimeOffset();
var duration = meeting.Duration?.ToTimeSpan();
```

> ⓘ **Note**
>
> The `Timestamp` type works with UTC times. `DateTimeOffset` values always have an offset of zero, and the `DateTime.Kind` property is always `DateTimeKind.Utc`.

Nullable types

The Protobuf code generation for C# uses the native types, such as `int` for `int32`. So the values are always included and can't be `null`.

For values that require explicit `null`, such as using `int?` in C# code, Protobuf's Well-Known Types include wrappers that are compiled to nullable C# types. To use them, import `wrappers.proto` into your `.proto` file, like the following code:

ProtoBuf

```
syntax = "proto3";

import "google/protobuf/wrappers.proto";

message Person {
    // ...
    google.protobuf.Int32Value age = 5;
}
```

`wrappers.proto` types aren't exposed in generated properties. Protobuf automatically maps them to appropriate .NET nullable types in C# messages. For example, a `google.protobuf.Int32Value` field generates an `int?` property. Reference type properties like `string` and `ByteString` are unchanged except `null` can be assigned to them without error.

The following table shows the complete list of wrapper types with their equivalent C# type:

Expand table

C# type	Well-Known Type wrapper
`bool?`	`google.protobuf.BoolValue`
`double?`	`google.protobuf.DoubleValue`
`float?`	`google.protobuf.FloatValue`
`int?`	`google.protobuf.Int32Value`
`long?`	`google.protobuf.Int64Value`
`uint?`	`google.protobuf.UInt32Value`
`ulong?`	`google.protobuf.UInt64Value`
`string`	`google.protobuf.StringValue`
`ByteString`	`google.protobuf.BytesValue`

Bytes

Binary payloads are supported in Protobuf with the `bytes` scalar value type. A generated property in C# uses `ByteString` as the property type.

Use `ByteString.CopyFrom(byte[] data)` to create a new instance from a byte array:

C#

```
var data = await File.ReadAllBytesAsync(path);

var payload = new PayloadResponse();
payload.Data = ByteString.CopyFrom(data);
```

`ByteString` data is accessed directly using `ByteString.Span` or `ByteString.Memory`. Or call `ByteString.ToByteArray()` to convert an instance back into a byte array:

C#

```
var payload = await client.GetPayload(new PayloadRequest());

await File.WriteAllBytesAsync(path, payload.Data.ToByteArray());
```

Decimals

Protobuf doesn't natively support the .NET `decimal` type, just `double` and `float`. There's an ongoing discussion in the Protobuf project about the possibility of adding a standard decimal type to the Well-Known Types, with platform support for languages and frameworks that support it. Nothing has been implemented yet.

It's possible to create a message definition to represent the `decimal` type that works for safe serialization between .NET clients and servers. But developers on other platforms would have to understand the format being used and implement their own handling for it.

Creating a custom decimal type for Protobuf

ProtoBuf

```
package CustomTypes;

// Example: 12345.6789 -> { units = 12345, nanos = 678900000 }
message DecimalValue {

    // Whole units part of the amount
    int64 units = 1;

    // Nano units of the amount (10^-9)
    // Must be same sign as units
    sfixed32 nanos = 2;
}
```

The `nanos` field represents values from `0.999_999_999` to `-0.999_999_999`. For example, the `decimal` value `1.5m` would be represented as `{ units = 1, nanos = 500_000_000 }`. This is why the `nanos` field in this example uses the `sfixed32` type, which encodes more efficiently than `int32` for larger values. If the `units` field is negative, the `nanos` field should also be negative.

> **Note**
>
> Additional algorithms are available for encoding `decimal` values as byte strings. The algorithm used by `DecimalValue`:
>
> - Is easy to understand.
> - Isn't affected by big-endian or little-endian on different platforms.
> - Supports decimal numbers ranging from positive `9,223,372,036,854,775,807.999999999` to negative `9,223,372,036,854,775,808.999999999` with a maximum precision of nine decimal places, which isn't the full range of a `decimal`.

Conversion between this type and the BCL `decimal` type might be implemented in C# like this:

C#

```
namespace CustomTypes
{
    public partial class DecimalValue
    {
        private const decimal NanoFactor = 1_000_000_000;
        public DecimalValue(long units, int nanos)
        {
            Units = units;
            Nanos = nanos;
        }

        public static implicit operator decimal(CustomTypes.DecimalValue
grpcDecimal)
        {
            return grpcDecimal.Units + grpcDecimal.Nanos / NanoFactor;
        }

        public static implicit operator CustomTypes.DecimalValue(decimal
value)
        {
            var units = decimal.ToInt64(value);
            var nanos = decimal.ToInt32((value - units) * NanoFactor);
            return new CustomTypes.DecimalValue(units, nanos);
```

```
        }
    }
}
```

The preceding code:

- Adds a partial class for `DecimalValue`. The partial class is combined with `DecimalValue` generated from the `.proto` file. The generated class declares the `Units` and `Nanos` properties.
- Has implicit operators for converting between `DecimalValue` and the BCL `decimal` type.

Collections

Lists

Lists in Protobuf are specified by using the `repeated` prefix keyword on a field. The following example shows how to create a list:

ProtoBuf

```
message Person {
    // ...
    repeated string roles = 8;
}
```

In the generated code, `repeated` fields are represented by the `Google.Protobuf.Collections.RepeatedField<T>` generic type.

C#

```
public class Person
{
    // ...
    public RepeatedField<string> Roles { get; }
}
```

`RepeatedField<T>` implements IList<T>. So you can use LINQ queries or convert it to an array or a list. `RepeatedField<T>` properties don't have a public setter. Items should be added to the existing collection.

C#

```
var person = new Person();

// Add one item.
person.Roles.Add("user");

// Add all items from another collection.
var roles = new [] { "admin", "manager" };
person.Roles.Add(roles);
```

Dictionaries

The .NET IDictionary<TKey,TValue> type is represented in Protobuf using `map<key_type, value_type>`.

ProtoBuf

```
message Person {
    // ...
    map<string, string> attributes = 9;
}
```

In generated .NET code, `map` fields are represented by the `Google.Protobuf.Collections.MapField<TKey, TValue>` generic type. `MapField<TKey, TValue>` implements IDictionary<TKey,TValue>. Like `repeated` properties, `map` properties don't have a public setter. Items should be added to the existing collection.

C#

```
var person = new Person();

// Add one item.
person.Attributes["created_by"] = "James";

// Add all items from another collection.
var attributes = new Dictionary<string, string>
{
    ["last_modified"] = DateTime.UtcNow.ToString()
};
person.Attributes.Add(attributes);
```

Unstructured and conditional messages

Protobuf is a contract-first messaging format. An app's messages, including its fields and types, must be specified in `.proto` files when the app is built. Protobuf's contract-

first design is great at enforcing message content but can limit scenarios where a strict contract isn't required:

- Messages with unknown payloads. For example, a message with a field that could contain any message.
- Conditional messages. For example, a message returned from a gRPC service might be a success result or an error result.
- Dynamic values. For example, a message with a field that contains an unstructured collection of values, similar to JSON.

Protobuf offers language features and types to support these scenarios.

Any

The `Any` type lets you use messages as embedded types without having their `.proto` definition. To use the `Any` type, import `any.proto`.

ProtoBuf

```
import "google/protobuf/any.proto";

message Status {
    string message = 1;
    google.protobuf.Any detail = 2;
}
```

C#

```
// Create a status with a Person message set to detail.
var status = new ErrorStatus();
status.Detail = Any.Pack(new Person { FirstName = "James" });

// Read Person message from detail.
if (status.Detail.Is(Person.Descriptor))
{
    var person = status.Detail.Unpack<Person>();
    // ...
}
```

Oneof

`oneof` fields are a language feature. The compiler handles the `oneof` keyword when it generates the message class. Using `oneof` to specify a response message that could either return a `Person` or `Error` might look like this:

ProtoBuf

```
message Person {
    // ...
}

message Error {
    // ...
}

message ResponseMessage {
  oneof result {
    Error error = 1;
    Person person = 2;
  }
}
```

Fields within the `oneof` set must have unique field numbers in the overall message declaration.

When using `oneof`, the generated C# code includes an enum that specifies which of the fields has been set. You can test the enum to find which field is set. Fields that aren't set return `null` or the default value, rather than throwing an exception.

C#

```
var response = await client.GetPersonAsync(new RequestMessage());

switch (response.ResultCase)
{
    case ResponseMessage.ResultOneofCase.Person:
        HandlePerson(response.Person);
        break;
    case ResponseMessage.ResultOneofCase.Error:
        HandleError(response.Error);
        break;
    default:
        throw new ArgumentException("Unexpected result.");
}
```

Value

The `Value` type represents a dynamically typed value. It can be either `null`, a number, a string, a boolean, a dictionary of values (`Struct`), or a list of values (`ValueList`). `Value` is a Protobuf Well-Known Type that uses the previously discussed `oneof` feature. To use the `Value` type, import `struct.proto`.

ProtoBuf

```
import "google/protobuf/struct.proto";

message Status {
    // ...
    google.protobuf.Value data = 3;
}
```

C#

```
// Create dynamic values.
var status = new Status();
status.Data = Value.ForStruct(new Struct
{
    Fields =
    {
        ["enabled"] = Value.ForBool(true),
        ["metadata"] = Value.ForList(
            Value.ForString("value1"),
            Value.ForString("value2"))
    }
});

// Read dynamic values.
switch (status.Data.KindCase)
{
    case Value.KindOneofCase.StructValue:
        foreach (var field in status.Data.StructValue.Fields)
        {
            // Read struct fields...
        }
        break;
    // ...
}
```

Using `Value` directly can be verbose. An alternative way to use `Value` is with Protobuf's built-in support for mapping messages to JSON. Protobuf's `JsonFormatter` and `JsonWriter` types can be used with any Protobuf message. `Value` is particularly well suited to being converted to and from JSON.

This is the JSON equivalent of the previous code:

C#

```
// Create dynamic values from JSON.
var status = new Status();
status.Data = Value.Parser.ParseJson(@"{
    ""enabled"": true,
    ""metadata"": [ ""value1"", ""value2"" ]
```

```
}");

// Convert dynamic values to JSON.
// JSON can be read with a library like System.Text.Json or Newtonsoft.Json
var json = JsonFormatter.Default.Format(status.Data);
var document = JsonDocument.Parse(json);
```

Versioning gRPC services

Article • 09/27/2024

By James Newton-King

New features added to an app can require gRPC services provided to clients to change, sometimes in unexpected and breaking ways. When gRPC services change:

- Consideration should be given on how changes impact clients.
- A versioning strategy to support changes should be implemented.

Backwards compatibility

The gRPC protocol is designed to support services that change over time. Generally, additions to gRPC services and methods are non-breaking. Non-breaking changes allow existing clients to continue working without changes. Changing or deleting gRPC services are breaking changes. When gRPC services have breaking changes, clients using that service have to be updated and redeployed.

Making non-breaking changes to a service has a number of benefits:

- Existing clients continue to run.
- Avoids work involved with notifying clients of breaking changes, and updating them.
- Only one version of the service needs to be documented and maintained.

Non-breaking changes

These changes are non-breaking at a gRPC protocol level and .NET binary level.

- **Adding a new service**
- **Adding a new method to a service**

- **Adding a field to a request message** - Fields added to a request message are deserialized with the default value on the server when not set. To be a non-breaking change, the service must succeed when the new field isn't set by older clients.
- **Adding a field to a response message** - If an older client hasn't been updated with the new field, the value is deserialized into the response message's unknown fields collection.
- **Adding a value to an enum** - Enums are serialized as a numeric value. New enum values are deserialized on the client to the enum value without an enum name. To be a non-breaking change, older clients must run correctly when receiving the new enum value.

Binary breaking changes

The following changes are non-breaking at a gRPC protocol level, but the client needs to be updated if it upgrades to the latest `.proto` contract or client .NET assembly. Binary compatibility is important if you plan to publish a gRPC library to NuGet.

- **Removing a field** - Values from a removed field are deserialized to a message's unknown fields. This isn't a gRPC protocol breaking change, but the client needs to be updated if it upgrades to the latest contract. It's important that a removed field number isn't accidentally reused in the future. To ensure this doesn't happen, specify deleted field numbers and names on the message using Protobuf's reserved keyword.
- **Renaming a message** - Message names aren't typically sent on the network, so this isn't a gRPC protocol breaking change. The client will need to be updated if it upgrades to the latest contract. One situation where message names **are** sent on the network is with Any fields, when the message name is used to identify the message type.
- **Nesting or unnesting a message** - Message types can be nested. Nesting or unnesting a message changes its message name. Changing how a message type is nested has the same impact on compatibility as renaming.
- **Changing csharp_namespace** - Changing `csharp_namespace` will change the namespace of generated .NET types. This isn't a gRPC protocol breaking change, but the client needs to be updated if it upgrades to the latest contract.

Protocol breaking changes

The following items are protocol and binary breaking changes:

- **Renaming a field** - With Protobuf content, the field names are only used in generated code. The field number is used to identify fields on the network. Renaming a field isn't a protocol breaking change for Protobuf. However, if a server is using JSON content then renaming a field is a breaking change.
- **Changing a field data type** - Changing a field's data type to an incompatible type will cause errors when deserializing the message. Even if the new data type is compatible, it's likely the client needs to be updated to support the new type if it upgrades to the latest contract.
- **Changing a field number** - With Protobuf payloads, the field number is used to identify fields on the network.
- **Renaming a package, service or method** - gRPC uses the package name, service name, and method name to build the URL. The client gets an *UNIMPLEMENTED* status from the server.
- **Removing a service or method** - The client gets an *UNIMPLEMENTED* status from the server when calling the removed method.

Behavior breaking changes

When making non-breaking changes, you must also consider whether older clients can continue working with the new service behavior. For example, adding a new field to a request message:

- Isn't a protocol breaking change.
- Returning an error status on the server if the new field isn't set makes it a breaking change for old clients.

Behavior compatibility is determined by your app-specific code.

Version number services

Services should strive to remain backwards compatible with old clients. Eventually changes to your app may require breaking changes. Breaking old clients and forcing them to be updated along with your service isn't a good user experience. A way to maintain backwards compatibility while making breaking changes is to publish multiple versions of a service.

gRPC supports an optional package specifier, which functions much like a .NET namespace. In fact, the `package` will be used as the .NET namespace for generated .NET types if `option csharp_namespace` is not set in the `.proto` file. The package can be used to specify a version number for your service and its messages:

ProtoBuf

```
syntax = "proto3";

package greet.v1;

service Greeter {
  rpc SayHello (HelloRequest) returns (HelloReply);
}

message HelloRequest {
  string name = 1;
}

message HelloReply {
  string message = 1;
}
```

The package name is combined with the service name to identify a service address. A service address allows multiple versions of a service to be hosted side-by-side:

- `greet.v1.Greeter`
- `greet.v2.Greeter`

Implementations of the versioned service are registered in `Startup.cs`:

C#

```
app.UseEndpoints(endpoints =>
{
    // Implements greet.v1.Greeter
    endpoints.MapGrpcService<GreeterServiceV1>();

    // Implements greet.v2.Greeter
    endpoints.MapGrpcService<GreeterServiceV2>();
});
```

Including a version number in the package name gives you the opportunity to publish a *v2* version of your service with breaking changes, while continuing to support older clients who call the *v1* version. Once clients have updated to use the *v2* service, you can choose to remove the old version. When planning to publish multiple versions of a service:

- Avoid breaking changes if reasonable.
- Don't update the version number unless making breaking changes.
- Do update the version number when you make breaking changes.

Publishing multiple versions of a service duplicates it. To reduce duplication, consider moving business logic from the service implementations to a centralized location that can be reused by the old and new implementations:

C#

```
using Greet.V1;
using Grpc.Core;
using System.Threading.Tasks;

namespace Services
{
    public class GreeterServiceV1 : Greeter.GreeterBase
    {
        private readonly IGreeter _greeter;
        public GreeterServiceV1(IGreeter greeter)
        {
            _greeter = greeter;
        }

        public override Task<HelloReply> SayHello(HelloRequest request,
ServerCallContext context)
        {
            return Task.FromResult(new HelloReply
            {
                Message = _greeter.GetHelloMessage(request.Name)
            });
        }
    }
}
```

Services and messages generated with different package names are **different .NET types**. Moving business logic to a centralized location requires mapping messages to common types.

Test gRPC services in ASP.NET Core

Article • 07/31/2024

By: James Newton-King

Testing is an important aspect of building stable and maintainable software. This article discusses how to test ASP.NET Core gRPC services.

There are three common approaches for testing gRPC services:

- **Unit testing**: Test gRPC services directly from a unit testing library.
- **Integration testing**: The gRPC app is hosted in TestServer, an in-memory test server from the Microsoft.AspNetCore.TestHost package. gRPC services are tested by calling them using a gRPC client from a unit testing library.
- **Manual testing**: Test gRPC servers with ad hoc calls. For information about how to use command-line and UI tooling with gRPC services, see Test gRPC services with gRPCurl and gRPCui in ASP.NET Core.

In unit testing, only the gRPC service is involved. Dependencies injected into the service must be mocked. In integration testing, the gRPC service and its auxiliary infrastructure are part of the test. This includes app startup, dependency injection, routing and authentication, and authorization.

Example testable service

To demonstrate service tests, review the following service in the sample app.

View or download sample code (how to download)

The `TesterService` returns greetings using gRPC's four method types.

```
C#
```

```
public class TesterService : Tester.TesterBase
{
    private readonly IGreeter _greeter;

    public TesterService(IGreeter greeter)
    {
        _greeter = greeter;
    }

    public override Task<HelloReply> SayHelloUnary(HelloRequest request,
        ServerCallContext context)
    {
        var message = _greeter.Greet(request.Name);
        return Task.FromResult(new HelloReply { Message = message });
    }

    public override async Task SayHelloServerStreaming(HelloRequest request,
        IServerStreamWriter<HelloReply> responseStream, ServerCallContext
context)
    {
        var i = 0;
        while (!context.CancellationToken.IsCancellationRequested)
        {
            var message = _greeter.Greet($"{request.Name} {++i}");
            await responseStream.WriteAsync(new HelloReply { Message =
message });

            await Task.Delay(1000);
        }
    }

    public override async Task<HelloReply> SayHelloClientStreaming(
        IAsyncStreamReader<HelloRequest> requestStream, ServerCallContext
context)
    {
        var names = new List<string>();

        await foreach (var request in requestStream.ReadAllAsync())
        {
            names.Add(request.Name);
        }

        var message = _greeter.Greet(string.Join(", ", names));
        return new HelloReply { Message = message };
    }

    public override async Task SayHelloBidirectionalStreaming(
        IAsyncStreamReader<HelloRequest> requestStream,
        IServerStreamWriter<HelloReply> responseStream,
        ServerCallContext context)
    {
        await foreach (var request in requestStream.ReadAllAsync())
        {
            await responseStream.WriteAsync(
```

```
                new HelloReply { Message = _greeter.Greet(request.Name) });
        }
    }
}
```

The preceding gRPC service:

- Follows the Explicit Dependencies Principle.
- Expects dependency injection (DI) to provide an instance of `IGreeter`.
- Can be tested with a mocked `IGreeter` service using a mock object framework, such as Moq. A *mocked object* is a fabricated object with a predetermined set of property and method behaviors used for testing. For more information, see Integration tests in ASP.NET Core.

Unit test gRPC services

A unit test library can directly test gRPC services by calling its methods. Unit tests test a gRPC service in isolation.

C#

```
[Fact]
public async Task SayHelloUnaryTest()
{
    // Arrange
    var mockGreeter = new Mock<IGreeter>();
    mockGreeter.Setup(
        m => m.Greet(It.IsAny<string>())).Returns((string s) => $"Hello
{s}");
    var service = new TesterService(mockGreeter.Object);

    // Act
    var response = await service.SayHelloUnary(
        new HelloRequest { Name = "Joe" }, TestServerCallContext.Create());

    // Assert
    mockGreeter.Verify(v => v.Greet("Joe"));
    Assert.Equal("Hello Joe", response.Message);
}
```

The preceding unit test:

- Mocks `IGreeter` using Moq.
- Executes the `SayHelloUnary` method with a request message and a `ServerCallContext`. All service methods have a `ServerCallContext` argument. In

this test, the type is provided using the `TestServerCallContext.Create()` helper method. This helper method is included in the sample code.

- Makes assertions:
  - Verifies the request name is passed to `IGreeter`.
  - The service returns the expected reply message.

Unit test `HttpContext` in gRPC methods

gRPC methods can access a request's HttpContext using the `ServerCallContext.GetHttpContext` extension method. To unit test a method that uses `HttpContext`, the context must be configured in test setup. If HttpContext isn't configured then `GetHttpContext` returns `null`.

To configure a `HttpContext` during test setup, create a new instance and add it to `ServerCallContext.UserState` collection using the `__HttpContext` key.

C#

```
var httpContext = new DefaultHttpContext();

var serverCallContext = TestServerCallContext.Create();
serverCallContext.UserState["__HttpContext"] = httpContext;
```

Execute service methods with this call context to use the configured `HttpContext` instance.

Integration test gRPC services

Integration tests evaluate an app's components on a broader level than unit tests. The gRPC app is hosted in TestServer, an in-memory test server from the Microsoft.AspNetCore.TestHost package.

A unit test library starts the gRPC app and then gRPC services are tested using the gRPC client.

The sample code contains infrastructure to make integration testing possible:

- The `GrpcTestFixture<TStartup>` class configures the ASP.NET Core host and starts the gRPC app in an in-memory test server.
- The `IntegrationTestBase` class is the base type that integration tests inherit from. It contains the fixture state and APIs for creating a gRPC client to call the gRPC app.

C#

```
[Fact]
public async Task SayHelloUnaryTest()
{
    // Arrange
    var client = new Tester.TesterClient(Channel);

    // Act
    var response = await client.SayHelloUnaryAsync(new HelloRequest { Name =
"Joe" });

    // Assert
    Assert.Equal("Hello Joe", response.Message);
}
```

The preceding integration test:

- Creates a gRPC client using the channel provided by `IntegrationTestBase`. This type is included in the sample code.
- Calls the `SayHelloUnary` method using the gRPC client.
- Asserts the service returns the expected reply message.

Inject mock dependencies

Use `ConfigureWebHost` on the fixture to override dependencies. Overriding dependencies is useful when an external dependency is unavailable in the test environment. For example, an app that uses an external payment gateway shouldn't call the external dependency when executing tests. Instead, use a mock gateway for the test.

C#

```
public MockedGreeterServiceTests(GrpcTestFixture<Startup> fixture,
    ITestOutputHelper outputHelper) : base(fixture, outputHelper)
{
    var mockGreeter = new Mock<IGreeter>();
    mockGreeter.Setup(
        m => m.Greet(It.IsAny<string>())).Returns((string s) =>
        {
            if (string.IsNullOrEmpty(s))
            {
                throw new ArgumentException("Name not provided.");
            }
            return $"Test {s}";
        });

    Fixture.ConfigureWebHost(builder =>
    {
        builder.ConfigureServices(
```

```
            services => services.AddSingleton(mockGreeter.Object));
    });
}

[Fact]
public async Task SayHelloUnaryTest_MockGreeter_Success()
{
    // Arrange
    var client = new Tester.TesterClient(Channel);

    // Act
    var response = await client.SayHelloUnaryAsync(
        new HelloRequest { Name = "Joe" });

    // Assert
    Assert.Equal("Test Joe", response.Message);
}
```

The preceding integration test:

- In the test class's (`MockedGreeterServiceTests`) constructor:
  - Mocks `IGreeter` using Moq.
  - Overrides the `IGreeter` registered with dependency injection using `ConfigureWebHost`.
- Calls the `SayHelloUnary` method using the gRPC client.
- Asserts the expected reply message based on the mock `IGreeter` instance.

Call gRPC services with the .NET client

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

A .NET gRPC client library is available in the Grpc.Net.Client NuGet package. This document explains how to:

- Configure a gRPC client to call gRPC services.
- Make gRPC calls to unary, server streaming, client streaming, and bi-directional streaming methods.

Configure gRPC client

gRPC clients are concrete client types that are generated from .proto files. The concrete gRPC client has methods that translate to the gRPC service in the `.proto` file. For example, a service called `Greeter` generates a `GreeterClient` type with methods to call the service.

A gRPC client is created from a channel. Start by using `GrpcChannel.ForAddress` to create a channel, and then use the channel to create a gRPC client:

C#

```
var channel = GrpcChannel.ForAddress("https://localhost:5001");
var client = new Greet.GreeterClient(channel);
```

A channel represents a long-lived connection to a gRPC service. When a channel is created, it's configured with options related to calling a service. For example, the `HttpClient` used to make calls, the maximum send and receive message size, and logging can be specified on `GrpcChannelOptions` and used with `GrpcChannel.ForAddress`. For a complete list of options, see client configuration options.

C#

```
var channel = GrpcChannel.ForAddress("https://localhost:5001");

var greeterClient = new Greet.GreeterClient(channel);
var counterClient = new Count.CounterClient(channel);

// Use clients to call gRPC services
```

Configure TLS

A gRPC client must use the same connection-level security as the called service. gRPC client Transport Layer Security (TLS) is configured when the gRPC channel is created. A gRPC client throws an error when it calls a service and the connection-level security of the channel and service don't match.

To configure a gRPC channel to use TLS, ensure the server address starts with `https`. For example, `GrpcChannel.ForAddress("https://localhost:5001")` uses HTTPS protocol. The gRPC channel automatically negotiates a connection secured by TLS and uses a secure connection to make gRPC calls.

> **Tip**
>
> gRPC supports client certificate authentication over TLS. For information on configuring client certificates with a gRPC channel, see **Authentication and authorization in gRPC for ASP.NET Core**.

To call unsecured gRPC services, ensure the server address starts with `http`. For example, `GrpcChannel.ForAddress("http://localhost:5000")` uses HTTP protocol. In .NET Core 3.1, additional configuration is required to call insecure gRPC services with the .NET client.

Client performance

Channel and client performance and usage:

- Creating a channel can be an expensive operation. Reusing a channel for gRPC calls provides performance benefits.
- A channel manages connections to the server. If the connection is closed or lost, the channel automatically reconnects the next time a gRPC call is made.
- gRPC clients are created with channels. gRPC clients are lightweight objects and don't need to be cached or reused.

- Multiple gRPC clients can be created from a channel, including different types of clients.
- A channel and clients created from the channel can safely be used by multiple threads.
- Clients created from the channel can make multiple simultaneous calls.

`GrpcChannel.ForAddress` isn't the only option for creating a gRPC client. If calling gRPC services from an ASP.NET Core app, consider gRPC client factory integration. gRPC integration with `HttpClientFactory` offers a centralized alternative to creating gRPC clients.

> **Note**
>
> Calling gRPC over HTTP/2 with `Grpc.Net.Client` is currently not supported on Xamarin. We are working to improve HTTP/2 support in a future Xamarin release. Grpc.Core and gRPC-Web are viable alternatives that work today.

Make gRPC calls

A gRPC call is initiated by calling a method on the client. The gRPC client will handle message serialization and addressing the gRPC call to the correct service.

gRPC has different types of methods. How the client is used to make a gRPC call depends on the type of method called. The gRPC method types are:

- Unary
- Server streaming
- Client streaming
- Bi-directional streaming

Unary call

A unary call starts with the client sending a request message. A response message is returned when the service finishes.

C#

```
var client = new Greet.GreeterClient(channel);
var response = await client.SayHelloAsync(new HelloRequest { Name = "World"
});
```

```
Console.WriteLine("Greeting: " + response.Message);
// Greeting: Hello World
```

Each unary service method in the `.proto` file will result in two .NET methods on the concrete gRPC client type for calling the method: an asynchronous method and a blocking method. For example, on `GreeterClient` there are two ways of calling `SayHello`:

- `GreeterClient.SayHelloAsync` - calls `Greeter.SayHello` service asynchronously. Can be awaited.
- `GreeterClient.SayHello` - calls `Greeter.SayHello` service and blocks until complete. Don't use in asynchronous code.

Server streaming call

A server streaming call starts with the client sending a request message. `ResponseStream.MoveNext()` reads messages streamed from the service. The server streaming call is complete when `ResponseStream.MoveNext()` returns `false`.

C#

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHellos(new HelloRequest { Name = "World" });

while (await call.ResponseStream.MoveNext())
{
    Console.WriteLine("Greeting: " + call.ResponseStream.Current.Message);
    // "Greeting: Hello World" is written multiple times
}
```

When using C# 8 or later, the `await foreach` syntax can be used to read messages. The `IAsyncStreamReader<T>.ReadAllAsync()` extension method reads all messages from the response stream:

C#

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHellos(new HelloRequest { Name = "World" });

await foreach (var response in call.ResponseStream.ReadAllAsync())
{
    Console.WriteLine("Greeting: " + response.Message);
    // "Greeting: Hello World" is written multiple times
}
```

The type returned from starting a server streaming call implements `IDisposable`. Always dispose a streaming call to ensure it's stopped and all resources are cleaned up.

Client streaming call

A client streaming call starts *without* the client sending a message. The client can choose to send messages with `RequestStream.WriteAsync`. When the client has finished sending messages, `RequestStream.CompleteAsync()` should be called to notify the service. The call is finished when the service returns a response message.

C#

```
var client = new Counter.CounterClient(channel);
using var call = client.AccumulateCount();

for (var i = 0; i < 3; i++)
{
    await call.RequestStream.WriteAsync(new CounterRequest { Count = 1 });
}
await call.RequestStream.CompleteAsync();

var response = await call;
Console.WriteLine($"Count: {response.Count}");
// Count: 3
```

The type returned from starting a client streaming call implements `IDisposable`. Always dispose a streaming call to ensure it's stopped and all resources are cleaned up.

Bi-directional streaming call

A bi-directional streaming call starts *without* the client sending a message. The client can choose to send messages with `RequestStream.WriteAsync`. Messages streamed from the service are accessible with `ResponseStream.MoveNext()` or `ResponseStream.ReadAllAsync()`. The bi-directional streaming call is complete when the `ResponseStream` has no more messages.

C#

```
var client = new Echo.EchoClient(channel);
using var call = client.Echo();

Console.WriteLine("Starting background task to receive messages");
var readTask = Task.Run(async () =>
{
    await foreach (var response in call.ResponseStream.ReadAllAsync())
```

```
    {
        Console.WriteLine(response.Message);
        // Echo messages sent to the service
    }
});

Console.WriteLine("Starting to send messages");
Console.WriteLine("Type a message to echo then press enter.");
while (true)
{
    var result = Console.ReadLine();
    if (string.IsNullOrEmpty(result))
    {
        break;
    }

    await call.RequestStream.WriteAsync(new EchoMessage { Message = result
});
}

Console.WriteLine("Disconnecting");
await call.RequestStream.CompleteAsync();
await readTask;
```

For best performance, and to avoid unnecessary errors in the client and service, try to complete bi-directional streaming calls gracefully. A bi-directional call completes gracefully when the server has finished reading the request stream and the client has finished reading the response stream. The preceding sample call is one example of a bi-directional call that ends gracefully. In the call, the client:

1. Starts a new bi-directional streaming call by calling `EchoClient.Echo`.
2. Creates a background task to read messages from the service using `ResponseStream.ReadAllAsync()`.
3. Sends messages to the server with `RequestStream.WriteAsync`.
4. Notifies the server it has finished sending messages with `RequestStream.CompleteAsync()`.
5. Waits until the background task has read all incoming messages.

During a bi-directional streaming call, the client and service can send messages to each other at any time. The best client logic for interacting with a bi-directional call varies depending upon the service logic.

The type returned from starting a bi-directional streaming call implements `IDisposable`. Always dispose a streaming call to ensure it's stopped and all resources are cleaned up.

Access gRPC headers

gRPC calls return response headers. HTTP response headers pass name/value metadata about a call that isn't related the returned message.

Headers are accessible using `ResponseHeadersAsync`, which returns a collection of metadata. Headers are typically returned with the response message; therefore, you must await them.

C#

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHelloAsync(new HelloRequest { Name = "World" });

var headers = await call.ResponseHeadersAsync;
var myValue = headers.GetValue("my-trailer-name");

var response = await call.ResponseAsync;
```

`ResponseHeadersAsync` usage:

- Must await the result of `ResponseHeadersAsync` to get the headers collection.
- Doesn't have to be accessed before `ResponseAsync` (or the response stream when streaming). If a response has been returned, then `ResponseHeadersAsync` returns headers instantly.
- Will throw an exception if there was a connection or server error and headers weren't returned for the gRPC call.

Access gRPC trailers

gRPC calls may return response trailers. Trailers are used to provide name/value metadata about a call. Trailers provide similar functionality to HTTP headers, but are received at the end of the call.

Trailers are accessible using `GetTrailers()`, which returns a collection of metadata. Trailers are returned after the response is complete. Therefore, you must await all response messages before accessing the trailers.

Unary and client streaming calls must await `ResponseAsync` before calling `GetTrailers()`:

C#

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHelloAsync(new HelloRequest { Name = "World" });
var response = await call.ResponseAsync;

Console.WriteLine("Greeting: " + response.Message);
```

```
// Greeting: Hello World

var trailers = call.GetTrailers();
var myValue = trailers.GetValue("my-trailer-name");
```

Server and bidirectional streaming calls must finish awaiting the response stream before calling `GetTrailers()`:

C#

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHellos(new HelloRequest { Name = "World" });

await foreach (var response in call.ResponseStream.ReadAllAsync())
{
    Console.WriteLine("Greeting: " + response.Message);
    // "Greeting: Hello World" is written multiple times
}

var trailers = call.GetTrailers();
var myValue = trailers.GetValue("my-trailer-name");
```

Trailers are also accessible from `RpcException`. A service may return trailers together with a non-OK gRPC status. In this situation, the trailers are retrieved from the exception thrown by the gRPC client:

C#

```
var client = new Greet.GreeterClient(channel);
string myValue = null;

try
{
    using var call = client.SayHelloAsync(new HelloRequest { Name = "World"
});
    var response = await call.ResponseAsync;

    Console.WriteLine("Greeting: " + response.Message);
    // Greeting: Hello World

    var trailers = call.GetTrailers();
    myValue = trailers.GetValue("my-trailer-name");
}
catch (RpcException ex)
{
    var trailers = ex.Trailers;
    myValue = trailers.GetValue("my-trailer-name");
}
```

Configure deadline

Configuring a gRPC call deadline is recommended because it provides an upper limit on how long a call can run for. It stops misbehaving services from running forever and exhausting server resources. Deadlines are a useful tool for building reliable apps.

Configure `CallOptions.Deadline` to set a deadline for a gRPC call:

C#

```
var client = new Greet.GreeterClient(channel);

try
{
    var response = await client.SayHelloAsync(
        new HelloRequest { Name = "World" },
        deadline: DateTime.UtcNow.AddSeconds(5));

    // Greeting: Hello World
    Console.WriteLine("Greeting: " + response.Message);
}
catch (RpcException ex) when (ex.StatusCode == StatusCode.DeadlineExceeded)
{
    Console.WriteLine("Greeting timeout.");
}
```

For more information, see Reliable gRPC services with deadlines and cancellation.

gRPC client factory integration in .NET

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

gRPC integration with `HttpClientFactory` offers a centralized way to create gRPC clients. It can be used as an alternative to configuring stand-alone gRPC client instances. Factory integration is available in the Grpc.Net.ClientFactory NuGet package.

The factory offers the following benefits:

- Provides a central location for configuring logical gRPC client instances.
- Manages the lifetime of the underlying `HttpClientMessageHandler`.
- Automatic propagation of deadline and cancellation in an ASP.NET Core gRPC service.

Register gRPC clients

To register a gRPC client, the generic `AddGrpcClient` extension method can be used within an instance of WebApplicationBuilder at the app's entry point in `Program.cs`, specifying the gRPC typed client class and service address:

C#

```
builder.Services.AddGrpcClient<Greeter.GreeterClient>(o =>
{
    o.Address = new Uri("https://localhost:5001");
});
```

The gRPC client type is registered as transient with dependency injection (DI). The client can now be injected and consumed directly in types created by DI. ASP.NET Core MVC controllers, SignalR hubs and gRPC services are places where gRPC clients can automatically be injected:

C#

```
public class AggregatorService : Aggregator.AggregatorBase
{
    private readonly Greeter.GreeterClient _client;

    public AggregatorService(Greeter.GreeterClient client)
    {
        _client = client;
    }

    public override async Task SayHellos(HelloRequest request,
        IServerStreamWriter<HelloReply> responseStream, ServerCallContext
context)
    {
        // Forward the call on to the greeter service
        using (var call = _client.SayHellos(request))
        {
            await foreach (var response in
call.ResponseStream.ReadAllAsync())
            {
                await responseStream.WriteAsync(response);
            }
        }
    }
}
```

Configure HttpHandler

`HttpClientFactory` creates the `HttpMessageHandler` used by the gRPC client. Standard `HttpClientFactory` methods can be used to add outgoing request middleware or to configure the underlying `HttpClientHandler` of the `HttpClient`:

C#

```
builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .ConfigurePrimaryHttpMessageHandler(() =>
    {
        var handler = new HttpClientHandler();
        handler.ClientCertificates.Add(LoadCertificate());
        return handler;
    });
```

For more information, see Make HTTP requests using IHttpClientFactory.

Configure Interceptors

gRPC interceptors can be added to clients using the `AddInterceptor` method.

```
C#

builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .AddInterceptor<LoggingInterceptor>();
```

The preceding code:

- Registers the `GreeterClient` type.
- Configures a `LoggingInterceptor` for this client. `LoggingInterceptor` is created once and shared between `GreeterClient` instances.

By default, an interceptor is created once and shared between clients. This behavior can be overridden by specifying a scope when registering an interceptor. The client factory can be configured to create a new interceptor for each client by specifying `InterceptorScope.Client`.

```
C#

builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .AddInterceptor<LoggingInterceptor>(InterceptorScope.Client);
```

Creating client scoped interceptors is useful when an interceptor requires scoped or transient scoped services from DI.

A gRPC interceptor or channel credentials can be used to send `Authorization` metadata with each request. For more information about configuring authentication, see Send a bearer token with gRPC client factory.

Configure Channel

Additional configuration can be applied to a channel using the `ConfigureChannel` method:

C#

```
builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .ConfigureChannel(o =>
    {
        o.Credentials = new CustomCredentials();
    });
```

`ConfigureChannel` is passed a `GrpcChannelOptions` instance. For more information, see configure client options.

> **Note**
>
> Some properties are set on `GrpcChannelOptions` before the `ConfigureChannel` callback is run:
>
> - `HttpHandler` is set to the result from ConfigurePrimaryHttpMessageHandler.
> - `LoggerFactory` is set to the ILoggerFactory resolved from DI.
>
> These values can be overridden by `ConfigureChannel`.

Call credentials

An authentication header can be added to gRPC calls using the `AddCallCredentials` method:

C#

```
builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .AddCallCredentials((context, metadata) =>
    {
        if (!string.IsNullOrEmpty(_token))
        {
            metadata.Add("Authorization", $"Bearer {_token}");
        }
        return Task.CompletedTask;
    });
```

For more information about configuring call credentials, see Bearer token with gRPC client factory.

Deadline and cancellation propagation

gRPC clients created by the factory in a gRPC service can be configured with `EnableCallContextPropagation()` to automatically propagate the deadline and cancellation token to child calls. The `EnableCallContextPropagation()` extension method is available in the Grpc.AspNetCore.Server.ClientFactory NuGet package.

Call context propagation works by reading the deadline and cancellation token from the current gRPC request context and automatically propagating them to outgoing calls made by the gRPC client. Call context propagation is an excellent way of ensuring that complex, nested gRPC scenarios always propagate the deadline and cancellation.

C#

```
builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .EnableCallContextPropagation();
```

By default, `EnableCallContextPropagation` raises an error if the client is used outside the context of a gRPC call. The error is designed to alert you that there isn't a call context to propagate. If you want to use the client outside of a call context, suppress the error when the client is configured with `SuppressContextNotFoundErrors`:

C#

```
builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .EnableCallContextPropagation(o => o.SuppressContextNotFoundErrors =
true);
```

For more information about deadlines and RPC cancellation, see Reliable gRPC services with deadlines and cancellation.

Named clients

Typically, a gRPC client type is registered once and then injected directly into a type's constructor by DI. However, there are scenarios where it's useful to have multiple configurations for one client. For example, a client that makes gRPC calls with and without authentication.

Multiple clients with the same type can be registered by giving each client a name. Each named client can have its own configuration. The generic `AddGrpcClient` extension method has an overload that includes a name parameter:

C#

```
builder.Services
    .AddGrpcClient<Greeter.GreeterClient>("Greeter", o =>
    {
        o.Address = new Uri("https://localhost:5001");
    });

builder.Services
    .AddGrpcClient<Greeter.GreeterClient>("GreeterAuthenticated", o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .ConfigureChannel(o =>
    {
        o.Credentials = new CustomCredentials();
    });
```

The preceding code:

- Registers the `GreeterClient` type twice, specifying a unique name for each.
- Configures different settings for each named client. The `GreeterAuthenticated` registration adds credentials to the channel so that gRPC calls made with it are authenticated.

A named gRPC client is created in app code using `GrpcClientFactory`. The type and name of the desired client is specified using the generic `GrpcClientFactory.CreateClient` method:

C#

```
public class AggregatorService : Aggregator.AggregatorBase
{
    private readonly Greeter.GreeterClient _client;

    public AggregatorService(GrpcClientFactory grpcClientFactory)
    {
        _client = grpcClientFactory.CreateClient<Greeter.GreeterClient>
("GreeterAuthenticated");
```

```
    }
}
```

Reliable gRPC services with deadlines and cancellation

Article • 07/31/2024

> **ⓘ Important**
>

By James Newton-King

Deadlines and cancellation are features used by gRPC clients to abort in-progress calls. This article discusses why deadlines and cancellation are important, and how to use them in .NET gRPC apps.

Deadlines

A deadline allows a gRPC client to specify how long it will wait for a call to complete. When a deadline is exceeded, the call is canceled. Setting a deadline is important because it provides an upper limit on how long a call can run for. It stops misbehaving services from running forever and exhausting server resources. Deadlines are a useful tool for building reliable apps and should be configured.

Deadline configuration:

- A deadline is configured using `CallOptions.Deadline` when a call is made.
- There is no default deadline value. gRPC calls aren't time limited unless a deadline is specified.
- A deadline is the UTC time of when the deadline is exceeded. For example, `DateTime.UtcNow.AddSeconds(5)` is a deadline of 5 seconds from now.
- If a past or current time is used then the call immediately exceeds the deadline.
- The deadline is sent with the gRPC call to the service and is independently tracked by both the client and the service. It is possible that a gRPC call completes on one machine, but by the time the response has returned to the client the deadline has been exceeded.

If a deadline is exceeded, the client and service have different behavior:

- The client immediately aborts the underlying HTTP request and throws a `DeadlineExceeded` error. The client app can choose to catch the error and display a timeout message to the user.
- On the server, the executing HTTP request is aborted and ServerCallContext.CancellationToken is raised. Although the HTTP request is aborted, the gRPC call continues to run on the server until the method completes. It's important that the cancellation token is passed to async methods so they are cancelled along with the call. For example, passing a cancellation token to async database queries and HTTP requests. Passing a cancellation token allows the canceled call to complete quickly on the server and free up resources for other calls.

Configure `CallOptions.Deadline` to set a deadline for a gRPC call:

C#

```
var client = new Greet.GreeterClient(channel);

try
{
    var response = await client.SayHelloAsync(
        new HelloRequest { Name = "World" },
        deadline: DateTime.UtcNow.AddSeconds(5));

    // Greeting: Hello World
    Console.WriteLine("Greeting: " + response.Message);
}
catch (RpcException ex) when (ex.StatusCode == StatusCode.DeadlineExceeded)
{
    Console.WriteLine("Greeting timeout.");
}
```

Using `ServerCallContext.CancellationToken` in a gRPC service:

C#

```
public override async Task<HelloReply> SayHello(HelloRequest request,
    ServerCallContext context)
{
    var user = await _databaseContext.GetUserAsync(request.Name,
        context.CancellationToken);

    return new HelloReply { Message = "Hello " + user.DisplayName };
}
```

Deadlines and retries

When a gRPC call is configured with retry fault handling and a deadline, the deadline tracks time across all retries for a gRPC call. If the deadline is exceeded, a gRPC call immediately aborts the underlying HTTP request, skips any remaining retries, and throws a `DeadlineExceeded` error.

Propagating deadlines

When a gRPC call is made from an executing gRPC service, the deadline should be propagated. For example:

1. Client app calls `FrontendService.GetUser` with a deadline.
2. `FrontendService` calls `UserService.GetUser`. The deadline specified by the client should be specified with the new gRPC call.
3. `UserService.GetUser` receives the deadline. It correctly times-out if the client app's deadline is exceeded.

The call context provides the deadline with `ServerCallContext.Deadline`:

C#

```
public override async Task<UserResponse> GetUser(UserRequest request,
    ServerCallContext context)
{
    var client = new User.UserServiceClient(_channel);
    var response = await client.GetUserAsync(
        new UserRequest { Id = request.Id },
        deadline: context.Deadline);

    return response;
}
```

Manually propagating deadlines can be cumbersome. The deadline needs to be passed to every call, and it's easy to accidentally miss. An automatic solution is available with gRPC client factory. Specifying `EnableCallContextPropagation`:

- Automatically propagates the deadline and cancellation token to child calls.
- Doesn't propagate the deadline if the child call specifies a smaller deadline. For example, a propagated deadline of 10 seconds isn't used if a child call specifies a new deadline of 5 seconds using `CallOptions.Deadline`. When multiple deadlines are available, the smallest deadline is used.
- Is an excellent way of ensuring that complex, nested gRPC scenarios always propagate the deadline and cancellation.

C#

```
services
    .AddGrpcClient<User.UserServiceClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .EnableCallContextPropagation();
```

For more information, see gRPC client factory integration in .NET.

Cancellation

Cancellation allows a gRPC client to cancel long running calls that are no longer needed. For example, a gRPC call that streams realtime updates is started when the user visits a page on a website. The stream should be canceled when the user navigates away from the page.

A gRPC call can be canceled in the client by passing a cancellation token with CallOptions.CancellationToken or calling `Dispose` on the call.

C#

```
private AsyncServerStreamingCall<HelloReply> _call;

public void StartStream()
{
    _call = client.SayHellos(new HelloRequest { Name = "World" });

    // Read response in background task.
    _ = Task.Run(async () =>
    {
        await foreach (var response in _call.ResponseStream.ReadAllAsync())
        {
            Console.WriteLine("Greeting: " + response.Message);
        }
    });
}

public void StopStream()
{
    _call.Dispose();
}
```

gRPC services that can be cancelled should:

- Pass `ServerCallContext.CancellationToken` to async methods. Canceling async methods allows the call on the server to complete quickly.

- Propagate the cancellation token to child calls. Propagating the cancellation token ensures that child calls are canceled with their parent. gRPC client factory and `EnableCallContextPropagation()` automatically propagates the cancellation token.

Additional resources

- Call gRPC services with the .NET client
- gRPC client factory integration in .NET

By James Newton-King

gRPC retries is a feature that allows gRPC clients to automatically retry failed calls. This article discusses how to configure a retry policy to make resilient, fault tolerant gRPC apps in .NET.

gRPC retries requires Grpc.Net.Client version 2.36.0 or later.

Transient fault handling

gRPC calls can be interrupted by transient faults. Transient faults include:

- Momentary loss of network connectivity.
- Temporary unavailability of a service.
- Timeouts due to server load.

When a gRPC call is interrupted, the client throws an `RpcException` with details about the error. The client app must catch the exception and choose how to handle the error.

C#

```
var client = new Greeter.GreeterClient(channel);
try
{
    var response = await client.SayHelloAsync(
        new HelloRequest { Name = ".NET" });

    Console.WriteLine("From server: " + response.Message);
}
catch (RpcException ex)
{
```

```
    // Write logic to inspect the error and retry
    // if the error is from a transient fault.
}
```

Duplicating retry logic throughout an app is verbose and error prone. Fortunately the .NET gRPC client has a built-in support for automatic retries.

Configure a gRPC retry policy

A retry policy is configured once when a gRPC channel is created:

C#

```
var defaultMethodConfig = new MethodConfig
{
    Names = { MethodName.Default },
    RetryPolicy = new RetryPolicy
    {
        MaxAttempts = 5,
        InitialBackoff = TimeSpan.FromSeconds(1),
        MaxBackoff = TimeSpan.FromSeconds(5),
        BackoffMultiplier = 1.5,
        RetryableStatusCodes = { StatusCode.Unavailable }
    }
};

var channel = GrpcChannel.ForAddress("https://localhost:5001", new
GrpcChannelOptions
{
    ServiceConfig = new ServiceConfig { MethodConfigs = {
defaultMethodConfig } }
});
```

The preceding code:

- Creates a `MethodConfig`. Retry policies can be configured per-method and methods are matched using the `Names` property. This method is configured with `MethodName.Default`, so it's applied to all gRPC methods called by this channel.
- Configures a retry policy. This policy instructs clients to automatically retry gRPC calls that fail with the status code `Unavailable`.
- Configures the created channel to use the retry policy by setting `GrpcChannelOptions.ServiceConfig`.

gRPC clients created with the channel will automatically retry failed calls:

C#

```
var client = new Greeter.GreeterClient(channel);
var response = await client.SayHelloAsync(
    new HelloRequest { Name = ".NET" });

Console.WriteLine("From server: " + response.Message);
```

When retries are valid

Calls are retried when:

- The failing status code matches a value in `RetryableStatusCodes`.
- The previous number of attempts is less than `MaxAttempts`.
- The call hasn't been commited.
- The deadline hasn't been exceeded.

A gRPC call becomes committed in two scenarios:

- The client receives response headers. Response headers are sent by the server when `ServerCallContext.WriteResponseHeadersAsync` is called, or when the first message is written to the server response stream.
- The client's outgoing message (or messages if streaming) has exceeded the client's maximum buffer size. `MaxRetryBufferSize` and `MaxRetryBufferPerCallSize` are configured on the channel.

Committed calls won't retry, regardless of the status code or the previous number of attempts.

Streaming calls

Streaming calls can be used with gRPC retries, but there are important considerations when they are used together:

- **Server streaming**, **bidirectional streaming**: Streaming RPCs that return multiple messages from the server won't retry after the first message has been received. Apps must add additional logic to manually re-establish server and bidirectional streaming calls.
- **Client streaming**, **bidirectional streaming**: Streaming RPCs that send multiple messages to the server won't retry if the outgoing messages have exceeded the client's maximum buffer size. The maximum buffer size can be increased with configuration.

For more information, see When retries are valid.

Retry backoff delay

The backoff delay between retry attempts is configured with `InitialBackoff`, `MaxBackoff`, and `BackoffMultiplier`. More information about each option is available in the gRPC retry options section.

The actual delay between retry attempts is randomized. A randomized delay between 0 and the current backoff determines when the next retry attempt is made. Consider that even with exponential backoff configured, increasing the current backoff between attempts, the actual delay between attempts isn't always larger. The delay is randomized to prevent retries from multiple calls from clustering together and potentially overloading the server.

Detect retries with metadata

gRPC retries can be detected by the presence of `grpc-previous-rpc-attempts` metadata. The `grpc-previous-rpc-attempts` metadata:

- Is automatically added to retried calls and sent to the server.
- Value represents the number of preceding retry attempts.
- Value is always an integer.

Consider the following retry scenario:

1. Client makes a gRPC call to the server.
2. Server fails and returns a retriable status code response.
3. Client retries the gRPC call. Because there was one previous attempt, `grpc-previous-rpc-attempts` metadata has a value of `1`. Metadata is sent to the server with the retry.
4. Server succeeds and returns OK.
5. Client reports success. `grpc-previous-rpc-attempts` is in the response metadata and has a value of `1`.

The `grpc-previous-rpc-attempts` metadata is not present on the initial gRPC call, is `1` for the first retry, `2` for the second retry, and so on.

gRPC retry options

The following table describes options for configuring gRPC retry policies:

Expand table

Option	Description
`MaxAttempts`	The maximum number of call attempts, including the original attempt. This value is limited by `GrpcChannelOptions.MaxRetryAttempts` which defaults to 5. A value is required and must be greater than 1.
`InitialBackoff`	The initial backoff delay between retry attempts. A randomized delay between 0 and the current backoff determines when the next retry attempt is made. After each attempt, the current backoff is multiplied by `BackoffMultiplier`. A value is required and must be greater than zero.
`MaxBackoff`	The maximum backoff places an upper limit on exponential backoff growth. A value is required and must be greater than zero.
`BackoffMultiplier`	The backoff will be multiplied by this value after each retry attempt and will increase exponentially when the multiplier is greater than 1. A value is required and must be greater than zero.
`RetryableStatusCodes`	A collection of status codes. A gRPC call that fails with a matching status will be automatically retried. For more information about status codes, see Status codes and their use in gRPC. At least one retryable status code is required.

Hedging

Hedging is an alternative retry strategy. Hedging enables aggressively sending multiple copies of a single gRPC call without waiting for a response. Hedged gRPC calls may be executed multiple times on the server and the first successful result is used. It's important that hedging is only enabled for methods that are safe to execute multiple times without adverse effect.

Hedging has pros and cons when compared to retries:

- An advantage to hedging is it might return a successful result faster. It allows for multiple simultaneously gRPC calls and will complete when the first successful result is available.
- A disadvantage to hedging is it can be wasteful. Multiple calls could be made and all succeed. Only the first result is used and the rest are discarded.

Configure a gRPC hedging policy

A hedging policy is configured like a retry policy. Note that a hedging policy can't be combined with a retry policy.

```
C#
```

```
var defaultMethodConfig = new MethodConfig
{
    Names = { MethodName.Default },
    HedgingPolicy = new HedgingPolicy
    {
        MaxAttempts = 5,
        NonFatalStatusCodes = { StatusCode.Unavailable }
    }
};

var channel = GrpcChannel.ForAddress("https://localhost:5001", new
GrpcChannelOptions
{
    ServiceConfig = new ServiceConfig { MethodConfigs = {
defaultMethodConfig } }
});
```

gRPC hedging options

The following table describes options for configuring gRPC hedging policies:

Expand table

Option	Description
`MaxAttempts`	The hedging policy will send up to this number of calls. `MaxAttempts` represents the total number of all attempts, including the original attempt. This value is limited by `GrpcChannelOptions.MaxRetryAttempts` which defaults to 5. A value is required and must be 2 or greater.
`HedgingDelay`	The first call is sent immediately, subsequent hedging calls are delayed by this value. When the delay is set to zero or `null`, all hedged calls are sent immediately. `HedgingDelay` is optional and defaults to zero. A value must be zero or greater.
`NonFatalStatusCodes`	A collection of status codes which indicate other hedge calls may still succeed. If a non-fatal status code is returned by the server, hedged calls will continue. Otherwise, outstanding requests will be canceled and the error returned to the app. For more information about status codes, see Status codes and their use in gRPC.

gRPC client-side load balancing

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

Client-side load balancing is a feature that allows gRPC clients to distribute load optimally across available servers. This article discusses how to configure client-side load balancing to create scalable, high-performance gRPC apps in .NET.

Client-side load balancing requires:

- .NET 5 or later.
- Grpc.Net.Client version 2.45.0 or later.

Configure gRPC client-side load balancing

Client-side load balancing is configured when a channel is created. The two components to consider when using load balancing:

- The resolver, which resolves the addresses for the channel. Resolvers support getting addresses from an external source. This is also known as service discovery.
- The load balancer, which creates connections and picks the address that a gRPC call will use.

Built-in implementations of resolvers and load balancers are included in Grpc.Net.Client. Load balancing can also be extended by writing custom resolvers and load balancers.

Addresses, connections and other load balancing state is stored in a `GrpcChannel` instance. A channel must be reused when making gRPC calls for load balancing to work correctly.

> **Note**

Some load balancing configuration uses dependency injection (DI). Apps that don't use DI can create a ServiceCollection instance.

If an app already has DI setup, like an ASP.NET Core website, then types should be registered with the existing DI instance. `GrpcChannelOptions.ServiceProvider` is configured by getting an IServiceProvider from DI.

Configure resolver

The resolver is configured using the address a channel is created with. The URI scheme of the address specifies the resolver.

Expand table

Scheme	Type	Description
`dns`	`DnsResolverFactory`	Resolves addresses by querying the hostname for DNS address records.
`static`	`StaticResolverFactory`	Resolves addresses that the app has specified. Recommended if an app already knows the addresses it calls.

A channel doesn't directly call a URI that matches a resolver. Instead, a matching resolver is created and used to resolve the addresses.

For example, using `GrpcChannel.ForAddress("dns:///my-example-host", new GrpcChannelOptions { Credentials = ChannelCredentials.Insecure })`:

- The `dns` scheme maps to `DnsResolverFactory`. A new instance of a DNS resolver is created for the channel.
- The resolver makes a DNS query for `my-example-host` and gets two results: `127.0.0.100` and `127.0.0.101`.
- The load balancer uses `127.0.0.100:80` and `127.0.0.101:80` to create connections and make gRPC calls.

DnsResolverFactory

The `DnsResolverFactory` creates a resolver designed to get addresses from an external source. DNS resolution is commonly used to load balance over pod instances that have a Kubernetes headless services.

```
C#
```

```
var channel = GrpcChannel.ForAddress(
    "dns:///my-example-host",
    new GrpcChannelOptions { Credentials = ChannelCredentials.Insecure });
var client = new Greet.GreeterClient(channel);

var response = await client.SayHelloAsync(new HelloRequest { Name = "world"
});
```

The preceding code:

- Configures the created channel with the address `dns:///my-example-host`.
  - The `dns` scheme maps to `DnsResolverFactory`.
  - `my-example-host` is the hostname to resolve.
  - No port is specified in the address, so gRPC calls are sent to port 80. This is the default port for unsecured channels. A port can optionally be specified after the hostname. For example, `dns:///my-example-host:8080` configures gRPC calls to be sent to port 8080.
- Doesn't specify a load balancer. The channel defaults to a pick first load balancer.
- Starts the gRPC call `SayHello`:
  - DNS resolver gets addresses for the hostname `my-example-host`.
  - Pick first load balancer attempts to connect to one of the resolved addresses.
  - The call is sent to the first address the channel successfully connects to.

DNS address caching

Performance is important when load balancing. The latency of resolving addresses is eliminated from gRPC calls by caching the addresses. A resolver will be invoked when making the first gRPC call, and subsequent calls use the cache.

Addresses are automatically refreshed if a connection is interrupted. Refreshing is important in scenarios where addresses change at runtime. For example, in Kubernetes a restarted pod triggers the DNS resolver to refresh and get the pod's new address.

By default, a DNS resolver is refreshed if a connection is interrupted. The DNS resolver can also optionally refresh itself on a periodic interval. This can be useful for quickly detecting new pod instances.

C#

```
services.AddSingleton<ResolverFactory>(
    sp => new DnsResolverFactory(refreshInterval:
TimeSpan.FromSeconds(30)));
```

The preceding code creates a `DnsResolverFactory` with a refresh interval and registers it with dependency injection. For more information on using a custom-configured resolver, see Configure custom resolvers and load balancers.

StaticResolverFactory

A static resolver is provided by `StaticResolverFactory`. This resolver:

- Doesn't call an external source. Instead, the client app configures the addresses.
- Is designed for situations where an app already knows the addresses it calls.

C#

```
var factory = new StaticResolverFactory(addr => new[]
{
    new BalancerAddress("localhost", 80),
    new BalancerAddress("localhost", 81)
});

var services = new ServiceCollection();
services.AddSingleton<ResolverFactory>(factory);

var channel = GrpcChannel.ForAddress(
    "static:///my-example-host",
    new GrpcChannelOptions
    {
        Credentials = ChannelCredentials.Insecure,
        ServiceProvider = services.BuildServiceProvider()
    });
var client = new Greet.GreeterClient(channel);
```

The preceding code:

- Creates a `StaticResolverFactory`. This factory knows about two addresses: `localhost:80` and `localhost:81`.
- Registers the factory with dependency injection (DI).
- Configures the created channel with:
  - The address `static:///my-example-host`. The `static` scheme maps to a static resolver.
  - Sets `GrpcChannelOptions.ServiceProvider` with the DI service provider.

This example creates a new ServiceCollection for DI. Suppose an app already has DI setup, like an ASP.NET Core website. In that case, types should be registered with the existing DI instance. `GrpcChannelOptions.ServiceProvider` is configured by getting an IServiceProvider from DI.

Configure load balancer

A load balancer is specified in a service config using the `ServiceConfig.LoadBalancingConfigs` collection. Two load balancers are built-in and map to load balancer config names:

Expand table

Name	Type	Description
`pick_first`	`PickFirstLoadBalancerFactory`	Attempts to connect to addresses until a connection is successfully made. gRPC calls are all made to the first successful connection.
`round_robin`	`RoundRobinLoadBalancerFactory`	Attempts to connect to all addresses. gRPC calls are distributed across all successful connections using round-robin logic.

`service config` is an abbreviation of service configuration and is represented by the `ServiceConfig` type. There are a couple of ways a channel can get a `service config` with a load balancer configured:

- An app can specify a `service config` when a channel is created using `GrpcChannelOptions.ServiceConfig`.
- Alternatively, a resolver can resolve a `service config` for a channel. This feature allows an external source to specify how its callers should perform load balancing. Whether a resolver supports resolving a `service config` is dependent on the resolver implementation. Disable this feature with `GrpcChannelOptions.DisableResolverServiceConfig`.
- If no `service config` is provided, or the `service config` doesn't have a load balancer configured, the channel defaults to `PickFirstLoadBalancerFactory`.

C#

```
var channel = GrpcChannel.ForAddress(
    "dns:///my-example-host",
    new GrpcChannelOptions
    {
        Credentials = ChannelCredentials.Insecure,
        ServiceConfig = new ServiceConfig { LoadBalancingConfigs = { new
RoundRobinConfig() } }
    });
var client = new Greet.GreeterClient(channel);
```

```
var response = await client.SayHelloAsync(new HelloRequest { Name = "world"
});
```

The preceding code:

- Specifies a `RoundRobinLoadBalancerFactory` in the `service config`.
- Starts the gRPC call `SayHello`:
  - `DnsResolverFactory` creates a resolver that gets addresses for the hostname `my-example-host`.
  - Round-robin load balancer attempts to connect to all resolved addresses.
  - gRPC calls are distributed evenly using round-robin logic.

Configure channel credentials

A channel must know whether gRPC calls are sent using transport security. `http` and `https` are no longer part of the address, the scheme now specifies a resolver, so `Credentials` must be configured on channel options when using load balancing.

- `ChannelCredentials.SecureSsl` - gRPC calls are secured with Transport Layer Security (TLS). Equivalent to an `https` address.
- `ChannelCredentials.Insecure` - gRPC calls don't use transport security. Equivalent to an `http` address.

C#

```
var channel = GrpcChannel.ForAddress(
    "dns:///my-example-host",
    new GrpcChannelOptions { Credentials = ChannelCredentials.Insecure });
var client = new Greet.GreeterClient(channel);

var response = await client.SayHelloAsync(new HelloRequest { Name = "world"
});
```

Use load balancing with gRPC client factory

gRPC client factory can be configured to use load balancing:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
```

```
    {
        o.Address = new Uri("dns:///my-example-host");
    })
    .ConfigureChannel(o => o.Credentials = ChannelCredentials.Insecure);

builder.Services.AddSingleton<ResolverFactory>(
    sp => new DnsResolverFactory(refreshInterval:
TimeSpan.FromSeconds(30)));

var app = builder.Build();
```

The preceding code:

- Configures the client with a load-balancing address.
- Specifies channel credentials.
- Registers DI types with the app's IServiceCollection.

Write custom resolvers and load balancers

Client-side load balancing is extensible:

- Implement `Resolver` to create a custom resolver and resolve addresses from a new data source.
- Implement `LoadBalancer` to create a custom load balancer with new load balancing behavior.

> **ⓘ Important**
>
> The APIs used to extend client-side load balancing are experimental. They can change without notice.

Create a custom resolver

A resolver:

- Implements `Resolver` and is created by a `ResolverFactory`. Create a custom resolver by implementing these types.
- Is responsible for resolving the addresses a load balancer uses.
- Can optionally provide a service configuration.

C#

```
public class FileResolver : PollingResolver
{
```

```
    private readonly Uri _address;
    private readonly int _port;

    public FileResolver(Uri address, int defaultPort, ILoggerFactory
loggerFactory)
        : base(loggerFactory)
    {
        _address = address;
        _port = defaultPort;
    }

    public override async Task ResolveAsync(CancellationToken
cancellationToken)
    {
        // Load JSON from a file on disk and deserialize into endpoints.
        var jsonString = await File.ReadAllTextAsync(_address.LocalPath);
        var results = JsonSerializer.Deserialize<string[]>(jsonString);
        var addresses = results.Select(r => new BalancerAddress(r,
_port)).ToArray();

        // Pass the results back to the channel.
        Listener(ResolverResult.ForResult(addresses));
    }
}

public class FileResolverFactory : ResolverFactory
{
    // Create a FileResolver when the URI has a 'file' scheme.
    public override string Name => "file";

    public override Resolver Create(ResolverOptions options)
    {
        return new FileResolver(options.Address, options.DefaultPort,
options.LoggerFactory);
    }
}
```

In the preceding code:

- `FileResolverFactory` implements `ResolverFactory`. It maps to the `file` scheme and creates `FileResolver` instances.
- `FileResolver` implements `PollingResolver`. `PollingResolver` is an abstract base type that makes it easy to implement a resolver with asynchronous logic by overriding `ResolveAsync`.
- In `ResolveAsync`:
  - The file URI is converted to a local path. For example, `file:///c:/addresses.json` becomes `c:\addresses.json`.
  - JSON is loaded from disk and converted into a collection of addresses.

- Listener is called with results to let the channel know that addresses are available.

Create a custom load balancer

A load balancer:

- Implements `LoadBalancer` and is created by a `LoadBalancerFactory`. Create a custom load balancer and factory by implementing these types.
- Is given addresses from a resolver and creates `Subchannel` instances.
- Tracks state about the connection and creates a `SubchannelPicker`. The channel internally uses the picker to pick addresses when making gRPC calls.

The `SubchannelsLoadBalancer` is:

- An abstract base class that implements `LoadBalancer`.
- Manages creating `Subchannel` instances from addresses.
- Makes it easy to implement a custom picking policy over a collection of subchannels.

C#

```
public class RandomBalancer : SubchannelsLoadBalancer
{
    public RandomBalancer(IChannelControlHelper controller, ILoggerFactory
loggerFactory)
        : base(controller, loggerFactory)
    {
    }

    protected override SubchannelPicker CreatePicker(List<Subchannel>
readySubchannels)
    {
        return new RandomPicker(readySubchannels);
    }

    private class RandomPicker : SubchannelPicker
    {
        private readonly List<Subchannel> _subchannels;

        public RandomPicker(List<Subchannel> subchannels)
        {
            _subchannels = subchannels;
        }

        public override PickResult Pick(PickContext context)
        {
            // Pick a random subchannel.
            return
```

```
PickResult.ForSubchannel(_subchannels[Random.Shared.Next(0,
_subchannels.Count)]);
        }
    }
}

public class RandomBalancerFactory : LoadBalancerFactory
{
    // Create a RandomBalancer when the name is 'random'.
    public override string Name => "random";

    public override LoadBalancer Create(LoadBalancerOptions options)
    {
        return new RandomBalancer(options.Controller,
options.LoggerFactory);
    }
}
```

In the preceding code:

- `RandomBalancerFactory` implements `LoadBalancerFactory`. It maps to the `random` policy name and creates `RandomBalancer` instances.
- `RandomBalancer` implements `SubchannelsLoadBalancer`. It creates a `RandomPicker` that randomly picks a subchannel.

Configure custom resolvers and load balancers

Custom resolvers and load balancers need to be registered with dependency injection (DI) when they are used. There are a couple of options:

- If an app is already using DI, such as an ASP.NET Core web app, they can be registered with the existing DI configuration. An IServiceProvider can be resolved from DI and passed to the channel using `GrpcChannelOptions.ServiceProvider`.
- If an app isn't using DI then create:
  - A ServiceCollection with types registered with it.
  - A service provider using BuildServiceProvider.

C#

```
var services = new ServiceCollection();
services.AddSingleton<ResolverFactory, FileResolverFactory>();
services.AddSingleton<LoadBalancerFactory, RandomLoadBalancerFactory>();

var channel = GrpcChannel.ForAddress(
    "file:///c:/data/addresses.json",
    new GrpcChannelOptions
    {
```

```
        Credentials = ChannelCredentials.Insecure,
        ServiceConfig = new ServiceConfig { LoadBalancingConfigs = { new
LoadBalancingConfig("random") } },
        ServiceProvider = services.BuildServiceProvider()
    });
var client = new Greet.GreeterClient(channel);
```

The preceding code:

- Creates a `ServiceCollection` and registers new resolver and load balancer implementations.
- Creates a channel configured to use the new implementations:
  - `ServiceCollection` is built into an `IServiceProvider` and set to `GrpcChannelOptions.ServiceProvider`.
  - Channel address is `file:///c:/data/addresses.json`. The `file` scheme maps to `FileResolverFactory`.
  - `service config` load balancer name is `random`. Maps to `RandomLoadBalancerFactory`.

Why load balancing is important

HTTP/2 multiplexes multiple calls on a single TCP connection. If gRPC and HTTP/2 are used with a network load balancer (NLB), the connection is forwarded to a server, and all gRPC calls are sent to that one server. The other server instances on the NLB are idle.

Network load balancers are a common solution for load balancing because they are fast and lightweight. For example, Kubernetes by default uses a network load balancer to balance connections between pod instances. However, network load balancers are not effective at distributing load when used with gRPC and HTTP/2.

Proxy or client-side load balancing?

gRPC and HTTP/2 can be effectively load balanced using either an application load balancer proxy or client-side load balancing. Both of these options allow individual gRPC calls to be distributed across available servers. Deciding between proxy and client-side load balancing is an architectural choice. There are pros and cons for each.

- **Proxy**: gRPC calls are sent to the proxy, the proxy makes a load balancing decision, and the gRPC call is sent on to the final endpoint. The proxy is responsible for knowing about endpoints. Using a proxy adds:
  - An additional network hop to gRPC calls.
  - Latency and consumes additional resources.

    - Proxy server must be setup and configured correctly.

- **Client-side load balancing**: The gRPC client makes a load balancing decision when a gRPC call is started. The gRPC call is sent directly to the final endpoint. When using client-side load balancing:
    - The client is responsible for knowing about available endpoints and making load balancing decisions.
    - Additional client configuration is required.
    - High-performance, load balanced gRPC calls eliminate the need for a proxy.

Use gRPC client with .NET Standard 2.0

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By James Newton-King

This article discusses how to use the .NET gRPC client with .NET implementations that support .NET Standard 2.0.

.NET implementations

The following .NET implementations (or later) support Grpc.Net.Client but don't have full support for HTTP/2:

- .NET Core 2.1
- .NET Framework 4.6.1
- Mono 5.4
- Xamarin.iOS 10.14
- Xamarin.Android 8.0
- Universal Windows Platform 10.0.16299
- Unity 2018.1

The .NET gRPC client can call services from these .NET implementations with some additional configuration.

HttpHandler configuration

An HTTP provider must be configured using `GrpcChannelOptions.HttpHandler`. If a handler isn't configured, an error is thrown:

> `System.PlatformNotSupportedException`: gRPC requires extra configuration to successfully make RPC calls on .NET implementations that don't have support for gRPC over HTTP/2. An HTTP provider must be specified using

> `GrpcChannelOptions.HttpHandler`. The configured HTTP provider must either support HTTP/2 or be configured to use gRPC-Web.

.NET implementations that don't support HTTP/2, such as UWP, Xamarin, and Unity, can use gRPC-Web as an alternative.

C#

```
var channel = GrpcChannel.ForAddress("https://localhost:5001", new
GrpcChannelOptions
    {
        HttpHandler = new GrpcWebHandler(new HttpClientHandler())
    });

var client = new Greeter.GreeterClient(channel);
var response = await client.SayHelloAsync(new HelloRequest { Name = ".NET"
});
```

Clients can also be created using the gRPC client factory. An HTTP provider is configured using the ConfigurePrimaryHttpMessageHandler extension method.

C#

```
builder.Services
    .AddGrpcClient<Greet.GreeterClient>(options =>
    {
        options.Address = new Uri("https://localhost:5001");
    })
    .ConfigurePrimaryHttpMessageHandler(
        () => new GrpcWebHandler(new HttpClientHandler()));
```

For more information, see Configure gRPC-Web with the .NET gRPC client.

> ⓘ **Important**
>
> gRPC-Web requires the client ***and*** server to support it. gRPC-Web can be **quickly configured by an ASP.NET Core gRPC server**. Other gRPC server implementations require a proxy to support gRPC-Web.

.NET Framework

.NET Framework has limited support for gRPC over HTTP/2. To enable gRPC over HTTP/2 on .NET Framework, configure the channel to use WinHttpHandler.

Requirements and restrictions to using `WinHttpHandler`:

- Windows 11 or later, Windows Server 2019 or later.
  - gRPC client is fully supported on Windows 11 or later.
  - gRPC client is partially supported on Windows Server 2019 and Windows Server 2022. Unary and server streaming methods are supported. Client and bidirectional streaming methods are ***not*** supported.
- A reference to System.Net.Http.WinHttpHandler version 6.0.1 or later.
- Configure `WinHttpHandler` on the channel using `GrpcChannelOptions.HttpHandler`.
- .NET Framework 4.6.1 or later.
- Only gRPC calls over TLS are supported.

C#

```
var channel = GrpcChannel.ForAddress("https://localhost:5001", new
GrpcChannelOptions
    {
        HttpHandler = new WinHttpHandler()
    });

var client = new Greeter.GreeterClient(channel);
var response = await client.SayHelloAsync(new HelloRequest { Name = ".NET"
});
```

gRPC C# core-library

An alternative option for .NET Framework and Xamarin has been to use gRPC C# core-library to make gRPC calls. gRPC C# core-library is:

- A third party library that supports making gRPC calls over HTTP/2 on .NET Framework and Xamarin.
- Not supported by Microsoft.
- In maintenance mode and will be deprecated in favour of gRPC for .NET.
- Not recommended for new apps.

Additional resources

- Call gRPC services with the .NET client
- Use gRPC in browser apps
- gRPC C# core-library

Mock gRPC client in tests

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By: James Newton-King

Testing is an important aspect of building stable and maintainable software. Part of writing high-quality tests is removing external dependencies. This article discusses using mock gRPC clients in tests to remove gRPC calls to external servers.

Example testable client app

To demonstrate client app tests, review the following type in the sample app.

View or download sample code (how to download)

The `Worker` is a BackgroundService that makes calls to a gRPC server.

C#

```
public class Worker : BackgroundService
{
    private readonly Tester.TesterClient _client;
    private readonly IGreetRepository _greetRepository;

    public Worker(Tester.TesterClient client, IGreetRepository
greetRepository)
    {
        _client = client;
        _greetRepository = greetRepository;
    }

    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        var count = 0;
        while (!stoppingToken.IsCancellationRequested)
        {
```

```
            count++;

            var reply = await _client.SayHelloUnaryAsync(
                new HelloRequest { Name = $"Worker {count}" });

            _greetRepository.SaveGreeting(reply.Message);

            await Task.Delay(1000, stoppingToken);
        }
    }
}
```

The preceding type:

- Follows the Explicit Dependencies Principle.
- `TesterClient` is generated automatically by the tooling package Grpc.Tools based on the *test.proto* file, during the build process.
- Expects dependency injection (DI) to provide instances of `TesterClient` and `IGreetRepository`. The app is configured to use the gRPC client factory to create `TesterClient`.
- Can be tested with a mocked `IGreetRepository` service and `TesterClient` client using a mock object framework, such as Moq. A *mocked object* is a fabricated object with a predetermined set of property and method behaviors used for testing. For more information, see Integration tests in ASP.NET Core.

For more information on the C# assets automatically generated by Grpc.Tools, see gRPC services with C#: Generated C# assets.

Mock a gRPC client

gRPC clients are concrete client types that are generated from .proto files. The concrete gRPC client has methods that translate to the gRPC service in the `.proto` file. For example, a service called `Greeter` generates a `GreeterClient` type with methods to call the service.

A mocking framework can mock a gRPC client type. When a mocked client is passed to the type, the test uses the mocked method instead of sending a gRPC call to a server.

C#

```
[Fact]
public async Task Greeting_Success_RepositoryCalled()
{
    // Arrange
    var mockRepository = new Mock<IGreetRepository>();
```

```
    var mockCall = CallHelpers.CreateAsyncUnaryCall(new HelloReply { Message
= "Test" });
    var mockClient = new Mock<Tester.TesterClient>();
    mockClient
        .Setup(m => m.SayHelloUnaryAsync(
            It.IsAny<HelloRequest>(), null, null, CancellationToken.None))
        .Returns(mockCall);

    var worker = new Worker(mockClient.Object, mockRepository.Object);

    // Act
    await worker.StartAsync(CancellationToken.None);

    // Assert
    mockRepository.Verify(v => v.SaveGreeting("Test"));
}
```

The preceding unit test:

- Mocks `IGreetRepository` and `TesterClient` using Moq.
- Starts the worker.
- Verifies `SaveGreeting` is called with the greeting message returned by the mocked `TesterClient`.

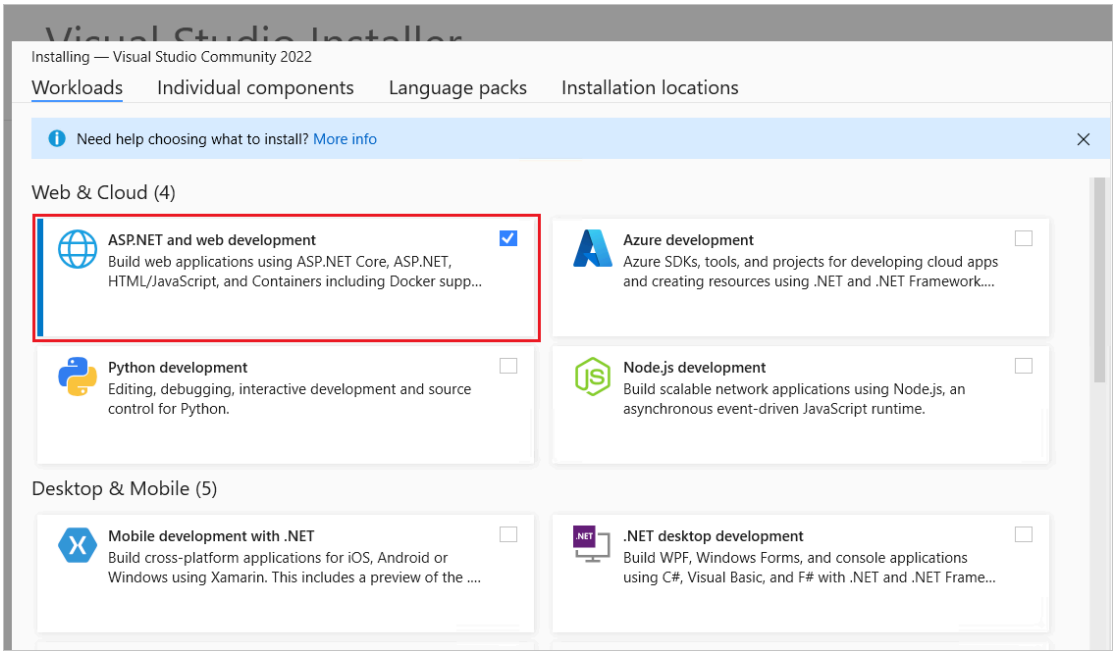
gRPC services with ASP.NET Core

Article • 07/31/2024



> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This document shows how to get started with gRPC services using ASP.NET Core.

Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.

Get started with gRPC service in ASP.NET Core

View or download sample code (how to download).

Visual Studio

See Get started with gRPC services for detailed instructions on how to create a gRPC project.

Add gRPC services to an ASP.NET Core app

gRPC requires the Grpc.AspNetCore package.

Configure gRPC

In `Program.cs`:

- gRPC is enabled with the `AddGrpc` method.
- Each gRPC service is added to the routing pipeline through the `MapGrpcService` method.

C#

```
using GrpcGreeter.Services;

var builder = WebApplication.CreateBuilder(args);

// Additional configuration is required to successfully run gRPC on macOS.
// For instructions on how to configure Kestrel and gRPC clients on macOS,
visit https://go.microsoft.com/fwlink/?linkid=2099682

// Add services to the container.
builder.Services.AddGrpc();

var app = builder.Build();

// Configure the HTTP request pipeline.
app.MapGrpcService<GreeterService>();
app.MapGet("/", () => "Communication with gRPC endpoints must be made
through a gRPC client. To learn how to create a client, visit:
https://go.microsoft.com/fwlink/?linkid=2086909");

app.Run();
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

ASP.NET Core middleware and features share the routing pipeline, therefore an app can be configured to serve additional request handlers. The additional request handlers,

such as MVC controllers, work in parallel with the configured gRPC services.

Server options

gRPC services can be hosted by all built-in ASP.NET Core servers.

- ✓ Kestrel
- ✓ TestServer
- ✓ IIS†
- ✓ HTTP.sys†

†Requires .NET 5 and Windows 11 Build 22000 or Windows Server 2022 Build 20348 or later.

For more information about choosing the right server for an ASP.NET Core app, see Web server implementations in ASP.NET Core.

Kestrel

Kestrel is a cross-platform web server for ASP.NET Core. Kestrel focuses on high performance and memory utilization, but it doesn't have some of the advanced features in HTTP.sys such as port sharing.

Kestrel gRPC endpoints:

- Require HTTP/2.
- Should be secured with Transport Layer Security (TLS).

HTTP/2

gRPC requires HTTP/2. gRPC for ASP.NET Core validates HttpRequest.Protocol is `HTTP/2`.

Kestrel supports HTTP/2 on most modern operating systems. Kestrel endpoints are configured to support HTTP/1.1 and HTTP/2 connections by default.

TLS

Kestrel endpoints used for gRPC should be secured with TLS. In development, an endpoint secured with TLS is automatically created at `https://localhost:5001` when the ASP.NET Core development certificate is present. No configuration is required. An `https` prefix verifies the Kestrel endpoint is using TLS.

In production, TLS must be explicitly configured. In the following `appsettings.json` example, an HTTP/2 endpoint secured with TLS is provided:

JSON

```
{
  "Kestrel": {
    "Endpoints": {
      "HttpsInlineCertFile": {
        "Url": "https://localhost:5001",
        "Protocols": "Http2",
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "<certificate password>"
        }
      }
    }
  }
}
```

Alternatively, Kestrel endpoints can be configured in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(options =>
{
    options.Listen(IPAddress.Any, 5001, listenOptions =>
    {
        listenOptions.Protocols = HttpProtocols.Http2;
        listenOptions.UseHttps("<path to .pfx file>",
            "<certificate password>");
    });
});
```

For more information on enabling TLS with Kestrel, see Kestrel HTTPS endpoint configuration.

Protocol negotiation

TLS is used for more than securing communication. The TLS Application-Layer Protocol Negotiation (ALPN) handshake is used to negotiate the connection protocol between the client and the server when an endpoint supports multiple protocols. This negotiation determines whether the connection uses HTTP/1.1 or HTTP/2.

If an HTTP/2 endpoint is configured without TLS, the endpoint's ListenOptions.Protocols must be set to `HttpProtocols.Http2`. An endpoint with multiple protocols, such as `HttpProtocols.Http1AndHttp2` for example, can't be used without TLS because there's no negotiation. All connections to the unsecured endpoint default to HTTP/1.1, and gRPC calls fail.

For more information on enabling HTTP/2 and TLS with Kestrel, see Kestrel endpoint configuration.

> **Note**
>
> macOS doesn't support ASP.NET Core gRPC with TLS before .NET 8. Additional configuration is required to successfully run gRPC services on macOS when using .NET 7 or earlier. For more information, see **Unable to start ASP.NET Core gRPC app on macOS**.

IIS

Internet Information Services (IIS) is a flexible, secure and manageable Web Server for hosting web apps, including ASP.NET Core. .NET 5 and Windows 11 Build 22000 or Windows Server 2022 Build 20348 or later are required to host gRPC services with IIS.

IIS must be configured to use TLS and HTTP/2. For more information, see Use ASP.NET Core with HTTP/2 on IIS.

HTTP.sys

HTTP.sys is a web server for ASP.NET Core that only runs on Windows. .NET 5 and Windows 11 Build 22000 or Windows Server 2022 Build 20348 or later are required to host gRPC services with HTTP.sys.

HTTP.sys must be configured to use TLS and HTTP/2. For more information, see HTTP.sys web server HTTP/2 support.

Host gRPC in non-ASP.NET Core projects

An ASP.NET Core gRPC server is typically created from the gRPC template. The project file created by the template uses `Microsoft.NET.SDK.Web` as the SDK:

```
XML
```

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <ItemGroup>
    <PackageReference Include="Grpc.AspNetCore" Version="2.47.0" />
    <Protobuf Include="Protos\greet.proto" GrpcServices="Server" />
  </ItemGroup>

</Project>
```

The `Microsoft.NET.SDK.Web` SDK value automatically adds a reference to the ASP.NET Core framework. The reference allows the app to use ASP.NET Core types required to host a server.

You can add a gRPC server to non-ASP.NET Core projects with the following project file settings:

XML

```
<Project Sdk="Microsoft.NET.Sdk">

  <ItemGroup>
    <PackageReference Include="Grpc.AspNetCore" Version="2.47.0" />
    <Protobuf Include="Protos\greet.proto" GrpcServices="Server" />

    <FrameworkReference Include="Microsoft.AspNetCore.App" />
  </ItemGroup>

</Project>
```

The preceding project file:

- Doesn't use `Microsoft.NET.SDK.Web` as the SDK.
- Adds a framework reference to `Microsoft.AspNetCore.App`.
  - The framework reference allows non-ASP.NET Core apps, such as Windows Services, WPF apps, or WinForms apps to use ASP.NET Core APIs.
  - The app can now use ASP.NET Core APIs to start an ASP.NET Core server.
- Adds gRPC requirements:
  - NuGet package reference to Grpc.AspNetCore.
  - `.proto` file.

For more information about using the `Microsoft.AspNetCore.App` framework reference, see Use the ASP.NET Core shared framework.

Integration with ASP.NET Core APIs

gRPC services have full access to the ASP.NET Core features such as Dependency Injection (DI) and Logging. For example, the service implementation can resolve a logger service from the DI container via the constructor:

C#

```
public class GreeterService : Greeter.GreeterBase
{
    public GreeterService(ILogger<GreeterService> logger)
    {
    }
}
```

By default, the gRPC service implementation can resolve other DI services with any lifetime (Singleton, Scoped, or Transient).

Resolve HttpContext in gRPC methods

The gRPC API provides access to some HTTP/2 message data, such as the method, host, header, and trailers. Access is through the `ServerCallContext` argument passed to each gRPC method:

C#

```
public class GreeterService : Greeter.GreeterBase
{
    public override Task<HelloReply> SayHello(
        HelloRequest request, ServerCallContext context)
    {
        return Task.FromResult(new HelloReply
        {
            Message = "Hello " + request.Name
        });
    }
}
```

`ServerCallContext` doesn't provide full access to `HttpContext` in all ASP.NET APIs. The `GetHttpContext` extension method provides full access to the `HttpContext` representing the underlying HTTP/2 message in ASP.NET APIs:

C#

```
public class GreeterService : Greeter.GreeterBase
{
    public override Task<HelloReply> SayHello(
        HelloRequest request, ServerCallContext context)
    {
```

```
        var httpContext = context.GetHttpContext();
        var clientCertificate = httpContext.Connection.ClientCertificate;

        return Task.FromResult(new HelloReply
        {
            Message = "Hello " + request.Name + " from " +
clientCertificate.Issuer
        });
    }
}
```

gRPC on .NET supported platforms

Article • 11/06/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By James Newton-King

This article discusses the requirements and supported platforms for using gRPC with .NET. There are different requirements for the two major gRPC workloads:

- Hosting gRPC services in ASP.NET Core
- Calling gRPC from .NET client apps

Wire-formats

gRPC takes advantage of advanced features available in HTTP/2. HTTP/2 isn't supported everywhere, but a second wire-format using HTTP/1.1 is available for gRPC:

- application/grpc - gRPC over HTTP/2 is how gRPC is typically used.
- application/grpc-web - gRPC-Web modifies the gRPC protocol to be compatible with HTTP/1.1. gRPC-Web can be used in more places. gRPC-Web can be used by browser apps and in networks without complete support for HTTP/2. Two advanced gRPC features are no longer supported: client streaming and bidirectional streaming.

gRPC on .NET supports both wire-formats. `application/grpc` is used by default. gRPC-Web must be configured on the client and the server for successful gRPC-Web calls. For information on setting up gRPC-Web, see gRPC-Web in ASP.NET Core gRPC apps.

ASP.NET Core gRPC server requirements

Hosting gRPC services with ASP.NET Core requires .NET Core 3.x or later.

✔ .NET 5 or later

- ✔ .NET Core 3

ASP.NET Core gRPC services can be hosted on all operating system that .NET Core supports.

- ✔ Windows
- ✔ Linux
- ✔ macOS

Supported ASP.NET Core servers

All built-in ASP.NET Core servers are supported.

- ✔ Kestrel
- ✔ TestServer
- ✔ IIS†
- ✔ HTTP.sys†

†Requires .NET 5 and Windows 11 Build 22000 or Windows Server 2022 Build 20348 or later.

For information about configuring ASP.NET Core servers to run gRPC, see gRPC services with ASP.NET Core.

Azure services

- ✔ Azure Kubernetes Service (AKS)
- ✔ Azure Container Apps
- ✔ Azure App Service †

†gRPC requires a Linux-based environment on Azure App Service. See How-to deploy a .NET 6 gRPC app on App Service for Azure App Service deployment information.

.NET gRPC client requirements

The Grpc.Net.Client package supports gRPC calls over HTTP/2 on .NET Core 3 and .NET 5 or later.

Limited support is available for gRPC over HTTP/2 on .NET Framework. Other .NET versions such as UWP, Xamarin and Unity don't have required HTTP/2 support, and must use gRPC-Web instead.

The following table lists .NET implementations and their gRPC client support:

Expand table

.NET implementation	gRPC over HTTP/2	gRPC-Web
.NET 5 or later	✔	✔
.NET Core 3	✔	✔
.NET Core 2.1	✘	✔
.NET Framework 4.6.1	⚠†	✔
Blazor WebAssembly	✘	✔
Mono 5.4	✘	✔
Xamarin.iOS 10.14	✘	✔
Xamarin.Android 8.0	✘	✔
Universal Windows Platform 10.0.16299	✘	✔
Unity 2018.1	✘	✔

†.NET Framework requires configuration of WinHttpHandler and Windows 11 or later, Windows Server 2019 or later. For more information, see Make gRPC calls on .NET Framework.

Using `Grpc.Net.Client` with gRPC-Web requires additional configuration. For more information:

- Configure gRPC-Web with the .NET gRPC client
- Use gRPC client with .NET Standard 2.0

> **Important**
>
> gRPC-Web requires the client ***and*** server to support it. gRPC-Web can be **quickly configured by an ASP.NET Core gRPC server**. Other gRPC server implementations require a proxy to support gRPC-Web.

Additional resources

- Use gRPC client with .NET Standard 2.0
- gRPC C# core-library

Use gRPC in browser apps

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By James Newton-King

It's not possible to directly call a gRPC service from a browser. gRPC uses HTTP/2 features, and no browser provides the level of control required over web requests to support a gRPC client.

gRPC on ASP.NET Core offers two browser-compatible solutions, gRPC-Web and gRPC JSON transcoding.

gRPC-Web

gRPC-Web allows browser apps to call gRPC services with the gRPC-Web client and Protobuf.

- Similar to normal gRPC, but it has a slightly different wire-protocol, which makes it compatible with HTTP/1.1 and browsers.
- Requires the browser app to generate a gRPC client from a `.proto` file.
- Allows browser apps to benefit from the high-performance and low network usage of binary messages.

.NET has built-in support for gRPC-Web. For more information, see gRPC-Web in ASP.NET Core gRPC apps.

gRPC JSON transcoding

gRPC JSON transcoding allows browser apps to call gRPC services as if they were RESTful APIs with JSON.

- The browser app doesn't need to generate a gRPC client or know anything about gRPC.
- RESTful APIs are automatically created from gRPC services by annotating the `.proto` file with HTTP metadata.
- Allows an app to support both gRPC and JSON web APIs without duplicating the effort of building separate services for both.

.NET has built-in support for creating JSON web APIs from gRPC services. For more information, see gRPC JSON transcoding in ASP.NET Core gRPC apps.

> **Note**
>
> gRPC JSON transcoding requires .NET 7 or later.

Additional resources

- gRPC-Web in ASP.NET Core gRPC apps
- gRPC JSON transcoding in ASP.NET Core gRPC apps

gRPC-Web in ASP.NET Core gRPC apps

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By James Newton-King

Learn how to configure an existing ASP.NET Core gRPC service to be callable from browser apps, using the gRPC-Web protocol. gRPC-Web allows browser JavaScript and Blazor apps to call gRPC services. It's not possible to call an HTTP/2 gRPC service from a browser-based app. gRPC services hosted in ASP.NET Core can be configured to support gRPC-Web alongside HTTP/2 gRPC.

For instructions on adding a gRPC service to an existing ASP.NET Core app, see Add gRPC services to an ASP.NET Core app.

For instructions on creating a gRPC project, see Create a .NET Core gRPC client and server in ASP.NET Core.

ASP.NET Core gRPC-Web versus Envoy

There are two choices for how to add gRPC-Web to an ASP.NET Core app:

- Support gRPC-Web alongside gRPC HTTP/2 in ASP.NET Core. This option uses middleware provided by the Grpc.AspNetCore.Web package.
- Use the Envoy proxy's gRPC-Web support to translate gRPC-Web to gRPC HTTP/2. The translated call is then forwarded onto the ASP.NET Core app.

There are pros and cons to each approach. If an app's environment is already using Envoy as a proxy, it might make sense to also use Envoy to provide gRPC-Web support. For a basic solution for gRPC-Web that only requires ASP.NET Core, `Grpc.AspNetCore.Web` is a good choice.

Configure gRPC-Web in ASP.NET Core

gRPC services hosted in ASP.NET Core can be configured to support gRPC-Web alongside HTTP/2 gRPC. gRPC-Web doesn't require any changes to services. The only modification is in setting the middleware in `Program.cs`.

To enable gRPC-Web with an ASP.NET Core gRPC service:

- Add a reference to the Grpc.AspNetCore.Web package.
- Configure the app to use gRPC-Web by adding `UseGrpcWeb` and `EnableGrpcWeb` to `Program.cs`:

C#

```
using GrpcGreeter.Services;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddGrpc();

var app = builder.Build();

app.UseGrpcWeb();

app.MapGrpcService<GreeterService>().EnableGrpcWeb();
app.MapGet("/", () => "This gRPC service is gRPC-Web enabled and is callable
from browser apps using the gRPC-Web protocol");

app.Run();
```

The preceding code:

- Adds the gRPC-Web middleware, `UseGrpcWeb`, after routing and before endpoints.
- Specifies that the `endpoints.MapGrpcService<GreeterService>()` method supports gRPC-Web with `EnableGrpcWeb`.

Alternatively, the gRPC-Web middleware can be configured so that all services support gRPC-Web by default and `EnableGrpcWeb` isn't required. Specify `new GrpcWebOptions { DefaultEnabled = true }` when the middleware is added.

C#

```
using GrpcGreeter.Services;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddGrpc();

var app = builder.Build();
```

```
app.UseGrpcWeb(new GrpcWebOptions { DefaultEnabled = true });

app.MapGrpcService<GreeterService>().EnableGrpcWeb();
app.MapGet("/", () => "All gRPC service are supported by default in this
example, and are callable from browser apps using the gRPC-Web protocol");

app.Run();
```

> **Note**
>
> There is a known issue that causes gRPC-Web to fail when hosted by HTTP.sys in .NET Core 3.x.
>
> A workaround to get gRPC-Web working on HTTP.sys is available in Grpc-web experimental and UseHttpSys()? (grpc/grpc-dotnet #853).

gRPC-Web and CORS

Browser security prevents a web page from making requests to a different domain than the one that served the web page. This restriction applies to making gRPC-Web calls with browser apps. For example, a browser app served by `https://www.contoso.com` is blocked from calling gRPC-Web services hosted on `https://services.contoso.com`. Cross-Origin Resource Sharing (CORS) can be used to relax this restriction.

To allow a browser app to make cross-origin gRPC-Web calls, set up CORS in ASP.NET Core. Use the built-in CORS support, and expose gRPC-specific headers with WithExposedHeaders.

C#

```
using GrpcGreeter.Services;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddGrpc();

builder.Services.AddCors(o => o.AddPolicy("AllowAll", builder =>
{
    builder.AllowAnyOrigin()
           .AllowAnyMethod()
           .AllowAnyHeader()
           .WithExposedHeaders("Grpc-Status", "Grpc-Message", "Grpc-
Encoding", "Grpc-Accept-Encoding");
}));

var app = builder.Build();
```

```
app.UseGrpcWeb();
app.UseCors();

app.MapGrpcService<GreeterService>().EnableGrpcWeb()
                                    .RequireCors("AllowAll");

app.MapGet("/", () => "This gRPC service is gRPC-Web enabled, CORS enabled,
and is callable from browser apps using the gRPC-Web protocol");

app.Run();
```

The preceding code:

- Calls `AddCors` to add CORS services and configure a CORS policy that exposes gRPC-specific headers.
- Calls `UseCors` to add the CORS middleware after routing configuration and before endpoints configuration.
- Specifies that the `endpoints.MapGrpcService<GreeterService>()` method supports CORS with `RequireCors`.

gRPC-Web and streaming

Traditional gRPC over HTTP/2 supports client, server and bidirectional streaming. gRPC-Web offers limited support for streaming:

- gRPC-Web browser clients don't support calling client streaming and bidirectional streaming methods.
- gRPC-Web .NET clients don't support calling client streaming and bidirectional streaming methods over HTTP/1.1.
- ASP.NET Core gRPC services hosted on Azure App Service and IIS don't support bidirectional streaming.

When using gRPC-Web, we only recommend the use of unary methods and server streaming methods.

HTTP protocol

The ASP.NET Core gRPC service template, included in the .NET SDK, creates an app that's only configured for HTTP/2. This is a good default when an app only supports traditional gRPC over HTTP/2. gRPC-Web, however, works with both HTTP/1.1 and HTTP/2. Some platforms, such as UWP or Unity, can't use HTTP/2. To support all client apps, configure the server to enable HTTP/1.1 and HTTP/2.

Update the default protocol in `appsettings.json`:

JSON

```
{
  "Kestrel": {
    "EndpointDefaults": {
      "Protocols": "Http1AndHttp2"
    }
  }
}
```

Alternatively, configure Kestrel endpoints in startup code.

Enabling HTTP/1.1 and HTTP/2 on the same port requires TLS for protocol negotiation. For more information, see ASP.NET Core gRPC protocol negotiation.

Call gRPC-Web from the browser

Browser apps can use gRPC-Web to call gRPC services. There are some requirements and limitations when calling gRPC services with gRPC-Web from the browser:

- The server must contain configuration to support gRPC-Web.
- Client streaming and bidirectional streaming calls aren't supported. Server streaming is supported.
- Calling gRPC services on a different domain requires CORS configuration on the server.

JavaScript gRPC-Web client

A JavaScript gRPC-Web client exists. For instructions on how to use gRPC-Web from JavaScript, see write JavaScript client code with gRPC-Web.

Configure gRPC-Web with the .NET gRPC client

The .NET gRPC client can be configured to make gRPC-Web calls. This is useful for Blazor WebAssembly apps, which are hosted in the browser and have the same HTTP limitations of JavaScript code. Calling gRPC-Web with a .NET client is the same as HTTP/2 gRPC. The only modification is how the channel is created.

To use gRPC-Web:

- Add a reference to the Grpc.Net.Client.Web package.

- Ensure the reference to Grpc.Net.Client package is version 2.29.0 or later.
- Configure the channel to use the `GrpcWebHandler`:

```
C#
```

```
var channel = GrpcChannel.ForAddress("https://localhost:53305", new
GrpcChannelOptions
{
    HttpHandler = new GrpcWebHandler(new HttpClientHandler())
});

var client = new Greeter.GreeterClient(channel);
var response = await client.SayHelloAsync(
                  new HelloRequest { Name = "GreeterClient" });
```

The preceding code:

- Configures a channel to use gRPC-Web.
- Creates a client and makes a call using the channel.

`GrpcWebHandler` has the following configuration options:

- `InnerHandler`: The underlying HttpMessageHandler that makes the gRPC HTTP request, for example, `HttpClientHandler`.
- `GrpcWebMode`: An enumeration type that specifies whether the gRPC HTTP request `Content-Type` is `application/grpc-web` or `application/grpc-web-text`.
  - `GrpcWebMode.GrpcWeb` configures sending content without encoding. Default value.
  - `GrpcWebMode.GrpcWebText` configures base64-encoded content. Required for server streaming calls in browsers.
- `HttpVersion`: HTTP protocol `Version` used to set HttpRequestMessage.Version on the underlying gRPC HTTP request. gRPC-Web doesn't require a specific version and doesn't override the default unless specified.

> **ⓘ Important**
>
> Generated gRPC clients have synchronous and asynchronous methods for calling unary methods. For example, `SayHello` is synchronous, and `SayHelloAsync` is asynchronous. Asynchronous methods are always required in Blazor WebAssembly. Calling a synchronous method in a Blazor WebAssembly app causes the app to become unresponsive.

Use gRPC client factory with gRPC-Web

Create a .NET client compatible with gRPC-Web using the gRPC client factory:

- Add package references to the project file for the following packages:
  - Grpc.Net.Client.Web
  - Grpc.Net.ClientFactory
- Register a gRPC client with dependency injection (DI) using the generic `AddGrpcClient` extension method. In a Blazor WebAssembly app, services are registered with DI in `Program.cs`.
- Configure `GrpcWebHandler` using the ConfigurePrimaryHttpMessageHandler extension method.

C#

```
builder.Services
    .AddGrpcClient<Greet.GreeterClient>(options =>
    {
        options.Address = new Uri("https://localhost:5001");
    })
    .ConfigurePrimaryHttpMessageHandler(
        () => new GrpcWebHandler(new HttpClientHandler()));
```

For more information, see gRPC client factory integration in .NET.

gRPC JSON transcoding in ASP.NET Core

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By James Newton-King

gRPC is a high-performance Remote Procedure Call (RPC) framework. gRPC uses HTTP/2, streaming, Protobuf, and message contracts to create high-performance, real-time services.

One limitation with gRPC is that not every platform can use it. Browsers don't fully support HTTP/2, making REST APIs and JSON the primary way to get data into browser apps. Despite the benefits that gRPC brings, REST APIs and JSON have an important place in modern apps. Building gRPC ***and*** JSON Web APIs adds unwanted overhead to app development.

This document discusses how to create JSON Web APIs using gRPC services.

Overview

gRPC JSON transcoding is an extension for ASP.NET Core that creates RESTful JSON APIs for gRPC services. Once configured, transcoding allows apps to call gRPC services with familiar HTTP concepts:

- HTTP verbs
- URL parameter binding
- JSON requests/responses

gRPC can still be used to call services.

> **Note**

gRPC JSON transcoding replaces gRPC HTTP API, an alternative experimental extension.

Usage

1. Add a package reference to Microsoft.AspNetCore.Grpc.JsonTranscoding.
2. Register transcoding in server startup code by adding `AddJsonTranscoding`: In the `Program.cs` file, change `builder.Services.AddGrpc();` to `builder.Services.AddGrpc().AddJsonTranscoding();`.
3. Add `<IncludeHttpRuleProtos>true</IncludeHttpRuleProtos>` to the property group in the project file (`.csproj`):

JSON

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>net8.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
    <InvariantGlobalization>true</InvariantGlobalization>
    <IncludeHttpRuleProtos>true</IncludeHttpRuleProtos>
  </PropertyGroup>
```

4. Annotate gRPC methods in your `.proto` files with HTTP bindings and routes:

ProtoBuf

```
syntax = "proto3";

option csharp_namespace = "GrpcServiceTranscoding";
import "google/api/annotations.proto";

package greet;

// The greeting service definition.
service Greeter {
  rpc SayHello (HelloRequest) returns (HelloReply) {
    option (google.api.http) = {
      get: "/v1/greeter/{name}"
    };
  }
}

// The request message containing the user's name.
```

```
message HelloRequest {
  string name = 1;
}

// The response message containing the greetings.
message HelloReply {
  string message = 1;
}
```

The `SayHello` gRPC method can now be invoked as gRPC and as a JSON Web API:

- Request: `GET /v1/greeter/world`
- Response: `{ "message": "Hello world" }`

If the server is configured to write logs for each request, server logs show that a gRPC service executes the HTTP call. Transcoding maps the incoming HTTP request to a gRPC message and converts the response message to JSON.

text

```
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/1.1 GET https://localhost:5001/v1/greeter/world
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint 'gRPC - /v1/greeter/{name}'
info: Server.GreeterService[0]
      Sending hello to world
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint 'gRPC - /v1/greeter/{name}'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 1.996ms 200 application/json
```

Annotate gRPC methods

gRPC methods must be annotated with an HTTP rule before they support transcoding. The HTTP rule includes information about how to call the gRPC method, such as the HTTP method and route.

ProtoBuf

```
service Greeter {
  rpc SayHello (HelloRequest) returns (HelloReply) {
    option (google.api.http) = {
      get: "/v1/greeter/{name}"
    };
  }
}
```

The proceeding example:

- Defines a `Greeter` service with a `SayHello` method. The method has an HTTP rule specified using the name `google.api.http`.
- The method is accessible with `GET` requests and the `/v1/greeter/{name}` route.
- The `name` field on the request message is bound to a route parameter.

Many options are available for customizing how a gRPC method binds to a RESTful API. For more information about annotating gRPC methods and customizing JSON, see Configure HTTP and JSON for gRPC JSON transcoding.

Streaming methods

Traditional gRPC over HTTP/2 supports streaming in all directions. Transcoding is limited to server streaming only. Client streaming and bidirectional streaming methods aren't supported.

Server streaming methods use line-delimited JSON. Each message written using `WriteAsync` is serialized to JSON and followed by a new line.

The following server streaming method writes three messages:

C#

```
public override async Task StreamingFromServer(ExampleRequest request,
    IServerStreamWriter<ExampleResponse> responseStream, ServerCallContext
context)
{
    for (var i = 1; i <= 3; i++)
    {
        await responseStream.WriteAsync(new ExampleResponse { Text =
$"Message {i}" });
        await Task.Delay(TimeSpan.FromSeconds(1));
    }
}
```

The client receives three line-delimited JSON objects:

JSON

```
{"Text":"Message 1"}
{"Text":"Message 2"}
{"Text":"Message 3"}
```

Note that the `WriteIndented` JSON setting doesn't apply to server streaming methods. Pretty printing adds new lines and whitespace to JSON, which can't be used with line-delimited JSON.

View or download an ASP.NET Core gPRC transcoding and streaming app sample.

HTTP protocol

The ASP.NET Core gRPC service template, included in the .NET SDK, creates an app that's only configured for HTTP/2. HTTP/2 is a good default when an app only supports traditional gRPC over HTTP/2. Transcoding, however, works with both HTTP/1.1 and HTTP/2. Some platforms, such as UWP or Unity, can't use HTTP/2. To support all client apps, configure the server to enable HTTP/1.1 and HTTP/2.

Update the default protocol in `appsettings.json`:

JSON

```
{
  "Kestrel": {
    "EndpointDefaults": {
      "Protocols": "Http1AndHttp2"
    }
  }
}
```

Alternatively, configure Kestrel endpoints in startup code.

Enabling HTTP/1.1 and HTTP/2 on the same port requires TLS for protocol negotiation. For more information about configuring HTTP protocols in a gRPC app, see ASP.NET Core gRPC protocol negotiation.

gRPC JSON transcoding vs gRPC-Web

Both transcoding and gRPC-Web allow gRPC services to be called from a browser. However, the way each does this is different:

- gRPC-Web lets browser apps call gRPC services from the browser with the gRPC-Web client and Protobuf. gRPC-Web requires the browser app to generate a gRPC client and has the advantage of sending small, fast Protobuf messages.
- Transcoding allows browser apps to call gRPC services as if they were RESTful APIs with JSON. The browser app doesn't need to generate a gRPC client or know anything about gRPC.

The previous `Greeter` service can be called using browser JavaScript APIs:

JavaScript

```
var name = nameInput.value;

fetch('/v1/greeter/' + name)
  .then((response) => response.json())
  .then((result) => {
    console.log(result.message);
    // Hello world
  });
```

grpc-gateway

grpc-gateway is another technology for creating RESTful JSON APIs from gRPC services. It uses the same `.proto` annotations to map HTTP concepts to gRPC services.

grpc-gateway uses code generation to create a reverse-proxy server. The reverse proxy translates RESTful calls into gRPC+Protobuf and sends the calls over HTTP/2 to the gRPC service. The benefit of this approach is the gRPC service doesn't know about the RESTful JSON APIs. Any gRPC server can use grpc-gateway.

Meanwhile, gRPC JSON transcoding runs inside an ASP.NET Core app. It deserializes JSON into Protobuf messages, then invokes the gRPC service directly. Transcoding in ASP.NET Core offers advantages to .NET app developers:

- Less complex: Both gRPC services and mapped RESTful JSON API run out of one ASP.NET Core app.
- Better performance: Transcoding deserializes JSON to Protobuf messages and invokes the gRPC service directly. There are significant performance benefits in doing this in-process versus making a new gRPC call to a different server.
- Lower cost: Fewer servers result in a smaller monthly hosting bill.

For installation and usage of grpc-gateway, see the grpc-gateway README.

Configure HTTP and JSON for gRPC JSON transcoding

Article • 07/31/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

gRPC JSON transcoding creates RESTful JSON web APIs from gRPC methods. It uses annotations and options for customizing how a RESTful API maps to the gRPC methods.

HTTP rules

gRPC methods must be annotated with an HTTP rule before they support transcoding. The HTTP rule includes information about calling the gRPC method as a RESTful API, such as the HTTP method and route.

ProtoBuf

```
import "google/api/annotations.proto";

service Greeter {
  rpc SayHello (HelloRequest) returns (HelloReply) {
    option (google.api.http) = {
      get: "/v1/greeter/{name}"
    };
  }
}
```

An HTTP rule is:

- An annotation on gRPC methods.
- Identified by the name `google.api.http`.
- Imported from the `google/api/annotations.proto` file. The google/api/http.proto and google/api/annotations.proto files need to be in the project.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

HTTP method

The HTTP method is specified by setting the route to the matching HTTP method field name:

- `get`
- `put`
- `post`
- `delete`
- `patch`

The `custom` field allows for other HTTP methods.

In the following example, the `CreateAddress` method is mapped to `POST` with the specified route:

ProtoBuf

```
service Address {
  rpc CreateAddress (CreateAddressRequest) returns (CreateAddressReply) {
    option (google.api.http) = {
      post: "/v1/address",
      body: "*"
    };
  }
}
```

Route

gRPC JSON transcoding routes support route parameters. For example, `{name}` in a route binds to the `name` field on the request message.

To bind a field on a nested message, specify the path to the field. In the following example, `{params.org}` binds to the `org` field on the `IssueParams` message:

ProtoBuf

```
service Repository {
  rpc GetIssue (GetIssueRequest) returns (GetIssueReply) {
    option (google.api.http) = {
      get: "/{apiVersion}/{params.org}/{params.repo}/issue/{params.issueId}"
    };
  }
}

message GetIssueRequest {
  int32 api_version = 1;
  IssueParams params = 2;
}
message IssueParams {
  string org = 1;
  string repo = 2;
  int32 issueId = 3;
}
```

Transcoding routes and ASP.NET Core routes have a similar syntax and feature set. However, some ASP.NET Core routing features aren't supported by transcoding. These include:

- Route constraints
- Default values
- Optional parameters
- Complex segments

Request body

Transcoding deserializes the request body JSON to the request message. The `body` field specifies how the HTTP request body maps to the request message. The value is either the name of the request field whose value is mapped to the HTTP request body or `*` for mapping all request fields.

In the following example, the HTTP request body is deserialized to the `address` field:

ProtoBuf

```
service Address {
  rpc AddAddress (AddAddressRequest) returns (AddAddressReply) {
    option (google.api.http) = {
      post: "/{apiVersion}/address",
      body: "address"
    };
  }
}
```

```
message AddAddressRequest {
  int32 api_version = 1;
  Address address = 2;
}
message Address {
  string street = 1;
  string city = 2;
  string country = 3;
}
```

Query parameters

Any fields in the request message that aren't bound by route parameters or the request body can be set using HTTP query parameters.

ProtoBuf

```
service Repository {
  rpc GetIssues (GetIssuesRequest) returns (GetIssuesReply) {
    option (google.api.http) = {
      get: "/v1/{org}/{repo}/issue"
    };
  }
}

message GetIssuesRequest {
  string org = 1;
  string repo = 2;
  string text = 3;
  PageParams page = 4;
}
message PageParams {
  int32 index = 1;
  int32 size = 2;
}
```

In the preceding example:

- `org` and `repo` fields are bound from route parameters.
- Other fields, such as `text` and the nested fields from `page`, can be bound from the query string: `?text=value&page.index=0&page.size=10`

Response body

By default, transcoding serializes the entire response message as JSON. The `response_body` field allows serialization of a subset of the response message.

ProtoBuf

```
service Address {
  rpc GetAddress (GetAddressRequest) returns (GetAddressReply) {
    option (google.api.http) = {
      get: "/v1/address/{id}",
      response_body: "address"
    };
  }
}

message GetAddressReply {
  int32 version = 1;
  Address address = 2;
}
message Address {
  string street = 1;
  string city = 2;
  string country = 3;
}
```

In the preceding example, the `address` field is serialized to the response body as JSON.

Specification

For more information about customizing gRPC transcoding, see the HttpRule specification.

Customize JSON

Messages are converted to and from JSON using the JSON mapping in the Protobuf specification. Protobuf's JSON mapping is a standardized way to convert between JSON and Protobuf, and all serialization follows these rules.

However, gRPC JSON transcoding offers some limited options for customizing JSON with GrpcJsonSettings, as shown in the following table.

Expand table

Option	Default Value	Description
IgnoreDefaultValues	`false`	If set to `true`, fields with default values are ignored during serialization.
WriteEnumsAsIntegers	`false`	If set to `true`, enum values are written as integers instead of

Option	Default Value	Description
		strings.
WriteInt64sAsStrings	`false`	If set to `true`, `Int64` and `UInt64` values are written as strings instead of numbers.
WriteIndented	`false`	If set to `true`, JSON is written using pretty printing. This option doesn't affect streaming methods, which write line-delimited JSON messages and can't use pretty printing.

C#

```
builder.Services.AddGrpc().AddJsonTranscoding(o =>
{
    o.JsonSettings.WriteIndented = true;
});
```

In the `.proto` file, the `json_name` field option customizes a field's name when it's serialized as JSON, as in the following example:

ProtoBuf

```
message TestMessage {
  string my_field = 1 [json_name="customFieldName"];
}
```

Transcoding doesn't support advanced JSON customization. Apps requiring precise JSON structure control should consider using ASP.NET Core Web API.

gRPC JSON transcoding documentation with Swagger / OpenAPI

Article • 09/23/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

OpenAPI (Swagger) is a language-agnostic specification for describing REST APIs. gRPC JSON transcoding supports generating OpenAPI from transcoded RESTful APIs. The Microsoft.AspNetCore.Grpc.Swagger package:

- Integrates gRPC JSON transcoding with Swashbuckle.
- Is experimental in .NET 7 to allow us to explore the best way to provide OpenAPI support.

Get started

To enable OpenAPI with gRPC JSON transcoding:

1. Add a package reference to Microsoft.AspNetCore.Grpc.Swagger. The version must be 0.3.0-xxx or later.
2. Configure Swashbuckle in startup. The `AddGrpcSwagger` method configures Swashbuckle to include gRPC endpoints.

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddGrpc().AddJsonTranscoding();
builder.Services.AddGrpcSwagger();
builder.Services.AddSwaggerGen(c =>
{
    c.SwaggerDoc("v1",
        new OpenApiInfo { Title = "gRPC transcoding", Version = "v1" });
});
```

```
var app = builder.Build();
app.UseSwagger();
if (app.Environment.IsDevelopment())
{
    app.UseSwaggerUI(c =>
    {
        c.SwaggerEndpoint("/swagger/v1/swagger.json", "My API V1");
    });
}
app.MapGrpcService<GreeterService>();

app.Run();
```

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Add OpenAPI descriptions from `.proto` comments

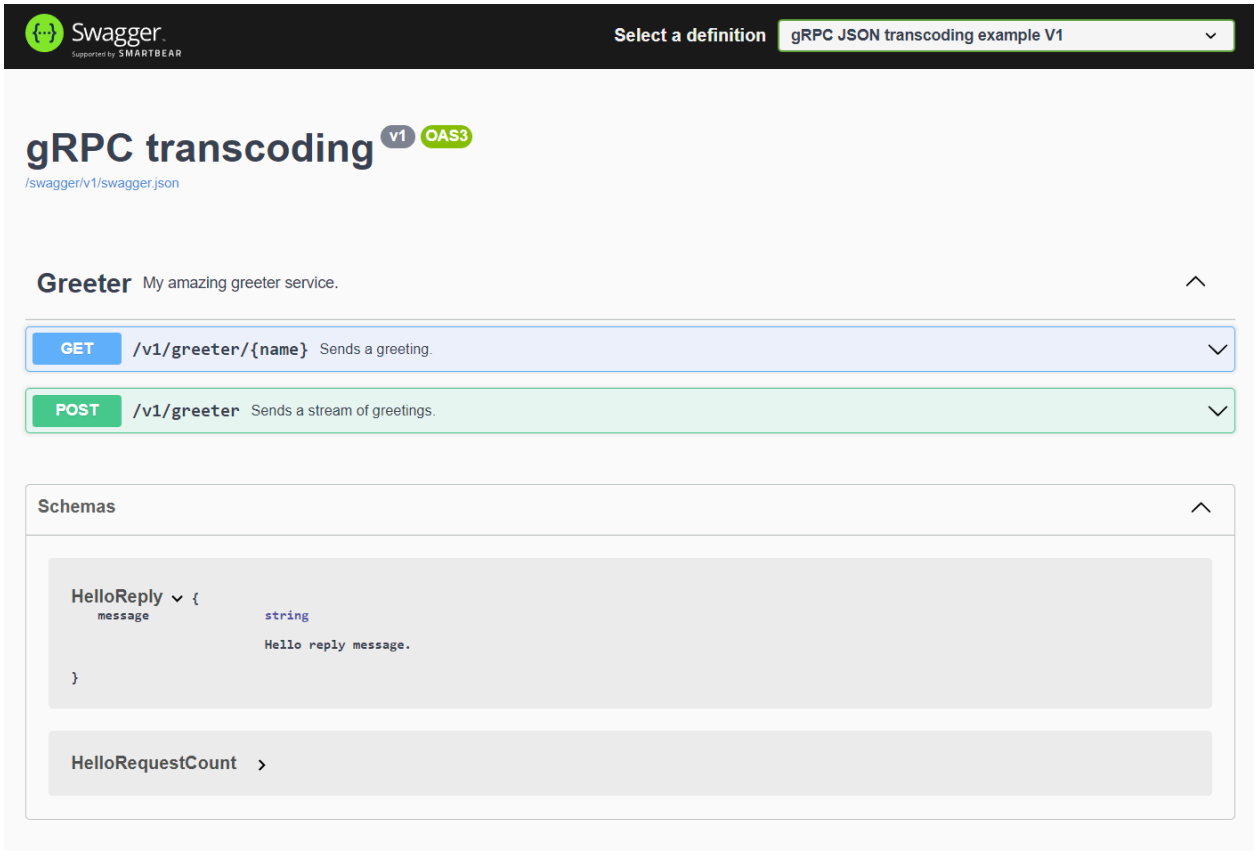
Generate OpenAPI descriptions from comments in the `.proto` contract, as in the following example:

ProtoBuf

```
// My amazing greeter service.
service Greeter {
  // Sends a greeting.
  rpc SayHello (HelloRequest) returns (HelloReply) {
    option (google.api.http) = {
      get: "/v1/greeter/{name}"
    };
  }
}

message HelloRequest {
  // Name to say hello to.
  string name = 1;
}
message HelloReply {
  // Hello reply message.
  string message = 1;
}
```

To enable gRPC OpenAPI comments:



1. Enable the XML documentation file in the server project with `<GenerateDocumentationFile>true</GenerateDocumentationFile>`.
2. Configure `AddSwaggerGen` to read the generated XML file. Pass the XML file path to `IncludeXmlComments` and `IncludeGrpcXmlComments`, as in the following example:

C#

```
builder.Services.AddSwaggerGen(c =>
{
    c.SwaggerDoc("v1",
        new OpenApiInfo { Title = "gRPC transcoding", Version = "v1" });

    var filePath = Path.Combine(System.AppContext.BaseDirectory,
"Server.xml");
    c.IncludeXmlComments(filePath);
    c.IncludeGrpcXmlComments(filePath, includeControllerXmlComments: true);
});
```

To confirm that Swashbuckle is generating OpenAPI with descriptions for the RESTful gRPC services, start the app and navigate to the Swagger UI page:

gRPC for .NET configuration

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Configure services options

gRPC services are configured with `AddGrpc` in `Startup.cs`. Configuration options are in the Grpc.AspNetCore.Server package.

The following table describes options for configuring gRPC services:

Expand table

Option	Default Value	Description
`MaxSendMessageSize`	`null`	The maximum message size in bytes that can be sent from the server. Attempting to send a message that exceeds the configured maximum message size results in an exception. When set to `null`, the message size is unlimited.
`MaxReceiveMessageSize`	4 MB	The maximum message size in bytes that can be received by the server. If the server receives a message that exceeds this limit, it throws an exception. Increasing this value allows the server to receive larger messages, but can negatively impact memory consumption. When set to `null`, the message size is unlimited.
`EnableDetailedErrors`	`false`	If `true`, detailed exception messages are returned to clients when an exception is thrown in a service method. The default is `false`. Setting `EnableDetailedErrors` to `true` can leak sensitive information.

Option	Default Value	Description
`CompressionProviders`	gzip	A collection of compression providers used to compress and decompress messages. Custom compression providers can be created and added to the collection. The default configured providers support **gzip** compression.
`ResponseCompressionAlgorithm`	`null`	The compression algorithm used to compress messages sent from the server. The algorithm must match a compression provider in `CompressionProviders`. For the algorithm to compress a response, the client must indicate it supports the algorithm by sending it in the **grpc-accept-encoding** header.
`ResponseCompressionLevel`	`null`	The compress level used to compress messages sent from the server.
`Interceptors`	None	A collection of interceptors that are run with each gRPC call. Interceptors are run in the order they are registered. Globally configured interceptors are run before interceptors configured for a single service. Interceptors have a per-request lifetime by default. The interceptor constructor is called and parameters are resolved from dependency injection (DI). An interceptor type can also be registered with DI to override how it is created and its lifetime. Interceptors offer similar functionalities compared to ASP.NET Core middleware. For more information, see gRPC Interceptors vs. Middleware.
`IgnoreUnknownServices`	`false`	If `true`, calls to unknown services and methods don't return an **UNIMPLEMENTED** status, and the request passes to the next registered middleware in ASP.NET Core.

Options can be configured for all services by providing an options delegate to the `AddGrpc` call in `Startup.ConfigureServices`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc(options =>
    {
        options.EnableDetailedErrors = true;
```

```
        options.MaxReceiveMessageSize = 2 * 1024 * 1024; // 2 MB
        options.MaxSendMessageSize = 5 * 1024 * 1024; // 5 MB
    });
}
```

Options for a single service override the global options provided in `AddGrpc` and can be configured using `AddServiceOptions<TService>`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc().AddServiceOptions<MyService>(options =>
    {
        options.MaxReceiveMessageSize = 2 * 1024 * 1024; // 2 MB
        options.MaxSendMessageSize = 5 * 1024 * 1024; // 5 MB
    });
}
```

Service interceptors have a per-request lifetime by default. Registering the interceptor type with DI overrides how an interceptor is created and its lifetime.

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc(options =>
    {
        options.Interceptors.Add<LoggingInterceptor>();
    });
    services.AddSingleton<LoggingInterceptor>();
}
```

ASP.NET Core server options

`Grpc.AspNetCore.Server` is hosted by an ASP.NET Core web server. There are a number of options for ASP.NET Core servers, including Kestrel, IIS and HTTP.sys. Each server offers additional options for how HTTP requests are served.

The server used by an ASP.NET Core app is configured in app startup code. The default server is Kestrel.

For more information about the different servers and their configuration options, see:

- Kestrel web server in ASP.NET Core
- HTTP.sys web server implementation in ASP.NET Core

- Host ASP.NET Core on Windows with IIS

Configure client options

gRPC client configuration is set on `GrpcChannelOptions`. Configuration options are in the Grpc.Net.Client package.

The following table describes options for configuring gRPC channels:

Expand table

Option	Default Value	Description
`HttpHandler`	New instance	The `HttpMessageHandler` used to make gRPC calls. A client can be set to configure a custom `HttpClientHandler` or add additional handlers to the HTTP pipeline for gRPC calls. If no `HttpMessageHandler` is specified, a new `HttpClientHandler` instance is created for the channel with automatic disposal.
`HttpClient`	`null`	The `HttpClient` used to make gRPC calls. This setting is an alternative to `HttpHandler`.
`DisposeHttpClient`	`false`	If set to `true` and an `HttpMessageHandler` or `HttpClient` is specified, then either the `HttpHandler` or `HttpClient`, respectively, is disposed when the `GrpcChannel` is disposed.
`LoggerFactory`	`null`	The `LoggerFactory` used by the client to log information about gRPC calls. A `LoggerFactory` instance can be resolved from dependency injection or created using `LoggerFactory.Create`. For examples of configuring logging, see Logging and diagnostics in gRPC on .NET.
`MaxSendMessageSize`	`null`	The maximum message size in bytes that can be sent from the client. Attempting to send a message that exceeds the configured maximum message size results in an exception. When set to `null`, the message size is unlimited.

Option	Default Value	Description
`MaxReceiveMessageSize`	4 MB	The maximum message size in bytes that can be received by the client. If the client receives a message that exceeds this limit, it throws an exception. Increasing this value allows the client to receive larger messages, but can negatively impact memory consumption. When set to `null`, the message size is unlimited.
`Credentials`	`null`	A `ChannelCredentials` instance. Credentials are used to add authentication metadata to gRPC calls.
`CompressionProviders`	gzip	A collection of compression providers used to compress and decompress messages. Custom compression providers can be created and added to the collection. The default configured providers support **gzip** compression.
`ThrowOperationCanceledOnCancellation`	`false`	If set to `true`, clients throw OperationCanceledException when a call is canceled or its deadline is exceeded.
`UnsafeUseInsecureChannelCallCredentials`	`false`	If set to `true`, `CallCredentials` are applied to gRPC calls made by an insecure channel. Sending authentication headers over an insecure connection has security implications and shouldn't be done in production environments.
`MaxRetryAttempts`	5	The maximum retry attempts. This value limits any retry and hedging attempt values specified in the service config. Setting this value alone doesn't enable retries. Retries are enabled in the service config, which can be done using `ServiceConfig`. A `null` value removes the maximum retry attempts limit. For more information about retries, see Transient fault handling with gRPC retries.
`MaxRetryBufferSize`	16 MB	The maximum buffer size in bytes that can be used to store sent messages when retrying or hedging calls. If the buffer limit is exceeded, then no more retry attempts are made and all hedging calls but one

Option	Default Value	Description
		will be canceled. This limit is applied across all calls made using the channel. A `null` value removes the maximum retry buffer size limit.
`MaxRetryBufferPerCallSize`	1 MB	The maximum buffer size in bytes that can be used to store sent messages when retrying or hedging calls. If the buffer limit is exceeded, then no more retry attempts are made and all hedging calls but one will be canceled. This limit is applied to one call. A `null` value removes the maximum retry buffer size limit per call.
`ServiceConfig`	`null`	The service config for a gRPC channel. A service config can be used to configure gRPC retries.

The following code:

- Sets the maximum send and receive message size on the channel.
- Creates a client.

C#

```
static async Task Main(string[] args)
{
    var channel = GrpcChannel.ForAddress("https://localhost:5001", new
GrpcChannelOptions
    {
        MaxReceiveMessageSize = 5 * 1024 * 1024, // 5 MB
        MaxSendMessageSize = 2 * 1024 * 1024 // 2 MB
    });
    var client = new Greeter.GreeterClient(channel);

    var reply = await client.SayHelloAsync(
                      new HelloRequest { Name = "GreeterClient" });
    Console.WriteLine("Greeting: " + reply.Message);
}
```

Note that client interceptors aren't configured with `GrpcChannelOptions`. Instead, client interceptors are configured using the `Intercept` extension method with a channel. This extension method is in the `Grpc.Core.Interceptors` namespace.

C#

```
static async Task Main(string[] args)
{
    var channel = GrpcChannel.ForAddress("https://localhost:5001");
    var callInvoker = channel.Intercept(new LoggingInterceptor());
    var client = new Greeter.GreeterClient(callInvoker);

    var reply = await client.SayHelloAsync(
                      new HelloRequest { Name = "GreeterClient" });
    Console.WriteLine("Greeting: " + reply.Message);
}
```

System.Net handler options

`Grpc.Net.Client` uses a HTTP transport derived from `HttpMessageHandler` to make HTTP requests. Each handler offers additional options for how HTTP requests are made.

The handler is configured on a channel and can be overridden by setting `GrpcChannelOptions.HttpHandler`. .NET Core 3 and .NET 5 or later uses SocketsHttpHandler by default. gRPC client apps on .NET Framework should configure WinHttpHandler.

For more information about the different handlers and their configuration options, see:

- System.Net.Http.SocketsHttpHandler
- System.Net.Http.WinHttpHandler

> For the current release, see the .NET 8 version of this article.

By James Newton-King

View or download sample code (how to download)

Authenticate users calling a gRPC service

gRPC can be used with ASP.NET Core authentication to associate a user with each call.

The following is an example of `Program.cs` which uses gRPC and ASP.NET Core authentication:

C#

```
app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.MapGrpcService<GreeterService>();
```

> **Note**
>
> The order in which you register the ASP.NET Core authentication middleware matters. Always call `UseAuthentication` and `UseAuthorization` after `UseRouting` and before `UseEndpoints`.

The authentication mechanism your app uses during a call needs to be configured. Authentication configuration is added in `Program.cs` and will be different depending

upon the authentication mechanism your app uses.

Once authentication has been setup, the user can be accessed in a gRPC service methods via the `ServerCallContext`.

C#

```
public override Task<BuyTicketsResponse> BuyTickets(
    BuyTicketsRequest request, ServerCallContext context)
{
    var user = context.GetHttpContext().User;

    // ... access data from ClaimsPrincipal ...
}
```

Bearer token authentication

The client can provide an access token for authentication. The server validates the token and uses it to identify the user.

On the server, bearer token authentication is configured using the JWT Bearer middleware.

In the .NET gRPC client, the token can be sent with calls by using the `Metadata` collection. Entries in the `Metadata` collection are sent with a gRPC call as HTTP headers:

C#

```
public bool DoAuthenticatedCall(
    Ticketer.TicketerClient client, string token)
{
    var headers = new Metadata();
    headers.Add("Authorization", $"Bearer {token}");

    var request = new BuyTicketsRequest { Count = 1 };
    var response = await client.BuyTicketsAsync(request, headers);

    return response.Success;
}
```

Set the bearer token with `CallCredentials`

Configuring `ChannelCredentials` on a channel is an alternative way to send the token to the service with gRPC calls. A `ChannelCredentials` can include `CallCredentials`, which

provide a way to automatically set `Metadata`.

Benefits of using `CallCredentials`:

- Authentication is centrally configured on the channel. The token doesn't need to be manually provided to the gRPC call.
- The `CallCredentials.FromInterceptor` callback is asynchronous. Call credentials can fetch a credential token from an external system if required. Asynchronous methods inside the callback should use the `CancellationToken` on `AuthInterceptorContext`.

> **Note**
>
> `CallCredentials` are only applied if the channel is secured with TLS. Sending authentication headers over an insecure connection has security implications and shouldn't be done in production environments. An app can configure a channel to ignore this behavior and always use `CallCredentials` by setting `UnsafeUseInsecureChannelCallCredentials` on a channel.

The credential in the following example configures the channel to send the token with every gRPC call:

C#

```
private static GrpcChannel CreateAuthenticatedChannel(ITokenProvder
tokenProvider)
{
    var credentials = CallCredentials.FromInterceptor(async (context,
metadata) =>
    {
        var token = await
tokenProvider.GetTokenAsync(context.CancellationToken);
        metadata.Add("Authorization", $"Bearer {token}");
    });

    var channel = GrpcChannel.ForAddress(address, new GrpcChannelOptions
    {
        Credentials = ChannelCredentials.Create(new SslCredentials(),
credentials)
    });
    return channel;
}
```

Bearer token with gRPC client factory

gRPC client factory can create clients that send a bearer token using `AddCallCredentials`. This method is available in Grpc.Net.ClientFactory version 2.46.0 or later.

The delegate passed to `AddCallCredentials` is executed for each gRPC call:

C#

```
builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .AddCallCredentials((context, metadata) =>
    {
        if (!string.IsNullOrEmpty(_token))
        {
            metadata.Add("Authorization", $"Bearer {_token}");
        }
        return Task.CompletedTask;
    });
```

Dependency injection (DI) can be combined with `AddCallCredentials`. An overload passes `IServiceProvider` to the delegate, which can be used to get a service constructed from DI using scoped and transient services.

Consider an app that has:

- A user-defined `ITokenProvider` for getting a bearer token. `ITokenProvider` is registered in DI with a scoped lifetime.
- gRPC client factory is configured to create clients that are injected into gRPC services and Web API controllers.
- gRPC calls should use `ITokenProvider` to get a bearer token.

C#

```
public interface ITokenProvider
{
    Task<string> GetTokenAsync(CancellationToken cancellationToken);
}

public class AppTokenProvider : ITokenProvider
{
    private string _token;

    public async Task<string> GetTokenAsync(CancellationToken
cancellationToken)
    {
```

```
        if (_token == null)
        {
            // App code to resolve the token here.
        }

        return _token;
    }
}
```

C#

```
builder.Services.AddScoped<ITokenProvider, AppTokenProvider>();

builder.Services
    .AddGrpcClient<Greeter.GreeterClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    })
    .AddCallCredentials(async (context, metadata, serviceProvider) =>
    {
        var provider = serviceProvider.GetRequiredService<ITokenProvider>();
        var token = await provider.GetTokenAsync(context.CancellationToken);
        metadata.Add("Authorization", $"Bearer {token}");
    }));
```

The preceding code:

- Defines `ITokenProvider` and `AppTokenProvider`. These types handle resolving the authentication token for gRPC calls.
- Registers the `AppTokenProvider` type with DI in a scoped lifetime. `AppTokenProvider` caches the token so that only the first call in the scope is required to calculate it.
- Registers the `GreeterClient` type with client factory.
- Configures `AddCallCredentials` for this client. The delegate is executed each time a call is made and adds the token returned by `ITokenProvider` to the metadata.

Client certificate authentication

A client could alternatively provide a client certificate for authentication. Certificate authentication happens at the TLS level, long before it ever gets to ASP.NET Core. When the request enters ASP.NET Core, the client certificate authentication package allows you to resolve the certificate to a `ClaimsPrincipal`.

> **Note**

Configure the server to accept client certificates. For information on accepting client certificates in Kestrel, IIS, and Azure, see Configure certificate authentication in ASP.NET Core.

In the .NET gRPC client, the client certificate is added to `HttpClientHandler` that is then used to create the gRPC client:

C#

```
public Ticketer.TicketerClient CreateClientWithCert(
    string baseAddress,
    X509Certificate2 certificate)
{
    // Add client cert to the handler
    var handler = new HttpClientHandler();
    handler.ClientCertificates.Add(certificate);

    // Create the gRPC channel
    var channel = GrpcChannel.ForAddress(baseAddress, new GrpcChannelOptions
    {
        HttpHandler = handler
    });

    return new Ticketer.TicketerClient(channel);
}
```

Other authentication mechanisms

Many ASP.NET Core supported authentication mechanisms work with gRPC:

- Microsoft Entra ID
- Client Certificate
- IdentityServer
- JWT Token
- OAuth 2.0
- OpenID Connect
- WS-Federation

For more information on configuring authentication on the server, see ASP.NET Core authentication.

Configuring the gRPC client to use authentication will depend on the authentication mechanism you are using. The previous bearer token and client certificate examples show a couple of ways the gRPC client can be configured to send authentication metadata with gRPC calls:

- Strongly typed gRPC clients use `HttpClient` internally. Authentication can be configured on HttpClientHandler, or by adding custom HttpMessageHandler instances to the `HttpClient`.
- Each gRPC call has an optional `CallOptions` argument. Custom headers can be sent using the option's headers collection.

> ⓘ Note
>
> Windows Authentication (NTLM/Kerberos/Negotiate) can't be used with gRPC. gRPC requires HTTP/2, and HTTP/2 doesn't support Windows Authentication.

Authorize users to access services and service methods

By default, all methods in a service can be called by unauthenticated users. To require authentication, apply the [Authorize] attribute to the service:

C#

```
[Authorize]
public class TicketerService : Ticketer.TicketerBase
{
}
```

You can use the constructor arguments and properties of the `[Authorize]` attribute to restrict access to only users matching specific authorization policies. For example, if you have a custom authorization policy called `MyAuthorizationPolicy`, ensure that only users matching that policy can access the service using the following code:

C#

```
[Authorize("MyAuthorizationPolicy")]
public class TicketerService : Ticketer.TicketerBase
{
}
```

Individual service methods can have the `[Authorize]` attribute applied as well. If the current user doesn't match the policies applied to **both** the method and the class, an error is returned to the caller:

C#

```
[Authorize]
public class TicketerService : Ticketer.TicketerBase
{
    public override Task<AvailableTicketsResponse> GetAvailableTickets(
        Empty request, ServerCallContext context)
    {
        // ... buy tickets for the current user ...
    }

    [Authorize("Administrators")]
    public override Task<BuyTicketsResponse> RefundTickets(
        BuyTicketsRequest request, ServerCallContext context)
    {
        // ... refund tickets (something only Administrators can do) ..
    }
}
```

Error handling with gRPC

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

This article discusses error handling and gRPC:

- Built-in error handling capabilities using gRPC status codes and error messages.
- Sending complex, structured error information using rich error handling.

Built-in error handling

gRPC calls communicate success or failure with a status code. When a gRPC call completes successfully the server returns an `OK` status to the client. If an error occurs, gRPC returns:

- An error status code, such as `CANCELLED` or `UNAVAILABLE`.
- An optional string error message.

The types commonly used with error handling are:

- `StatusCode`: An enumeration of gRPC status codes. `OK` signals success; other values are failure.
- `Status`: A `struct` that combines a `StatusCode` and an optional string error message. The error message provides further details about what happened.
- `RpcException`: An exception type that has `Status` value. This exception is thrown in gRPC server methods and caught by gRPC clients.

Built-in error handling only supports a status code and string description. To send complex error information from the server to the client, use rich error handling.

Throw server errors

A gRPC server call always returns a status. The server automatically returns `OK` when a method completes successfully.

cs

```
public class GreeterService : GreeterBase
{
    public override Task<HelloReply> SayHello(HelloRequest request,
ServerCallContext context)
    {
        return Task.FromResult(new HelloReply { Message = $"Hello
{request.Name}" });
    }

    public override async Task SayHelloStreaming(HelloRequest request,
        IServerStreamWriter<HelloReply> responseStream, ServerCallContext
context)
    {
        for (var i = 0; i < 5; i++)
        {
            await responseStream.WriteAsync(new HelloReply { Message =
$"Hello {request.Name} {i}" });
            await Task.Delay(TimeSpan.FromSeconds(1));
        }
    }
}
```

The preceding code:

- Implements the unary `SayHello` method that completes successfully when it returns a response message.
- Implements the server streaming `SayHelloStreaming` method that completes successfully when the method finished.

Server error status

gRPC methods return an error status code by throwing an exception. When an `RpcException` is thrown on the server, its status code and description is returned to the client:

cs

```
public class GreeterService : GreeterBase
{
    public override Task<HelloReply> SayHello(HelloRequest request,
ServerCallContext context)
    {
        if (string.IsNullOrEmpty(request.Name))
```

```
        {
            throw new RpcException(new Status(StatusCode.InvalidArgument,
"Name is required."));
        }
        return Task.FromResult(new HelloReply { Message = $"Hello
{request.Name}" });
    }
}
```

Thrown exception types that aren't `RpcException` also cause the call to fail, but with an `UNKNOWN` status code and a generic message `Exception was thrown by handler`.

`Exception was thrown by handler` is sent to the client rather than the exception message to prevent exposing potentially sensitive information. To see a more descriptive error message in a development environment, configure EnableDetailedErrors.

Handle client errors

When a gRPC client makes a call, the status code is automatically validated when accessing the response. For example, awaiting a unary gRPC call returns the message sent by the server if the call is successful, and throws an `RpcException` if there's a failure. Catch `RpcException` to handle errors in a client:

cs

```
var client = new Greet.GreeterClient(channel);

try
{
    var response = await client.SayHelloAsync(new HelloRequest { Name =
"World" });
    Console.WriteLine("Greeting: " + response.Message);
}
catch (RpcException ex)
{
    Console.WriteLine("Status code: " + ex.Status.StatusCode);
    Console.WriteLine("Message: " + ex.Status.Detail);
}
```

The preceding code:

- Makes a unary gRPC call to the `SayHello` method.
- Writes the response message to the console if it's successful.
- Catches `RpcException` and writes out the error details on failure.

Error scenarios

Errors are represented by `RpcException` with an error status code and optional detail message. `RpcException` is thrown in many scenarios:

- The call failed on the server and the server sent an error status code. For example, the gRPC client started a call that was missing required data from the request message and the server returns an `INVALID_ARGUMENT` status code.
- An error occurred inside the client when making the gRPC call. For example, a client makes a gRPC call, can't connect to the server, and throws an error with a status of `UNAVAILABLE`.
- The CancellationToken passed to the gRPC call is canceled. The gRPC call is stopped and the client throws an error with a status of `CANCELLED`.
- A gRPC call exceeds its configured deadline. The gRPC call is stopped and the client throws an error with a status of `DEADLINE_EXCEEDED`.

Rich error handling

Rich error handling allows complex, structured information to be sent with error messages. For example, validation of incoming message fields that returns a list of invalid field names and descriptions. The google.rpc.Status error model is often used to send complex error information between gRPC apps.

gRPC on .NET supports a rich error model using the Grpc.StatusProto package. This package has methods for creating rich error models on the server and reading them by a client. The rich error model builds on top of gRPC's built-in handling capabilities and they can be used side-by-side.

> **Important**
>
> Errors are included in headers, and total headers in responses are often limited to 8 KB (8,192 bytes). Ensure that the headers containing errors do not exceed 8 KB.

Creating rich errors on the server

Rich errors are created from `Google.Rpc.Status`. This type is ***different*** from `Grpc.Core.Status`.

`Google.Rpc.Status` has status, message, and details fields. The most important field is details, which is a repeating field of Any values. Details are where complex payloads are

added.

Although any message type can be used as a payload, it's recommended to use one of the standard error payloads:

- `BadRequest`
- `PreconditionFailure`
- `ErrorInfo`
- `ResourceInfo`
- `QuotaFailure`

Grpc.StatusProto includes the `ToRpcException` a helper method to convert `Google.Rpc.Status` to an error. Throw the error from the gRPC server method:

cs

```
public class GreeterService : Greeter.GreeterBase
{
    public override Task<HelloReply> SayHello(HelloRequest request,
ServerCallContext context)
    {
        ArgumentNotNullOrEmpty(request.Name);

        return Task.FromResult(new HelloReply { Message = "Hello " +
request.Name });
    }

    public static void ArgumentNotNullOrEmpty(string value,
[CallerArgumentExpression(nameof(value))] string? paramName = null)
    {
        if (string.IsNullOrEmpty(value))
        {
            var status = new Google.Rpc.Status
            {
                Code = (int)Code.InvalidArgument,
                Message = "Bad request",
                Details =
                {
                    Any.Pack(new BadRequest
                    {
                        FieldViolations =
                        {
                            new BadRequest.Types.FieldViolation { Field =
paramName, Description = "Value is null or empty" }
                        }
                    })
                }
            };
            throw status.ToRpcException();
        }
```

```
    }
}
```

Reading rich errors by a client

Rich errors are read from the `RpcException` caught in the client. Catch the exception and use helper methods provided by `Grpc.StatusCode` to get its `Google.Rpc.Status` instance:

cs

```
var client = new Greet.GreeterClient(channel);

try
{
    var reply = await client.SayHelloAsync(new HelloRequest { Name = name
});
    Console.WriteLine("Greeting: " + reply.Message);
}
catch (RpcException ex)
{
    Console.WriteLine($"Server error: {ex.Status.Detail}");
    var badRequest = ex.GetRpcStatus()?.GetDetail<BadRequest>();
    if (badRequest != null)
    {
        foreach (var fieldViolation in badRequest.FieldViolations)
        {
            Console.WriteLine($"Field: {fieldViolation.Field}");
            Console.WriteLine($"Description: {fieldViolation.Description}");
        }
    }
}
```

The preceding code:

- Makes a gRPC call inside a try/catch that catches `RpcException`.
- Calls `GetRpcStatus()` to attempt to get the rich error model from the exception.
- Calls `GetDetail<BadRequest>()` to attempt to get a `BadRequest` payload from the rich error.

gRPC interceptors on .NET

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Ernest Nguyen

Interceptors are a gRPC concept that allows apps to interact with incoming or outgoing gRPC calls. They offer a way to enrich the request processing pipeline.

Interceptors are configured for a channel or service and executed automatically for each gRPC call. Since interceptors are transparent to the user's application logic, they're an excellent solution for common cases, such as logging, monitoring, authentication, and validation.

`Interceptor` type

Interceptors can be implemented for both gRPC servers and clients by creating a class that inherits from the `Interceptor` type:

C#

```
public class ExampleInterceptor : Interceptor
{
}
```

By default, the `Interceptor` base class doesn't do anything. Add behavior to an interceptor by overriding the appropriate base class methods in an interceptor implementation.

Client interceptors

gRPC client interceptors intercept outgoing RPC invocations. They provide access to the sent request, the incoming response, and the context for a client-side call.

`Interceptor` methods to override for client:

- `BlockingUnaryCall`: Intercepts a blocking invocation of an unary RPC.
- `AsyncUnaryCall`: Intercepts an asynchronous invocation of an unary RPC.
- `AsyncClientStreamingCall`: Intercepts an asynchronous invocation of a client-streaming RPC.
- `AsyncServerStreamingCall`: Intercepts an asynchronous invocation of a server-streaming RPC.
- `AsyncDuplexStreamingCall`: Intercepts an asynchronous invocation of a bidirectional-streaming RPC.

> ⚠ **Warning**
>
> Although both `BlockingUnaryCall` and `AsyncUnaryCall` refer to unary RPCs, they aren't interchangeable. A blocking invocation isn't intercepted by `AsyncUnaryCall`, and an asynchronous invocation isn't intercepted by a `BlockingUnaryCall`.

Create a client gRPC interceptor

The following code presents a basic example of intercepting an asynchronous invocation of a unary call:

C#

```
public class ClientLoggingInterceptor : Interceptor
{
    private readonly ILogger _logger;

    public ClientLoggingInterceptor(ILoggerFactory loggerFactory)
    {
        _logger = loggerFactory.CreateLogger<ClientLoggingInterceptor>();
    }

    public override AsyncUnaryCall<TResponse> AsyncUnaryCall<TRequest,
TResponse>(
        TRequest request,
        ClientInterceptorContext<TRequest, TResponse> context,
        AsyncUnaryCallContinuation<TRequest, TResponse> continuation)
    {
        _logger.LogInformation("Starting call. Type/Method: {Type} /
{Method}",
            context.Method.Type, context.Method.Name);
        return continuation(request, context);
    }
}
```

Overriding `AsyncUnaryCall`:

- Intercepts an asynchronous unary call.
- Logs details about the call.
- Calls the `continuation` parameter passed into the method. This invokes the next interceptor in the chain or the underlying call invoker if this is the last interceptor.

Methods on `Interceptor` for each kind of service method have different signatures. However, the concept behind `continuation` and `context` parameters remains the same:

- `continuation` is a delegate which invokes the next interceptor in the chain or the underlying call invoker (if there is no interceptor left in the chain). It isn't an error to call it zero or multiple times. Interceptors aren't required to return a call representation (`AsyncUnaryCall` in case of unary RPC) returned from the `continuation` delegate. Omitting the delegate call and returning your own instance of call representation breaks the interceptors' chain and returns the associated response immediately.
- `context` carries scoped values associated with the client-side call. Use `context` to pass metadata, such as security principals, credentials, or tracing data. Moreover, `context` carries information about deadlines and cancellation. For more information, see Reliable gRPC services with deadlines and cancellation.

Awaiting response in client interceptor

An interceptor can await the response in unary and client streaming calls by updating the `AsyncUnaryCall<TResponse>.ResponseAsync` or `AsyncClientStreamingCall<TRequest, TResponse>.ResponseAsync` value.

C#

```
public class ErrorHandlerInterceptor : Interceptor
{
    public override AsyncUnaryCall<TResponse> AsyncUnaryCall<TRequest,
TResponse>(
        TRequest request,
        ClientInterceptorContext<TRequest, TResponse> context,
        AsyncUnaryCallContinuation<TRequest, TResponse> continuation)
    {
        var call = continuation(request, context);

        return new AsyncUnaryCall<TResponse>(
            HandleResponse(call.ResponseAsync),
            call.ResponseHeadersAsync,
            call.GetStatus,
            call.GetTrailers,
```

```
            call.Dispose);
    }

    private async Task<TResponse> HandleResponse<TResponse>(Task<TResponse>
inner)
    {
        try
        {
            return await inner;
        }
        catch (Exception ex)
        {
            throw new InvalidOperationException("Custom error", ex);
        }
    }
}
```

The preceding code:

- Creates a new interceptor that overrides `AsyncUnaryCall`.
- Overriding `AsyncUnaryCall`:
  - Calls the `continuation` parameter to invoke the next item in the interceptor chain.
  - Creates a new `AsyncUnaryCall<TResponse>` instance based on the result of the continuation.
  - Wraps the `ResponseAsync` task using the `HandleResponse` method.
  - Awaits the response with `HandleResponse`. Awaiting the response allows logic to be added after the client received the response. By awaiting the response in a try-catch block, errors from calls can be logged.

For more information on how to create a client interceptor, see the ClientLoggerInterceptor.cs example in the grpc/grpc-dotnet GitHub repository.

Configure client interceptors

gRPC client interceptors are configured on a channel.

The following code:

- Creates a channel by using `GrpcChannel.ForAddress`.
- Uses the `Intercept` extension method to configure the channel to use the interceptor. Note that this method returns a `CallInvoker`. Strongly-typed gRPC clients can be created from an invoker just like a channel.
- Creates a client from the invoker. gRPC calls made by the client automatically execute the interceptor.

```
C#
```

```
using var channel = GrpcChannel.ForAddress("https://localhost:5001");
var invoker = channel.Intercept(new ClientLoggerInterceptor());

var client = new Greeter.GreeterClient(invoker);
```

The `Intercept` extension method can be chained to configure multiple interceptors for a channel. Alternatively, there is an `Intercept` overload that accepts multiple interceptors. Any number of interceptors can be executed for a single gRPC call, as the following example demonstrates:

```
C#
```

```
var invoker = channel
    .Intercept(new ClientTokenInterceptor())
    .Intercept(new ClientMonitoringInterceptor())
    .Intercept(new ClientLoggerInterceptor());
```

Interceptors are invoked in reverse order of the chained `Intercept` extension methods. In the preceding code, interceptors are invoked in the following order:

1. `ClientLoggerInterceptor`
2. `ClientMonitoringInterceptor`
3. `ClientTokenInterceptor`

For information on how to configure interceptors with gRPC client factory, see gRPC client factory integration in .NET.

Server interceptors

gRPC server interceptors intercept incoming RPC requests. They provide access to the incoming request, the outgoing response, and the context for a server-side call.

`Interceptor` methods to override for server:

- `UnaryServerHandler`: Intercepts a unary RPC.
- `ClientStreamingServerHandler`: Intercepts a client-streaming RPC.
- `ServerStreamingServerHandler`: Intercepts a server-streaming RPC.
- `DuplexStreamingServerHandler`: Intercepts a bidirectional-streaming RPC.

Create a server gRPC interceptor

The following code presents an example of an intercepting an incoming unary RPC:

C#

```
public class ServerLoggerInterceptor : Interceptor
{
    private readonly ILogger _logger;

    public ServerLoggerInterceptor(ILogger<ServerLoggerInterceptor> logger)
    {
        _logger = logger;
    }

    public override async Task<TResponse> UnaryServerHandler<TRequest,
TResponse>(
        TRequest request,
        ServerCallContext context,
        UnaryServerMethod<TRequest, TResponse> continuation)
    {
        _logger.LogInformation("Starting receiving call. Type/Method: {Type}
/ {Method}",
            MethodType.Unary, context.Method);
        try
        {
            return await continuation(request, context);
        }
        catch (Exception ex)
        {
            _logger.LogError(ex, $"Error thrown by {context.Method}.");
            throw;
        }
    }
}
```

Overriding `UnaryServerHandler`:

- Intercepts an incoming unary call.
- Logs details about the call.
- Calls the `continuation` parameter passed into the method. This invokes the next interceptor in the chain or the service handler if this is the last interceptor.
- Logs any exceptions. Awaiting the continuation allows logic to be added after the service method has executed. By awaiting the continuation in a try-catch block, errors from methods can be logged.

The signature of both client and server interceptors methods are similar:

- `continuation` stands for a delegate for an incoming RPC calling the next interceptor in the chain or the service handler (if there is no interceptor left in the chain). Similar to client interceptors, you can call it any time and there's no need to

return a response directly from the continuation delegate. Outbound logic can be added after a service handler has executed by awaiting the continuation.
- `context` carries metadata associated with the server-side call, such as request metadata, deadlines and cancellation, or RPC result.

For more information on how to create a server interceptor, see the ServerLoggerInterceptor.cs example in the grpc/grpc-dotnet GitHub repository.

Configure server interceptors

gRPC server interceptors are configured at startup. The following code:

- Adds gRPC to the app with `AddGrpc`.
- Configures `ServerLoggerInterceptor` for all services by adding it to the service option's `Interceptors` collection.

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc(options =>
    {
        options.Interceptors.Add<ServerLoggerInterceptor>();
    });
}
```

An interceptor can also be configured for a specific service by using `AddServiceOptions` and specifying the service type.

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services
        .AddGrpc()
        .AddServiceOptions<GreeterService>(options =>
        {
            options.Interceptors.Add<ServerLoggerInterceptor>();
        });
}
```

Interceptors are run in the order that they're added to the `InterceptorCollection`. If both global and single service interceptors are configured, then globally-configured interceptors are run before those configured for a single service.

By default, gRPC server interceptors have a per-request lifetime. Overriding this behavior is possible through registering the interceptor type with dependency injection. The following example registers the `ServerLoggerInterceptor` with a singleton lifetime:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc(options =>
    {
        options.Interceptors.Add<ServerLoggerInterceptor>();
    });

    services.AddSingleton<ServerLoggerInterceptor>();
}
```

gRPC Interceptors versus Middleware

ASP.NET Core middleware offers similar functionalities compared to interceptors in C-core-based gRPC apps. ASP.NET Core middleware and interceptors are conceptually similar. Both:

- Are used to construct a pipeline that handles a gRPC request.
- Allow work to be performed before or after the next component in the pipeline.
- Provide access to `HttpContext`:
  - In middleware, the `HttpContext` is a parameter.
  - In interceptors, the `HttpContext` can be accessed using the `ServerCallContext` parameter with the `ServerCallContext.GetHttpContext` extension method. This feature is specific to interceptors running in ASP.NET Core.

gRPC Interceptor differences from ASP.NET Core Middleware:

- Interceptors:
  - Operate on the gRPC layer of abstraction using the ServerCallContext.
  - Provide access to:
    - The deserialized message sent to a call.
    - The message returned from the call before it's serialized.
  - Can catch and handle exceptions thrown from gRPC services.
- Middleware:
  - Runs for all HTTP requests.
  - Runs before gRPC interceptors.
  - Operates on the underlying HTTP/2 messages.
  - Can only access bytes from the request and response streams.

Logging and diagnostics in gRPC on .NET

Article • 07/31/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By James Newton-King

This article provides guidance for gathering diagnostics from a gRPC app to help troubleshoot issues. Topics covered include:

- **Logging** - Structured logs written to .NET Core logging. ILogger is used by app frameworks to write logs, and by users for their own logging in an app.
- **Tracing** - Events related to an operation written using `DiaganosticSource` and `Activity`. Traces from diagnostic source are commonly used to collect app telemetry by libraries such as Application Insights and OpenTelemetry.
- **Metrics** - Representation of data measures over intervals of time, for example, requests per second. Metrics are emitted using `EventCounter` and can be observed using dotnet-counters command-line tool or with Application Insights.

Logging

gRPC services and the gRPC client write logs using .NET Core logging. Logs are a good place to start when debugging unexpected behavior in service and client apps.

gRPC services logging

> **⚠ Warning**
>
> Server-side logs may contain sensitive information from your app. **Never** post raw logs from production apps to public forums like GitHub.

Since gRPC services are hosted on ASP.NET Core, it uses the ASP.NET Core logging system. In the default configuration, gRPC logs minimal information, but logging can be configured. See the documentation on ASP.NET Core logging for details on configuring ASP.NET Core logging.

gRPC adds logs under the `Grpc` category. To enable detailed logs from gRPC, configure the `Grpc` prefixes to the `Debug` level in the `appsettings.json` file by adding the following items to the `LogLevel` subsection in `Logging`:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Debug",
      "System": "Information",
      "Microsoft": "Information",
      "Grpc": "Debug"
    }
  }
}
```

Logging can also be configured in `Program.cs` with `ConfigureLogging`:

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureLogging(logging =>
        {
            logging.AddFilter("Grpc", LogLevel.Debug);
        })
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.UseStartup<Startup>();
        });
```

When not using JSON-based configuration, set the following configuration value in the configuration system:

- `Logging:LogLevel:Grpc` = `Debug`

Check the documentation for your configuration system to determine how to specify nested configuration values. For example, when using environment variables, two `_` characters are used instead of the `:` (for example, `Logging__LogLevel__Grpc`).

We recommend using the `Debug` level when gathering detailed diagnostics for an app. The `Trace` level produces low-level diagnostics and is rarely needed to diagnose issues.

Sample logging output

Here is an example of console output at the `Debug` level of a gRPC service:

Console

```
info: Microsoft.AspNetCore.Hosting.Diagnostics[1]
      Request starting HTTP/2 POST
https://localhost:5001/Greet.Greeter/SayHello application/grpc
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[0]
      Executing endpoint 'gRPC - /Greet.Greeter/SayHello'
dbug: Grpc.AspNetCore.Server.ServerCallHandler[1]
      Reading message.
info: GrpcService.GreeterService[0]
      Hello World
dbug: Grpc.AspNetCore.Server.ServerCallHandler[6]
      Sending message.
info: Microsoft.AspNetCore.Routing.EndpointMiddleware[1]
      Executed endpoint 'gRPC - /Greet.Greeter/SayHello'
info: Microsoft.AspNetCore.Hosting.Diagnostics[2]
      Request finished in 1.4113ms 200 application/grpc
```

Access server-side logs

How server-side logs are accessed depends on the app's environment.

As a console app

If you're running in a console app, the Console logger should be enabled by default. gRPC logs will appear in the console.

Other environments

If the app is deployed to another environment (for example, Docker, Kubernetes, or Windows Service), see Logging in .NET Core and ASP.NET Core for more information on how to configure logging providers suitable for the environment.

gRPC client logging

> ⚠ **Warning**

Client-side logs may contain sensitive information from your app. **Never** post raw logs from production apps to public forums like GitHub.

To get logs from the .NET client, set the `GrpcChannelOptions.LoggerFactory` property when the client's channel is created. When calling a gRPC service from an ASP.NET Core app, the logger factory can be resolved from dependency injection (DI):

C#

```
[ApiController]
[Route("[controller]")]
public class GreetingController : ControllerBase
{
    private ILoggerFactory _loggerFactory;

    public GreetingController(ILoggerFactory loggerFactory)
    {
        _loggerFactory = loggerFactory;
    }

    [HttpGet]
    public async Task<ActionResult<string>> Get(string name)
    {
        var channel = GrpcChannel.ForAddress("https://localhost:5001",
            new GrpcChannelOptions { LoggerFactory = _loggerFactory });
        var client = new Greeter.GreeterClient(channel);

        var reply = await client.SayHelloAsync(new HelloRequest { Name =
name });
        return Ok(reply.Message);
    }
}
```

An alternative way to enable client logging is to use the gRPC client factory to create the client. A gRPC client registered with the client factory and resolved from DI will automatically use the app's configured logging.

If the app isn't using DI, then create a new `ILoggerFactory` instance with LoggerFactory.Create. To access this method, add the Microsoft.Extensions.Logging package to your app.

C#

```
var loggerFactory = LoggerFactory.Create(logging =>
{
    logging.AddConsole();
    logging.SetMinimumLevel(LogLevel.Debug);
});
```

```
var channel = GrpcChannel.ForAddress("https://localhost:5001",
    new GrpcChannelOptions { LoggerFactory = loggerFactory });

var client = Greeter.GreeterClient(channel);
```

gRPC client log scopes

The gRPC client adds a logging scope to logs made during a gRPC call. The scope has metadata related to the gRPC call:

- **GrpcMethodType** - The gRPC method type. Possible values are names from `Grpc.Core.MethodType` enum. For example, `Unary`.
- **GrpcUri** - The relative URI of the gRPC method. For example, */greet.Greeter/SayHellos*.

Sample logging output

Here is an example of console output at the `Debug` level of a gRPC client:

Console

```
dbug: Grpc.Net.Client.Internal.GrpcCall[1]
      Starting gRPC call. Method type: 'Unary', URI:
'https://localhost:5001/Greet.Greeter/SayHello'.
dbug: Grpc.Net.Client.Internal.GrpcCall[6]
      Sending message.
dbug: Grpc.Net.Client.Internal.GrpcCall[1]
      Reading message.
dbug: Grpc.Net.Client.Internal.GrpcCall[4]
      Finished gRPC call.
```

Tracing

gRPC services and the gRPC client provide information about gRPC calls using DiagnosticSource and Activity.

- .NET gRPC uses an activity to represent a gRPC call.
- Tracing events are written to the diagnostic source at the start and stop of the gRPC call activity.
- Tracing doesn't capture information about when messages are sent over the lifetime of gRPC streaming calls.

gRPC service tracing

gRPC services are hosted on ASP.NET Core, which reports events about incoming HTTP requests. gRPC specific metadata is added to the existing HTTP request diagnostics that ASP.NET Core provides.

- Diagnostic source name is `Microsoft.AspNetCore`.
- Activity name is `Microsoft.AspNetCore.Hosting.HttpRequestIn`.
  - Name of the gRPC method invoked by the gRPC call is added as a tag with the name `grpc.method`.
  - Status code of the gRPC call when it is complete is added as a tag with the name `grpc.status_code`.

gRPC client tracing

The .NET gRPC client uses `HttpClient` to make gRPC calls. Although `HttpClient` writes diagnostic events, the .NET gRPC client provides a custom diagnostic source, activity, and events so that complete information about a gRPC call can be collected.

- Diagnostic source name is `Grpc.Net.Client`.
- Activity name is `Grpc.Net.Client.GrpcOut`.
  - Name of the gRPC method invoked by the gRPC call is added as a tag with the name `grpc.method`.
  - Status code of the gRPC call when it is complete is added as a tag with the name `grpc.status_code`.

Collecting tracing

The easiest way to use `DiagnosticSource` is to configure a telemetry library such as Application Insights or OpenTelemetry in your app. The library will process information about gRPC calls along-side other app telemetry.

Tracing can be viewed in a managed service like Application Insights, or run as your own distributed tracing system. OpenTelemetry supports exporting tracing data to Jaeger and Zipkin.

`DiagnosticSource` can consume tracing events in code using `DiagnosticListener`. For information about listening to a diagnostic source with code, see the DiagnosticSource user's guide.

> **Note**

Telemetry libraries do not capture gRPC specific `Grpc.Net.Client.GrpcOut` telemetry currently. Work to improve telemetry libraries capturing this tracing is ongoing.

Metrics

Metrics is a representation of data measures over intervals of time, for example, requests per second. Metrics data allows observation of the state of an app at a high level. .NET gRPC metrics are emitted using `EventCounter`.

gRPC service metrics

gRPC server metrics are reported on `Grpc.AspNetCore.Server` event source.

Expand table

Name	Description
`total-calls`	Total Calls
`current-calls`	Current Calls
`calls-failed`	Total Calls Failed
`calls-deadline-exceeded`	Total Calls Deadline Exceeded
`messages-sent`	Total Messages Sent
`messages-received`	Total Messages Received
`calls-unimplemented`	Total Calls Unimplemented

ASP.NET Core also provides its own metrics on `Microsoft.AspNetCore.Hosting` event source.

gRPC client metrics

gRPC client metrics are reported on `Grpc.Net.Client` event source.

Expand table

Name	Description
`total-calls`	Total Calls

Name	Description
`current-calls`	Current Calls
`calls-failed`	Total Calls Failed
`calls-deadline-exceeded`	Total Calls Deadline Exceeded
`messages-sent`	Total Messages Sent
`messages-received`	Total Messages Received

Observe metrics

dotnet-counters is a performance monitoring tool for ad-hoc health monitoring and first-level performance investigation. Monitor a .NET app with either `Grpc.AspNetCore.Server` or `Grpc.Net.Client` as the provider name.

Console

```
> dotnet-counters monitor --process-id 1902 Grpc.AspNetCore.Server

Press p to pause, r to resume, q to quit.
    Status: Running
[Grpc.AspNetCore.Server]
    Total Calls                                300
    Current Calls                              5
    Total Calls Failed                         0
    Total Calls Deadline Exceeded              0
    Total Messages Sent                        295
    Total Messages Received                    300
    Total Calls Unimplemented                  0
```

Another way to observe gRPC metrics is to capture counter data using Application Insights's Microsoft.ApplicationInsights.EventCounterCollector package. Once setup, Application Insights collects common .NET counters at runtime. gRPC's counters are not collected by default, but App Insights can be customized to include additional counters.

Specify the gRPC counters for Application Insight to collect in `Startup.cs`:

C#

```
    using Microsoft.ApplicationInsights.Extensibility.EventCounterCollector;

    public void ConfigureServices(IServiceCollection services)
    {
        //... other code...
```

```
        services.ConfigureTelemetryModule<EventCounterCollectionModule>(
            (module, o) =>
            {
                // Configure App Insights to collect gRPC counters gRPC
services hosted in an ASP.NET Core app
                module.Counters.Add(new
EventCounterCollectionRequest("Grpc.AspNetCore.Server", "current-calls"));
                module.Counters.Add(new
EventCounterCollectionRequest("Grpc.AspNetCore.Server", "total-calls"));
                module.Counters.Add(new
EventCounterCollectionRequest("Grpc.AspNetCore.Server", "calls-failed"));
            }
        );
    }
```

Security considerations in gRPC for ASP.NET Core

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

This article provides information on securing gRPC with .NET Core.

Transport security

gRPC messages are sent and received using HTTP/2. We recommend:

- Transport Layer Security (TLS) be used to secure messages in production gRPC apps.
- gRPC services should only listen and respond over secured ports.

TLS is configured in Kestrel. For more information on configuring Kestrel endpoints, see Kestrel endpoint configuration.

A TLS termination proxy can be combined with TLS. The benefits of using TLS termination should be considered against the security risks of sending unsecured HTTP requests between apps in the private network.

Exceptions

Exception messages are generally considered sensitive data that shouldn't be revealed to a client. By default, gRPC doesn't send the details of an exception thrown by a gRPC service to the client. Instead, the client receives a generic message indicating an error occurred. Exception message delivery to the client can be overridden (for example, in development or test) with EnableDetailedErrors. Exception messages shouldn't be exposed to the client in production apps.

Message size limits

Incoming messages to gRPC clients and services are loaded into memory. Message size limits are a mechanism to help prevent gRPC from consuming excessive resources.

gRPC uses per-message size limits to manage incoming and outgoing messages. By default, gRPC limits incoming messages to 4 MB. There is no limit on outgoing messages.

On the server, gRPC message limits can be configured for all services in an app with `AddGrpc`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc(options =>
    {
        options.MaxReceiveMessageSize = 1 * 1024 * 1024; // 1 MB
        options.MaxSendMessageSize = 1 * 1024 * 1024; // 1 MB
    });
}
```

Limits can also be configured for an individual service using `AddServiceOptions<TService>`. For more information on configuring message size limits, see gRPC configuration.

Client certificate validation

Client certificates are initially validated when the connection is established. By default, Kestrel doesn't perform additional validation of a connection's client certificate.

We recommend that gRPC services secured by client certificates use the Microsoft.AspNetCore.Authentication.Certificate package. ASP.NET Core certification authentication will perform additional validation on a client certificate, including:

- Certificate has a valid extended key use (EKU)
- Is within its validity period
- Check certificate revocation

Performance best practices with gRPC

Article • 10/04/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

gRPC is designed for high-performance services. This document explains how to get the best performance possible from gRPC.

Reuse gRPC channels

A gRPC channel should be reused when making gRPC calls. Reusing a channel allows calls to be multiplexed through an existing HTTP/2 connection.

If a new channel is created for each gRPC call then the amount of time it takes to complete can increase significantly. Each call will require multiple network round-trips between the client and the server to create a new HTTP/2 connection:

1. Opening a socket
2. Establishing TCP connection
3. Negotiating TLS
4. Starting HTTP/2 connection
5. Making the gRPC call

Channels are safe to share and reuse between gRPC calls:

- gRPC clients are created with channels. gRPC clients are lightweight objects and don't need to be cached or reused.
- Multiple gRPC clients can be created from a channel, including different types of clients.
- A channel and clients created from the channel can safely be used by multiple threads.
- Clients created from the channel can make multiple simultaneous calls.

gRPC client factory offers a centralized way to configure channels. It automatically reuses underlying channels. For more information, see gRPC client factory integration in .NET.

Connection concurrency

HTTP/2 connections typically have a limit on the number of maximum concurrent streams (active HTTP requests) on a connection at one time. By default, most servers set this limit to 100 concurrent streams.

A gRPC channel uses a single HTTP/2 connection, and concurrent calls are multiplexed on that connection. When the number of active calls reaches the connection stream limit, additional calls are queued in the client. Queued calls wait for active calls to complete before they are sent. Applications with high load, or long running streaming gRPC calls, could see performance issues caused by calls queuing because of this limit.

.NET 5 introduces the SocketsHttpHandler.EnableMultipleHttp2Connections property. When set to `true`, additional HTTP/2 connections are created by a channel when the concurrent stream limit is reached. When a `GrpcChannel` is created its internal `SocketsHttpHandler` is automatically configured to create additional HTTP/2 connections. If an app configures its own handler, consider setting `EnableMultipleHttp2Connections` to `true`:

C#

```
var channel = GrpcChannel.ForAddress("https://localhost", new
GrpcChannelOptions
{
    HttpHandler = new SocketsHttpHandler
    {
        EnableMultipleHttp2Connections = true,

        // ...configure other handler settings
    }
});
```

.NET Framework apps that make gRPC calls must be configured to use WinHttpHandler. .NET Framework apps can set the WinHttpHandler.EnableMultipleHttp2Connections property to `true` to create additional connections.

There are a couple of workarounds for .NET Core 3.1 apps:

- Create separate gRPC channels for areas of the app with high load. For example, the `Logger` gRPC service might have a high load. Use a separate channel to create

the `LoggerClient` in the app.

- Use a pool of gRPC channels, for example, create a list of gRPC channels. `Random` is used to pick a channel from the list each time a gRPC channel is needed. Using `Random` randomly distributes calls over multiple connections.

> **Important**
>
> Increasing the maximum concurrent stream limit on the server is another way to solve this problem. In Kestrel this is configured with MaxStreamsPerConnection.
>
> Increasing the maximum concurrent stream limit is not recommended. Too many streams on a single HTTP/2 connection introduces new performance issues:
>
> - Thread contention between streams trying to write to the connection.
> - Connection packet loss causes all calls to be blocked at the TCP layer.

`ServerGarbageCollection` in client apps

The .NET garbage collector has two modes: workstation garbage collection (GC) and server garbage collection. Each is each tuned for different workloads. ASP.NET Core apps use server GC by default.

Highly concurrent apps generally perform better with server GC. If a gRPC client app is sending and receiving a high number of gRPC calls at the same time, then there may be a performance benefit in updating the app to use server GC.

To enable server GC, set `<ServerGarbageCollection>` in the app's project file:

XML

```
<PropertyGroup>
  <ServerGarbageCollection>true</ServerGarbageCollection>
</PropertyGroup>
```

For more information about garbage collection, see Workstation and server garbage collection.

> **Note**
>
> ASP.NET Core apps use server GC by default. Enabling `<ServerGarbageCollection>` is only useful in non-server gRPC client apps, for example in a gRPC client console

app.

Load balancing

Some load balancers don't work effectively with gRPC. L4 (transport) load balancers operate at a connection level, by distributing TCP connections across endpoints. This approach works well for loading balancing API calls made with HTTP/1.1. Concurrent calls made with HTTP/1.1 are sent on different connections, allowing calls to be load balanced across endpoints.

Because L4 load balancers operate at a connection level, they don't work well with gRPC. gRPC uses HTTP/2, which multiplexes multiple calls on a single TCP connection. All gRPC calls over that connection go to one endpoint.

There are two options to effectively load balance gRPC:

- Client-side load balancing
- L7 (application) proxy load balancing

> ⓘ **Note**
>
> Only gRPC calls can be load balanced between endpoints. Once a streaming gRPC call is established, all messages sent over the stream go to one endpoint.

Client-side load balancing

With client-side load balancing, the client knows about endpoints. For each gRPC call, it selects a different endpoint to send the call to. Client-side load balancing is a good choice when latency is important. There's no proxy between the client and the service, so the call is sent to the service directly. The downside to client-side load balancing is that each client must keep track of the available endpoints that it should use.

Lookaside client load balancing is a technique where load balancing state is stored in a central location. Clients periodically query the central location for information to use when making load balancing decisions.

For more information, see gRPC client-side load balancing.

Proxy load balancing

An L7 (application) proxy works at a higher level than an L4 (transport) proxy. L7 proxies understand HTTP/2. The proxy receives gRPC calls multiplexed on one HTTP/2 connection and distributes them across multiple backend endpoints. Using a proxy is simpler than client-side load balancing, but adds extra latency to gRPC calls.

There are many L7 proxies available. Some options are:

- Envoy - A popular open source proxy.
- Linkerd - Service mesh for Kubernetes.
- YARP: Yet Another Reverse Proxy - An open source proxy written in .NET.

Inter-process communication

gRPC calls between a client and service are usually sent over TCP sockets. TCP is great for communicating across a network, but inter-process communication (IPC) is more efficient when the client and service are on the same machine.

Consider using a transport like Unix domain sockets or named pipes for gRPC calls between processes on the same machine. For more information, see Inter-process communication with gRPC.

Keep alive pings

Keep alive pings can be used to keep HTTP/2 connections alive during periods of inactivity. Having an existing HTTP/2 connection ready when an app resumes activity allows for the initial gRPC calls to be made quickly, without a delay caused by the connection being reestablished.

Keep alive pings are configured on SocketsHttpHandler:

C#

```
var handler = new SocketsHttpHandler
{
    PooledConnectionIdleTimeout = Timeout.InfiniteTimeSpan,
    KeepAlivePingDelay = TimeSpan.FromSeconds(60),
    KeepAlivePingTimeout = TimeSpan.FromSeconds(30),
    EnableMultipleHttp2Connections = true
};

var channel = GrpcChannel.ForAddress("https://localhost:5001", new
GrpcChannelOptions
{
```

```
    HttpHandler = handler
});
```

The preceding code configures a channel that sends a keep alive ping to the server every 60 seconds during periods of inactivity. The ping ensures the server and any proxies in use won't close the connection because of inactivity.

> ⓘ **Note**
>
> Keep alive pings only help keep the connection alive. Long-running gRPC calls on the connection may still be terminated by the server or intermediary proxies for inactivity.

Flow control

HTTP/2 flow control is a feature that prevents apps from being overwhelmed with data. When using flow control:

- Each HTTP/2 connection and request has an available buffer window. The buffer window is how much data the app can receive at once.
- Flow control activates if the buffer window is filled up. When activated, the sending app pauses sending more data.
- Once the receiving app has processed data, then space in the buffer window is available. The sending app resumes sending data.

Flow control can have a negative impact on performance when receiving large messages. If the buffer window is smaller than incoming message payloads or there's latency between the client and server, then data can be sent in start/stop bursts.

Flow control performance issues can be fixed by increasing buffer window size. In Kestrel, this is configured with InitialConnectionWindowSize and InitialStreamWindowSize at app startup:

C#

```
builder.WebHost.ConfigureKestrel(options =>
{
    var http2 = options.Limits.Http2;
    http2.InitialConnectionWindowSize = 1024 * 1024 * 2; // 2 MB
    http2.InitialStreamWindowSize = 1024 * 1024; // 1 MB
});
```

Recommendations:

- If a gRPC service often receives messages larger than 768 KB, Kestrel's default stream window size, then consider increasing the connection and stream window size.
- The connection window size should always be equal to or greater than the stream window size. A stream is part of the connection, and the sender is limited by both.

For more information about how flow control works, see HTTP/2 Flow Control (blog post).

> **Important**
>
> Increasing Kestrel's window size allows Kestrel to buffer more data on behalf of the app, which possibly increases memory usage. Avoid configuring an unnecessarily large window size.

Gracefully complete streaming calls

Try to complete streaming calls gracefully. Gracefully completing calls avoids unnecessary errors and allow servers to reuse internal data structures between requests.

A call is completed gracefully when the client and server have finished sending messages and the peer has read all the messages.

Client request stream:

1. The client has finished writing messages to the request stream and completes the stream with `call.RequestStream.CompleteAsync()`.
2. The server has read all messages from the request stream. Depending on how you're reading messages, either `requestStream.MoveNext()` returns `false` or `requestStream.ReadAllAsync()` has finished.

Server response stream:

1. The server has finished writing messages to the response stream and the server method has exited.
2. The client has read all messages from the response stream. Depending on how you're reading messages, either `call.ResponseStream.MoveNext()` returns `false` or `call.ResponseStream.ReadAllAsync()` has finished.

For an example of gracefully completing a bi-direction streaming call, see making a bi-directional streaming call.

Server streaming calls don't have a request stream. This means that the only way a client can communicate to the server that the stream should stop is by canceling it. If the overhead from canceled calls is impacting the app then consider changing the server streaming call to a bi-directional streaming call. In a bi-directional streaming call the client completing the request stream can be a signal to the server to end the call.

Dispose streaming calls

Always dispose streaming calls once they're no longer needed. The type returned when starting streaming calls implements `IDisposable`. Disposing a call once it is no longer needed ensures it is stopped and all resources are cleaned up.

In the following example, the using declaration on the `AccumulateCount()` call ensures it's always disposed if an unexpected error occurs.

C#

```
var client = new Counter.CounterClient(channel);
using var call = client.AccumulateCount();

for (var i = 0; i < 3; i++)
{
    await call.RequestStream.WriteAsync(new CounterRequest { Count = 1 });
}
await call.RequestStream.CompleteAsync();

var response = await call;
Console.WriteLine($"Count: {response.Count}");
// Count: 3
```

Ideally streaming calls should be completed gracefully. Disposing the call ensures the HTTP request between the client and the server is canceled if an unexpected error occurs. Streaming calls that are accidentally left running don't just leak memory and resources on the client, but are left running on the server as well. Many leaked streaming calls could impact the stability of the app.

Disposing of a streaming call that has already completed gracefully doesn't have any negative impact.

Replace unary calls with streaming

gRPC bidirectional streaming can be used to replace unary gRPC calls in high-performance scenarios. Once a bidirectional stream has started, streaming messages back and forth is faster than sending messages with multiple unary gRPC calls. Streamed

messages are sent as data on an existing HTTP/2 request and eliminates the overhead of creating a new HTTP/2 request for each unary call.

Example service:

C#

```
public override async Task SayHello(IAsyncStreamReader<HelloRequest>
requestStream,
    IServerStreamWriter<HelloReply> responseStream, ServerCallContext
context)
{
    await foreach (var request in requestStream.ReadAllAsync())
    {
        var helloReply = new HelloReply { Message = "Hello " + request.Name
};

        await responseStream.WriteAsync(helloReply);
    }
}
```

Example client:

C#

```
var client = new Greet.GreeterClient(channel);
using var call = client.SayHello();

Console.WriteLine("Type a name then press enter.");
while (true)
{
    var text = Console.ReadLine();

    // Send and receive messages over the stream
    await call.RequestStream.WriteAsync(new HelloRequest { Name = text });
    await call.ResponseStream.MoveNext();

    Console.WriteLine($"Greeting: {call.ResponseStream.Current.Message}");
}
```

Replacing unary calls with bidirectional streaming for performance reasons is an advanced technique and is not appropriate in many situations.

Using streaming calls is a good choice when:

1. High throughput or low latency is required.
2. gRPC and HTTP/2 are identified as a performance bottleneck.
3. A worker in the client is sending or receiving regular messages with a gRPC service.

Be aware of the additional complexity and limitations of using streaming calls instead of unary:

1. A stream can be interrupted by a service or connection error. Logic is required to restart stream if there is an error.
2. `RequestStream.WriteAsync` is not safe for multi-threading. Only one message can be written to a stream at a time. Sending messages from multiple threads over a single stream requires a producer/consumer queue like Channel<T> to marshall messages.
3. A gRPC streaming method is limited to receiving one type of message and sending one type of message. For example, `rpc StreamingCall(stream RequestMessage) returns (stream ResponseMessage)` receives `RequestMessage` and sends `ResponseMessage`. Protobuf's support for unknown or conditional messages using `Any` and `oneof` can work around this limitation.

Binary payloads

Binary payloads are supported in Protobuf with the `bytes` scalar value type. A generated property in C# uses `ByteString` as the property type.

ProtoBuf

```
syntax = "proto3";

message PayloadResponse {
    bytes data = 1;
}
```

Protobuf is a binary format that efficiently serializes large binary payloads with minimal overhead. Text based formats like JSON require encoding bytes to base64 and add 33% to the message size.

When working with large `ByteString` payloads there are some best practices to avoid unnecessary copies and allocations that are discussed below.

Send binary payloads

`ByteString` instances are normally created using `ByteString.CopyFrom(byte[] data)`. This method allocates a new `ByteString` and a new `byte[]`. Data is copied into the new byte array.

Additional allocations and copies can be avoided by using `UnsafeByteOperations.UnsafeWrap(ReadOnlyMemory<byte> bytes)` to create `ByteString` instances.

C#

```
var data = await File.ReadAllBytesAsync(path);

var payload = new PayloadResponse();
payload.Data = UnsafeByteOperations.UnsafeWrap(data);
```

Bytes are not copied with `UnsafeByteOperations.UnsafeWrap` so they must not be modified while the `ByteString` is in use.

`UnsafeByteOperations.UnsafeWrap` requires Google.Protobuf version 3.15.0 or later.

Read binary payloads

Data can be efficiently read from `ByteString` instances by using `ByteString.Memory` and `ByteString.Span` properties.

C#

```
var byteString = UnsafeByteOperations.UnsafeWrap(new byte[] { 0, 1, 2 });
var data = byteString.Span;

for (var i = 0; i < data.Length; i++)
{
    Console.WriteLine(data[i]);
}
```

These properties allow code to read data directly from a `ByteString` without allocations or copies.

Most .NET APIs have `ReadOnlyMemory<byte>` and `byte[]` overloads, so `ByteString.Memory` is the recommended way to use the underlying data. However, there are circumstances where an app might need to get the data as a byte array. If a byte array is required then the MemoryMarshal.TryGetArray method can be used to get an array from a `ByteString` without allocating a new copy of the data.

C#

```
var byteString = GetByteString();

ByteArrayContent content;
```

```
if (MemoryMarshal.TryGetArray(byteString.Memory, out var segment))
{
    // Success. Use the ByteString's underlying array.
    content = new ByteArrayContent(segment.Array, segment.Offset,
segment.Count);
}
else
{
    // TryGetArray didn't succeed. Fall back to creating a copy of the data
with ToByteArray.
    content = new ByteArrayContent(byteString.ToByteArray());
}

var httpRequest = new HttpRequestMessage();
httpRequest.Content = content;
```

The preceding code:

- Attempts to get an array from `ByteString.Memory` with MemoryMarshal.TryGetArray.
- Uses the `ArraySegment<byte>` if it was successfully retrieved. The segment has a reference to the array, offset and count.
- Otherwise, falls back to allocating a new array with `ByteString.ToByteArray()`.

gRPC services and large binary payloads

gRPC and Protobuf can send and receive large binary payloads. Although binary Protobuf is more efficient than text-based JSON at serializing binary payloads, there are still important performance characteristics to keep in mind when working with large binary payloads.

gRPC is a message-based RPC framework, which means:

- The entire message is loaded into memory before gRPC can send it.
- When the message is received, the entire message is deserialized into memory.

Binary payloads are allocated as a byte array. For example, a 10 MB binary payload allocates a 10 MB byte array. Messages with large binary payloads can allocate byte arrays on the large object heap. Large allocations impact server performance and scalability.

Advice for creating high-performance applications with large binary payloads:

- **Avoid** large binary payloads in gRPC messages. A byte array larger than 85,000 bytes is considered a large object. Keeping below that size avoids allocating on the large object heap.

- **Consider** splitting large binary payloads using gRPC streaming. Binary data is chunked and streamed over multiple messages. For more information on how to stream files, see examples in the grpc-dotnet repository:
  - gRPC streaming file download.
  - gRPC streaming file upload.
- **Consider** not using gRPC for large binary data. In ASP.NET Core, Web APIs can be used alongside gRPC services. An HTTP endpoint can access the request and response stream body directly:
  - Read the request body using minimal web API
  - Return stream response using minimal web API

gRPC and Native AOT

Article • 07/31/2024

By James Newton-King

gRPC supports .NET native ahead-of-time (AOT) in .NET 8. Native AOT enables publishing gRPC client and server apps as small, fast native executables.

> ⚠ **Warning**
>
> In .NET 8, not all ASP.NET Core features are compatible with Native AOT. For more information, see ASP.NET Core and Native AOT compatibility.

Get started

AOT compilation happens when the app is published. Native AOT is enabled with the `PublishAot` option.

1. Add `<PublishAot>true</PublishAot>` to the gRPC client or server app's project file. This will enable Native AOT compilation during publish and enable dynamic code usage analysis during build and editing.

   XML

   ```xml
   <Project Sdk="Microsoft.NET.Sdk.Web">

     <PropertyGroup>
       <TargetFramework>net8.0</TargetFramework>
       <PublishAot>true</PublishAot>
     </PropertyGroup>

     <ItemGroup>
       <PackageReference Include="Grpc.AspNetCore" Version="2.51.0" />
       <PackageReference Include="Google.Protobuf" Version="3.22.0" />
     </ItemGroup>

   </Project>
   ```

   Native AOT can also be enabled by specifying the `-aot` option with the ASP.NET Core gRPC template:

   .NET CLI

```
dotnet new grpc -aot
```

2. Publish the app for a specific runtime identifier (RID) using `dotnet publish -r <RID>`.

The app is available in the publish directory and contains all the code needed to run in it.

Native AOT analysis includes all of the app's code and the libraries the app depends on. Review Native AOT warnings and take corrective steps. It's a good idea to test publishing apps frequently to discover issues early in the development lifecycle.

Optimize publish size

A Native AOT executable contains just the code from external dependencies required to support the app. Unused code is automatically trimmed away.

The publish size of an ASP.NET Core gRPC service can be optimized by creating the host builder with `WebApplication.CreateSlimBuilder()`. This builder provides a minimal list of features required to run an ASP.NET Core app.

C#

```
var builder = WebApplication.CreateSlimBuilder(args);
builder.Services.AddGrpc();

var app = builder.Build();
app.MapGrpcService<GreeterService>();
app.Run();
```

Benefits of using Native AOT

Apps published with Native AOT have:

- Minimized disk footprint
- Reduced startup time
- Reduce memory demand

For more information and examples of the benefits that Native AOT provides, see Benefits of using Native AOT with ASP.NET Core.

Additional resources

- ASP.NET Core support for Native AOT
- Native AOT deployment

Inter-process communication with gRPC

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Processes running on the same machine can be designed to communicate with each other. Operating systems provide technologies for enabling fast and efficient inter-process communication (IPC). Popular examples of IPC technologies are Unix domain sockets and Named pipes.

.NET provides support for inter-process communication using gRPC.

Built-in support for Named pipes in ASP.NET Core requires .NET 8 or later.

Get started

IPC calls are sent from a client to a server. To communicate between apps on a machine with gRPC, at least one app must host an ASP.NET Core gRPC server.

An ASP.NET Core gRPC server is usually created from the gRPC template. The project file created by the template uses `Microsoft.NET.SDK.Web` as the SDK:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Web">

  <ItemGroup>
    <PackageReference Include="Grpc.AspNetCore" Version="2.47.0" />
    <Protobuf Include="Protos\greet.proto" GrpcServices="Server" />
  </ItemGroup>

</Project>
```

The `Microsoft.NET.SDK.Web` SDK value automatically adds a reference to the ASP.NET Core framework. The reference allows the app to use ASP.NET Core types required to host a server.

It's also possible to add a server to existing non-ASP.NET Core projects, such as Windows Services, WPF apps, or WinForms apps. See Host gRPC in non-ASP.NET Core projects for more information.

Inter-process communication (IPC) transports

gRPC calls between a client and server on different machines are usually sent over TCP sockets. TCP is a good choice for communicating across a network or the Internet. However, IPC transports offer advantages when communicating between processes on the same machine:

- Less overhead and faster transfer speeds.
- Integration with OS security features.
- Doesn't use TCP ports, which are a limited resource.

.NET supports multiple IPC transports:

- Unix domain sockets (UDS) is a widely supported IPC technology. UDS is the best choice for building cross-platform apps, and it's usable on Linux, macOS, and Windows 10/Windows Server 2019 or later.
- Named pipes are supported by all versions of Windows. Named pipes integrate well with Windows security, which can control client access to the pipe.
- Additional IPC transports by implementing IConnectionListenerFactory and registering the implementation at app startup.

Depending on the OS, cross-platform apps may choose different IPC transports. An app can check the OS on startup and choose the desired transport for that platform:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    if (OperatingSystem.IsWindows())
    {
        serverOptions.ListenNamedPipe("MyPipeName");
    }
    else
    {
        var socketPath = Path.Combine(Path.GetTempPath(), "socket.tmp");
        serverOptions.ListenUnixSocket(socketPath);
    }

    serverOptions.ConfigureEndpointDefaults(listenOptions =>
    {
        listenOptions.Protocols = HttpProtocols.Http2;
```

```
    });
});
```

Security considerations

IPC apps send and receive RPC calls. External communication is a potential attack vector for IPC apps and must be properly secured.

Secure IPC server app against unexpected callers

The IPC server app hosts RPC services for other apps to call. Incoming callers should be authenticated to prevent untrusted clients from making RPC calls to the server.

Transport security is one option for securing a server. IPC transports, such as Unix domain sockets and named pipes, support limiting access based on operating system permissions:

- Named pipes supports securing a pipe with the Windows access control model. Access rights can be configured in .NET when a server is started using the PipeSecurity class.
- Unix domain sockets support securing a socket with file permissions.

Another option for securing an IPC server is to use authentication and authorization built into ASP.NET Core. For example, the server could be configured to require certificate authentication. RPC calls made by client apps without the required certificate fail with an unauthorized response.

Validate the server in the IPC client app

It's important for the client app to validate the identity of the server it is calling. Validation is necessary to protect against a malicious actor from stopping the trusted server, running their own, and accepting incoming data from clients.

Named pipes provides support for getting the account that a server is running under. A client can validate the server was launched by the expected account:

cs

```
internal static bool CheckPipeConnectionOwnership(
    NamedPipeClientStream pipeStream, SecurityIdentifier expectedOwner)
{
    var remotePipeSecurity = pipeStream.GetAccessControl();
    var remoteOwner =
```

```
remotePipeSecurity.GetOwner(typeof(SecurityIdentifier));
    return expectedOwner.Equals(remoteOwner);
}
```

Another option for validating the server is to secure its endpoints with HTTPS inside ASP.NET Core. The client can configure `SocketsHttpHandler` to validate the server is using the expected certificate when the connection is established.

cs

```
var socketsHttpHandler = new SocketsHttpHandler()
{
    SslOptions = new SslOptions()
    {
        RemoteCertificateValidationCallback = (sender, certificate, chain,
sslPolicyErrors) =>
        {
            if (sslPolicyErrors != SslPolicyErrors.None)
            {
                return false;
            }

            // Validate server cert thumbprint matches the expected
thumbprint.
        }
    }
};
```

Protect against named pipe privilege escalation

Named pipes supports a feature called impersonation. Using impersonation, the named pipes server can execute code with the privileges of the client user. This is a powerful feature but can allow a low-privilege server to impersonate a high-privilege caller and then run malicious code.

Client's can protect against this attack by not allowing impersonation when connecting to a server. Unless required by a server, a TokenImpersonationLevel value of `None` or `Anonymous` should be used when creating a client connection:

cs

```
using var pipeClient = new NamedPipeClientStream(
    serverName: ".", pipeName: "testpipe", PipeDirection.In,
PipeOptions.None, TokenImpersonationLevel.None);
await pipeClient.ConnectAsync();
```

`TokenImpersonationLevel.None` is the default value in `NamedPipeClientStream` constructors that don't have an `impersonationLevel` parameter.

Configure client and server

The client and server must be configured to use an inter-process communication (IPC) transport. For more information about configuring Kestrel and SocketsHttpHandler to use IPC:

- Inter-process communication with gRPC and Unix domain sockets
- Inter-process communication with gRPC and Named pipes

> **Note**
>
> Built-in support for Named pipes in ASP.NET Core requires .NET 8 or later.

Inter-process communication with gRPC and Unix domain sockets

Article • 07/31/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

.NET supports inter-process communication (IPC) using gRPC. For more information about getting started with using gRPC to communicate between processes, see Inter-process communication with gRPC.

Unix domain sockets (UDS) is a widely supported IPC transport that's more efficient than TCP when the client and server are on the same machine. This article discusses how to configure gRPC communication over UDS.

Prerequisites

- .NET 5 or later
- Linux, macOS, or Windows 10/Windows Server 2019 or later

Server configuration

Unix domain sockets are supported by Kestrel, which is configured in `Program.cs`:

C#

```
var socketPath = Path.Combine(Path.GetTempPath(), "socket.tmp");

var builder = WebApplication.CreateBuilder(args);
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ListenUnixSocket(socketPath, listenOptions =>
    {
        listenOptions.Protocols = HttpProtocols.Http2;
```

```
    });
});
```

The preceding example:

- Configures Kestrel's endpoints in ConfigureKestrel.
- Calls ListenUnixSocket to listen to a UDS with the specified path.
- Creates a UDS endpoint that isn't configured to use HTTPS. For information about enabling HTTPS, see Kestrel HTTPS endpoint configuration.

Client configuration

`GrpcChannel` supports making gRPC calls over custom transports. When a channel is created, it can be configured with a SocketsHttpHandler that has a custom ConnectCallback. The callback allows the client to make connections over custom transports and then send HTTP requests over that transport.

> **Note**
>
> Some connectivity features of `GrpcChannel`, such as client side load balancing and channel status, can't be used together with Unix domain sockets.

Unix domain sockets connection factory example:

C#

```
public class UnixDomainSocketsConnectionFactory
{
    private readonly EndPoint endPoint;

    public UnixDomainSocketsConnectionFactory(EndPoint endPoint)
    {
        this.endPoint = endPoint;
    }

    public async ValueTask<Stream> ConnectAsync(SocketsHttpConnectionContext
_,
        CancellationToken cancellationToken = default)
    {
        var socket = new Socket(AddressFamily.Unix, SocketType.Stream,
ProtocolType.Unspecified);

        try
        {
            await socket.ConnectAsync(this.endPoint,
cancellationToken).ConfigureAwait(false);
```

```
            return new NetworkStream(socket, true);
        }
        catch
        {
            socket.Dispose();
            throw;
        }
    }
}
```

Using the custom connection factory to create a channel:

C#

```
public static readonly string SocketPath = Path.Combine(Path.GetTempPath(),
"socket.tmp");

public static GrpcChannel CreateChannel()
{
    var udsEndPoint = new UnixDomainSocketEndPoint(SocketPath);
    var connectionFactory = new
UnixDomainSocketsConnectionFactory(udsEndPoint);
    var socketsHttpHandler = new SocketsHttpHandler
    {
        ConnectCallback = connectionFactory.ConnectAsync
    };

    return GrpcChannel.ForAddress("http://localhost", new GrpcChannelOptions
    {
        HttpHandler = socketsHttpHandler
    });
}
```

Channels created using the preceding code send gRPC calls over Unix domain sockets.

Inter-process communication with gRPC and Named pipes

Article • 07/31/2024

By James Newton-King

.NET supports inter-process communication (IPC) using gRPC. For more information about getting started with using gRPC to communicate between processes, see Inter-process communication with gRPC.

Named pipes is an IPC transport that is supported on all versions of Windows. Named pipes integrate well with Windows security to control client access to the pipe. This article discusses how to configure gRPC communication over named pipes.

Prerequisites

- .NET 8 or later
- Windows

Server configuration

Named pipes are supported by Kestrel, which is configured in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ListenNamedPipe("MyPipeName", listenOptions =>
    {
        listenOptions.Protocols = HttpProtocols.Http2;
    });
});
```

The preceding example:

- Configures Kestrel's endpoints in ConfigureKestrel.
- Calls `ListenNamedPipe` to listen to a named pipe with the specified name.
- Creates a named pipe endpoint that isn't configured to use HTTPS. For information about enabling HTTPS, see Kestrel HTTPS endpoint configuration.

Client configuration

`GrpcChannel` supports making gRPC calls over custom transports. When a channel is created, it can be configured with a SocketsHttpHandler that has a custom ConnectCallback. The callback allows the client to make connections over custom transports and then send HTTP requests over that transport.

> **Note**
>
> Some connectivity features of `GrpcChannel`, such as client side load balancing and channel status, can't be used together with named pipes.

Named pipes connection factory example:

C#

```
public class NamedPipesConnectionFactory
{
    private readonly string pipeName;

    public NamedPipesConnectionFactory(string pipeName)
    {
        this.pipeName = pipeName;
    }

    public async ValueTask<Stream> ConnectAsync(SocketsHttpConnectionContext
_,
        CancellationToken cancellationToken = default)
    {
        var clientStream = new NamedPipeClientStream(
            serverName: ".",
            pipeName: this.pipeName,
            direction: PipeDirection.InOut,
            options: PipeOptions.WriteThrough | PipeOptions.Asynchronous,
            impersonationLevel: TokenImpersonationLevel.Anonymous);

        try
        {
            await
clientStream.ConnectAsync(cancellationToken).ConfigureAwait(false);
            return clientStream;
        }
        catch
        {
            clientStream.Dispose();
            throw;
        }
```

```
    }
}
```

Using the custom connection factory to create a channel:

C#

```
public static GrpcChannel CreateChannel()
{
    var connectionFactory = new NamedPipesConnectionFactory("MyPipeName");
    var socketsHttpHandler = new SocketsHttpHandler
    {
        ConnectCallback = connectionFactory.ConnectAsync
    };

    return GrpcChannel.ForAddress("http://localhost", new GrpcChannelOptions
    {
        HttpHandler = socketsHttpHandler
    });
}
```

Channels created using the preceding code send gRPC calls over named pipes.

Code-first gRPC services and clients with .NET

Article • 11/05/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King and Marc Gravell

Code-first gRPC uses .NET types to define service and message contracts.

Code-first is a good choice when an entire system uses .NET:

- .NET service and data contract types can be shared between the .NET server and clients.
- Avoids the need to define contracts in `.proto` files and code generation.

Code-first isn't recommended in polyglot systems with multiple languages. .NET service and data contract types can't be used with non-.NET platforms. To call a gRPC service written using code-first, other platforms must create a `.proto` contract that matches the service.

protobuf-net.Grpc

> **Important**
>
> For help with protobuf-net.Grpc, visit the protobuf-net.Grpc website or create an issue on the protobuf-net.Grpc GitHub repository.

protobuf-net.Grpc is a community project and isn't supported by Microsoft. It adds code-first support to `Grpc.AspNetCore` and `Grpc.Net.Client`. It uses .NET types annotated with attributes to define an app's gRPC services and messages.

The first step to creating a code-first gRPC service is defining the code contract:

- Create a new project that will be shared by the server and client.
- Add a protobuf-net.Grpc package reference.
- Create service and data contract types.

C#

```
using ProtoBuf.Grpc;
using System.Runtime.Serialization;
using System.ServiceModel;
using System.Threading.Tasks;

namespace Shared.Contracts;

[DataContract]
public class HelloReply
{
    [DataMember(Order = 1)]
    public string Message { get; set; }
}

[DataContract]
public class HelloRequest
{
    [DataMember(Order = 1)]
    public string Name { get; set; }
}

[ServiceContract]
public interface IGreeterService
{
    [OperationContract]
    Task<HelloReply> SayHelloAsync(HelloRequest request,
        CallContext context = default);
}
```

The preceding code:

- Defines `HelloRequest` and `HelloReply` messages.
- Defines the `IGreeterService` contract interface with the unary `SayHelloAsync` gRPC method.

The service contract is implemented on the server and called from the client.

Methods defined on service interfaces must match certain signatures depending on whether they're:

- Unary
- Server streaming
- Client streaming

- Bidirectional streaming

For more information on defining service contracts, see the protobuf-net.Grpc getting started documentation.

Create a code-first gRPC service

To add gRPC code-first service to an ASP.NET Core app:

- Add a protobuf-net.Grpc.AspNetCore package reference.
- Add a reference to the shared code-contract project.

```xml
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>net6.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="protobuf-net.Grpc.AspNetCore"
Version="1.0.152" />
  </ItemGroup>

  <ItemGroup>
      <ProjectReference Include="..\Shared\Shared.Contracts.csproj" />
  </ItemGroup>

</Project>
```

- Create a new `GreeterService.cs` file and implement the `IGreeterService` service interface:

```csharp
using Shared.Contracts;
using ProtoBuf.Grpc;

public class GreeterService : IGreeterService
{
    public Task<HelloReply> SayHelloAsync(HelloRequest request,
CallContext context = default)
    {
        return Task.FromResult(
                new HelloReply
```

```
                {
                    Message = $"Hello {request.Name}"
                });
    }
}
```

- Update the `Program.cs` file:

```C#
using ProtoBuf.Grpc.Server;

var builder = WebApplication.CreateBuilder(args);

// Additional configuration is required to successfully run gRPC on
macOS.
// For instructions on how to configure Kestrel and gRPC clients on
macOS, visit https://go.microsoft.com/fwlink/?linkid=2099682

// Add services to the container.
builder.Services.AddCodeFirstGrpc();

var app = builder.Build();

// Configure the HTTP request pipeline.
app.MapGrpcService<GreeterService>();
app.MapGet("/", () => "Communication with gRPC endpoints must be made
through a gRPC client. To learn how to create a client, visit:
https://go.microsoft.com/fwlink/?linkid=2086909");

app.Run();
```

  The preceding highlighted code updates the following:
  - `AddCodeFirstGrpc` registers services that enable code-first.
  - `MapGrpcService<GreeterService>` adds the code-first service endpoint.

gRPC services implemented with code-first and `.proto` files can co-exist in the same app. All gRPC services use gRPC service configuration.

Create a code-first gRPC client

A code-first gRPC client uses the service contract to call gRPC services.

- In the gRPC client `.csproj` file:
  - Add a protobuf-net.Grpc package reference.
  - Add a Grpc.Net.Client package reference.
  - Add a reference to the shared code-contract project.

XML

```xml
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <OutputType>Exe</OutputType>
    <TargetFramework>net6.0</TargetFramework>
    <ImplicitUsings>enable</ImplicitUsings>
    <Nullable>enable</Nullable>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Grpc.Net.Client" Version="2.52.0" />
    <PackageReference Include="protobuf-net.Grpc" Version="1.0.152" />
  </ItemGroup>

  <ItemGroup>
    <ProjectReference Include="..\Shared\Shared.Contracts.csproj" />
  </ItemGroup>

</Project>
```

- Update the client `program.cs`

C#

```csharp
// See https://aka.ms/new-console-template for more information
using Grpc.Net.Client;
using ProtoBuf.Grpc.Client;
using Shared.Contracts;

namespace GrpcGreeterClient;

internal class Program
{
    private static async Task Main(string[] args)
    {
        using var channel =
GrpcChannel.ForAddress("https://localhost:7184");
        var client = channel.CreateGrpcService<IGreeterService>();

        var reply = await client.SayHelloAsync(
            new HelloRequest { Name = "GreeterClient" });

        Console.WriteLine($"Greeting: {reply.Message}");
        Console.WriteLine("Press any key to exit...");
        Console.ReadKey();
    }
}
```

The preceding gRPC client `Program.cs` code:

- Creates a gRPC channel.
- Creates a code-first client from the channel with the `CreateGrpcService<IGreeterService>` extension method.
- Calls the gRPC service with `SayHelloAsync`.

A code-first gRPC client is created from a channel. Just like a regular client, a code-first client uses its channel configuration.

gRPC health checks in ASP.NET Core

Article • 08/28/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

The gRPC health checking protocol is a standard for reporting the health of gRPC server apps.

Health checks are exposed by an app as a gRPC service. They're typically used with an external monitoring service to check the status of an app. The service can be configured for various real-time monitoring scenarios:

- Health probes can be used by container orchestrators and load balancers to check an app's status. For example, Kubernetes supports gRPC liveness, readiness and startup probes. Kubernetes can be configured to reroute traffic or restart unhealthy containers based on gRPC health check results.
- Use of memory, disk, and other physical server resources can be monitored for healthy status.
- Health checks can test an app's dependencies, such as databases and external service endpoints, to confirm availability and normal functioning.

Set up gRPC health checks

gRPC ASP.NET Core has built-in support for gRPC health checks with the Grpc.AspNetCore.HealthChecks package. Results from .NET health checks are reported to callers.

To set up gRPC health checks in an app:

- Add a `Grpc.AspNetCore.HealthChecks` package reference.
- Register gRPC health checks service:
  - `AddGrpcHealthChecks` to register services that enable health checks.
  - `MapGrpcHealthChecksService` to add a health checks service endpoint.

- Add health checks by implementing IHealthCheck or using the AddCheck method.

C#

```
using GrpcServiceHC.Services;
using Microsoft.Extensions.Diagnostics.HealthChecks;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddGrpc();
builder.Services.AddGrpcHealthChecks()
                .AddCheck("Sample", () => HealthCheckResult.Healthy());

var app = builder.Build();

app.MapGrpcService<GreeterService>();
app.MapGrpcHealthChecksService();

// Code removed for brevity.
```

When health checks is set up:

- The health checks service is added to the server app.
- .NET health checks registered with the app are periodically executed for health results. By default, there's a 5-second delay after app startup, and then health checks are executed every 30 seconds. Health check execution interval can be customized with HealthCheckPublisherOptions.
- Health results determine what the gRPC service reports:
  - `Unknown` is reported when there are no health results.
  - `NotServing` is reported when there are any health results of HealthStatus.Unhealthy.
  - Otherwise, `Serving` is reported.

Health checks service security

gRPC health checks returns health status about an app, which could be sensitive information. Care should be taken to limit access to the gRPC health checks service.

Access to the service can be controlled through standard ASP.NET Core authorization extension methods, such as AllowAnonymous and RequireAuthorization.

For example, if an app has been configured to require authorization by default, configure the gRPC health checks endpoint with `AllowAnonymous` to skip authentication and authorization.

C#

```
app.MapGrpcHealthChecksService().AllowAnonymous();
```

Configure `Grpc.AspNetCore.HealthChecks`

By default, the gRPC health checks service uses all registered health checks to determine health status. gRPC health checks can be customized when registered to use a subset of health checks. The `MapService` method is used to map health results to service names, along with a predicate for filtering health results:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddGrpc();
builder.Services.AddGrpcHealthChecks(o =>
{
    o.Services.MapService("", r => r.Tags.Contains("public"));
});

var app = builder.Build();
```

The preceding code overrides the default service (`""`) to only use health results with the "public" tag.

gRPC health checks supports the client specifying a service name argument when checking health. Multiple services are supported by providing a service name to `MapService`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddGrpc();
builder.Services.AddGrpcHealthChecks(o =>
{
    o.Services.MapService("greet.Greeter", r => r.Tags.Contains("greeter"));
    o.Services.MapService("count.Counter", r => r.Tags.Contains("counter"));
});

var app = builder.Build();
```

The service name specified by the client is usually the default (`""`) or a package-qualified name of a service in your app. However, nothing prevents the client using arbitrary values to check app health.

Configure health checks execution interval

Health checks are run immediately when `Check` is called. `Watch` is a streaming method and has a different behavior than `Check`: The long running stream reports health checks results over time by periodically executing IHealthCheckPublisher to gather health results. By default, the publisher:

- Waits 5 seconds after app startup before running health checks.
- Runs health checks every 30 seconds.

Publisher intervals can be configured using HealthCheckPublisherOptions at startup:

C#

```
builder.Services.Configure<HealthCheckPublisherOptions>(options =>
{
    options.Delay = TimeSpan.Zero;
    options.Period = TimeSpan.FromSeconds(10);
});
```

Call gRPC health checks service

The Grpc.HealthCheck package includes a client for gRPC health checks:

C#

```
var channel = GrpcChannel.ForAddress("https://localhost:5001");
var client = new Health.HealthClient(channel);

var response = await client.CheckAsync(new HealthCheckRequest());
var status = response.Status;
```

There are two methods on the `Health` service:

- `Check` is a unary method for getting the current health status. Health checks are executed immediately when `Check` is called. The server returns a `NOT_FOUND` error response if the client requests an unknown service name. This can happen at app startup if health results haven't been published yet.
- `Watch` is a streaming method that reports changes in health status over time. IHealthCheckPublisher is periodically executed to gather health results. The server returns an `Unknown` status if the client requests an unknown service name.

The `Grpc.HealthCheck` client can be used in a client factory approach:

C#

```
builder.Services
    .AddGrpcClient<Health.HealthClient>(o =>
    {
        o.Address = new Uri("https://localhost:5001");
    });
```

In the previous example, a client factory for `Health.HealthClient` instances is registered with the dependency injection system. Then, these instances are injected into services for executing health check calls.

For more information, see gRPC client factory integration in .NET.

Manage Protobuf references with dotnet-grpc

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

`dotnet-grpc` is a .NET Core Global Tool for managing Protobuf (.proto) references within a .NET gRPC project. The tool can be used to add, refresh, remove, and list Protobuf references.

Installation

To install the `dotnet-grpc` .NET Core Global Tool, run the following command:

.NET CLI

```
dotnet tool install -g dotnet-grpc
```

> **Note**
>
> By default the architecture of the .NET binaries to install represents the currently running OS architecture. To specify a different OS architecture, see dotnet tool install, --arch option. For more information, see GitHub issue dotnet/AspNetCore.Docs #29262.

Add references

`dotnet-grpc` can be used to add Protobuf references as `<Protobuf />` items to the `.csproj` file:

XML

```
<Protobuf Include="Protos\greet.proto" GrpcServices="Server" />
```

The Protobuf references are used to generate the C# client and/or server assets. The `dotnet-grpc` tool can:

- Create a Protobuf reference from local files on disk.
- Create a Protobuf reference from a remote file specified by a URL.
- Ensure the correct gRPC package dependencies are added to the project.

For example, the `Grpc.AspNetCore` package is added to a web app. `Grpc.AspNetCore` contains gRPC server and client libraries and tooling support. Alternatively, the `Grpc.Net.Client`, `Grpc.Tools` and `Google.Protobuf` packages, which contain only the gRPC client libraries and tooling support, are added to a Console app.

Add file

The `add-file` command is used to add local files on disk as Protobuf references. The file paths provided:

- Can be relative to the current directory or absolute paths.
- May contain wild cards for pattern-based file globbing.

If any files are outside the project directory, a `Link` element is added to display the file under the folder `Protos` in Visual Studio.

Usage

.NET CLI

```
dotnet-grpc add-file [options] <files>...
```

Arguments

Expand table

Argument	Description
files	The protobuf file references. These can be a path to glob for local protobuf files.

Options

Expand table

Short option	Long option	Description
-p	--project	The path to the project file to operate on. If a file is not specified, the command searches the current directory for one.
-s	--services	The type of gRPC services that should be generated. If `Default` is specified, `Both` is used for Web projects and `Client` is used for non-Web projects. Accepted values are `Both`, `Client`, `Default`, `None`, `Server`.
-i	--additional-import-dirs	Additional directories to be used when resolving imports for the protobuf files. This is a semicolon separated list of paths.
	--access	The access modifier to use for the generated C# classes. The default value is `Public`. Accepted values are `Internal` and `Public`.

Add URL

The `add-url` command is used to add a remote file specified by an source URL as Protobuf reference. A file path must be provided to specify where to download the remote file. The file path can be relative to the current directory or an absolute path. If the file path is outside the project directory, a `Link` element is added to display the file under the virtual folder `Protos` in Visual Studio.

Usage

.NET CLI

```
dotnet-grpc add-url [options] <url>
```

Arguments

Expand table

Argument	Description
url	The URL to a remote protobuf file.

Options

Expand table

Short option	Long option	Description
-o	--output	Specifies the download path for the remote protobuf file. This is a required option.
-p	--project	The path to the project file to operate on. If a file is not specified, the command searches the current directory for one.
-s	--services	The type of gRPC services that should be generated. If `Default` is specified, `Both` is used for Web projects and `Client` is used for non-Web projects. Accepted values are `Both`, `Client`, `Default`, `None`, `Server`.
-i	--additional-import-dirs	Additional directories to be used when resolving imports for the protobuf files. This is a semicolon separated list of paths.
	--access	The access modifier to use for the generated C# classes. Default value is `Public`. Accepted values are `Internal` and `Public`.

Remove

The `remove` command is used to remove Protobuf references from the `.csproj` file. The command accepts path arguments and source URLs as arguments. The tool:

- Only removes the Protobuf reference.
- Does not delete the `.proto` file, even if it was originally downloaded from a remote URL.

Usage

.NET CLI

```
dotnet-grpc remove [options] <references>...
```

Arguments

Expand table

Argument	Description
references	The URLs or file paths of the protobuf references to remove.

Options

Expand table

Short option	Long option	Description
-p	--project	The path to the project file to operate on. If a file is not specified, the command searches the current directory for one.

Refresh

The `refresh` command is used to update a remote reference with the latest content from the source URL. Both the download file path and the source URL can be used to specify the reference to be updated. Note:

- The hashes of the file contents are compared to determine whether the local file should be updated.
- No timestamp information is compared.

The tool always replaces the local file with the remote file if an update is needed.

Usage

.NET CLI

```
dotnet-grpc refresh [options] [<references>...]
```

Arguments

Expand table

Argument	Description
references	The URLs or file paths to remote protobuf references that should be updated. Leave this argument empty to refresh all remote references.

Options

Expand table

Short option	Long option	Description
-p	--project	The path to the project file to operate on. If a file is not specified, the command searches the current directory for one.
	--dry-run	Outputs a list of files that would be updated without downloading any new content.

List

The `list` command is used to display all the Protobuf references in the project file. If all values of a column are default values, the column may be omitted.

Usage

.NET CLI

```
dotnet-grpc list [options]
```

Options

Expand table

Short option	Long option	Description
-p	--project	The path to the project file to operate on. If a file is not specified, the command searches the current directory for one.

Test gRPC services with gRPCurl and gRPCui in ASP.NET Core

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

Tooling is available for gRPC that allows developers to test services without building client apps:

- gRPCurl is an open-source command-line tool that provides interaction with gRPC services.
- gRPCui builds on top of gRPCurl and adds an open-source interactive web UI for gRPC.

This article discusses how to:

- Set up gRPC server reflection with a gRPC ASP.NET Core app.
- Interact with gRPC using test tools:
  - Discover and test gRPC services with `grpcurl`.
  - Interact with gRPC services via a browser using `grpcui`.

> **Note**
>
> To learn how to unit test gRPC services, see Test gRPC services in ASP.NET Core.

Set up gRPC reflection

Tooling must know the Protobuf contract of services before it can call them. There are two ways to do this:

- Set up gRPC reflection on the server. Tools, such as gRPCurl, use reflection to automatically discover service contracts.
- Add `.proto` files to the tool manually.

It's easier to use gRPC reflection. gRPC reflection adds a new gRPC service to the app that clients can call to discover services.

gRPC ASP.NET Core has built-in support for gRPC reflection with the Grpc.AspNetCore.Server.Reflection package. To configure reflection in an app:

- Add a `Grpc.AspNetCore.Server.Reflection` package reference.
- Register reflection in `Program.cs`:
  - `AddGrpcReflection` to register services that enable reflection.
  - `MapGrpcReflectionService` to add a reflection service endpoint.

C#

```
builder.Services.AddGrpc();
builder.Services.AddGrpcReflection();

var app = builder.Build();

app.MapGrpcService<GreeterService>();

IWebHostEnvironment env = app.Environment;

if (env.IsDevelopment())
{
    app.MapGrpcReflectionService();
}
```

When gRPC reflection is set up:

- A gRPC reflection service is added to the server app.
- Client apps that support gRPC reflection can call the reflection service to discover services hosted by the server.
- gRPC services are still called from the client. Reflection only enables service discovery and doesn't bypass server-side security. Endpoints protected by authentication and authorization require the caller to pass credentials for the endpoint to be called successfully.

Reflection service security

gRPC reflection returns a list of available APIs, which could contain sensitive information. Care should be taken to limit access to the gRPC reflection service.

gRPC reflection is usually only required in a local development environment. For local development, the reflection service should only be mapped when IsDevelopment returns true:

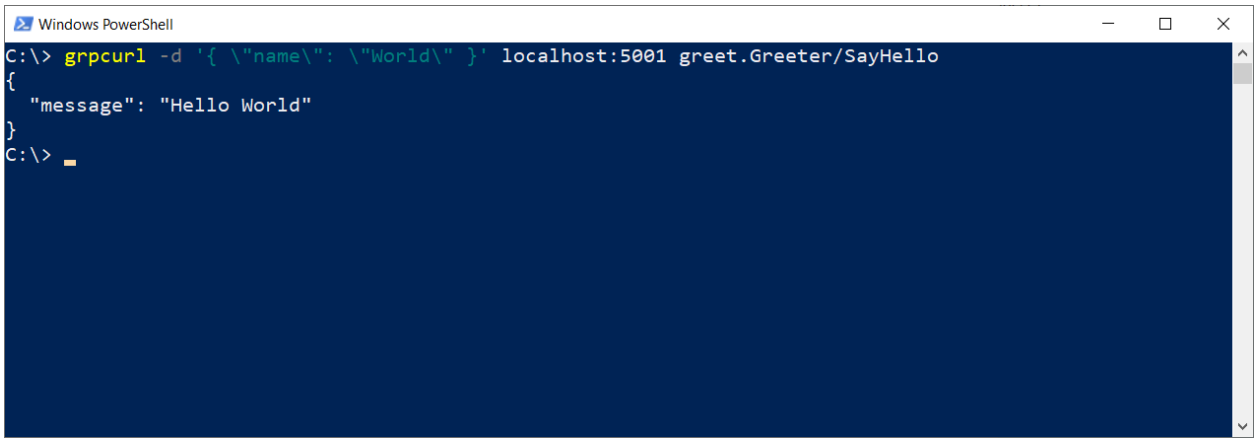
```
C#

if (env.IsDevelopment())
{
    app.MapGrpcReflectionService();
}
```

Access to the service can be controlled through standard ASP.NET Core authorization extension methods, such as AllowAnonymous and RequireAuthorization.

For example, if an app has been configured to require authorization by default, configuration the gRPC reflection endpoint with `AllowAnonymous` to skip authentication and authorization.

```
C#



if (env.IsDevelopment())
{
    app.MapGrpcReflectionService().AllowAnonymous();
}
```

gRPCurl

gRPCurl is a command-line tool created by the gRPC community. Its features include:

- Calling gRPC services, including streaming services.
- Service discovery using gRPC reflection.
- Listing and describing gRPC services.
- Works with secure (TLS) and insecure (plain-text) servers.

For information about downloading and installing `grpcurl`, see the gRPCurl GitHub homepage.

Use `grpcurl`

The `-help` argument explains `grpcurl` command-line options:

Console

```
$ grpcurl -help
```

Discover services

Use the `describe` verb to view the services defined by the server. Specify `<port>` as the localhost port number of the gRPC server. The port number is randomly assigned when the project is created and set in `Properties/launchSettings.json`:

Console

```
$ grpcurl localhost:<port> describe
greet.Greeter is a service:
service Greeter {
  rpc SayHello ( .greet.HelloRequest ) returns ( .greet.HelloReply );
  rpc SayHellos ( .greet.HelloRequest ) returns ( stream .greet.HelloReply
);
}
grpc.reflection.v1alpha.ServerReflection is a service:
service ServerReflection {
  rpc ServerReflectionInfo ( stream
.grpc.reflection.v1alpha.ServerReflectionRequest ) returns ( stream
.grpc.reflection.v1alpha.ServerReflectionResponse );
}
```

The preceding example:

- Runs the `describe` verb on server `localhost:<port>`. Where `<port>` is randomly assigned when the gRPC server project is created and set in

`Properties/launchSettings.json`

- Prints services and methods returned by gRPC reflection.
  - `Greeter` is a service implemented by the app.
  - `ServerReflection` is the service added by the `Grpc.AspNetCore.Server.Reflection` package.

Combine `describe` with a service, method, or message name to view its detail:

PowerShell

```
$ grpcurl localhost:<port> describe greet.HelloRequest
greet.HelloRequest is a message:
message HelloRequest {
  string name = 1;
}
```

Call gRPC services

Call a gRPC service by specifying a service and method name along with a JSON argument that represents the request message. The JSON is converted into Protobuf and sent to the service.

Console

```
$ grpcurl -d '{ \"name\": \"World\" }' localhost:<port>
greet.Greeter/SayHello
{
  "message": "Hello World"
}
```

In the preceding example:

- The `-d` argument specifies a request message with JSON. This argument must come before the server address and method name.
- Calls the `SayHello` method on the `greeter.Greeter` service.
- Prints the response message as JSON.
- Where `<port>` is randomly assigned when the gRPC server project is created and set in `Properties/launchSettings.json`

The preceding example uses `\` to escape the `"` character. Escaping `"` is required in a PowerShell console but must not be used in some consoles. For example, the previous command for a macOS console:

Console

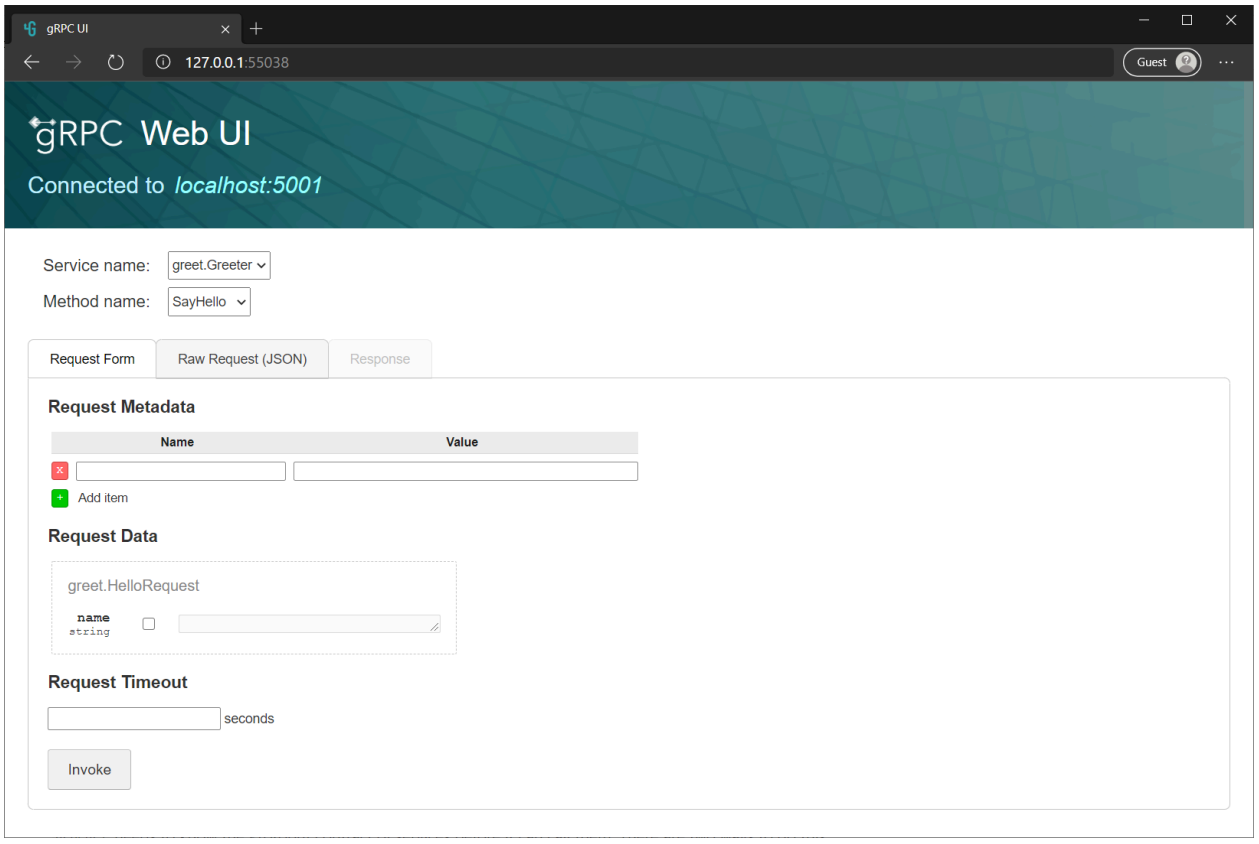
```
$ grpcurl -d '{ "name": "World" }' localhost:<port> greet.Greeter/SayHello
{
  "message": "Hello World"
}
```

gRPCui

gRPCui is an interactive web UI for gRPC. gRPCui builds on top of gRPCurl. gRPCui offers a GUI for discovering and testing gRPC services, similar to HTTP tools such as Swagger UI.

For information about downloading and installing `grpcui`, see the gRPCui GitHub homepage.

Using `grpcui`



Run `grpcui` with the server address to interact with as an argument:

PowerShell

```
$ grpcui localhost:<port>
gRPC Web UI available at http://127.0.0.1:55038/
```

In the preceding example, specify `<port>` as the localhost port number of the gRPC server. The port number is randomly assigned when the project is created and set in `Properties/launchSettings.json`

The tool launches a browser window with the interactive web UI. gRPC services are automatically discovered using gRPC reflection.

Migrate gRPC from C-core to gRPC for .NET

Article • 07/31/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Due to the implementation of the underlying stack, not all features work in the same way between C-core-based gRPC apps and gRPC for .NET. This document highlights the key differences for migrating between the two stacks.

> **ⓘ Important**
>
> gRPC C-core is in maintenance mode and will be deprecated in favor of gRPC for .NET. gRPC C-core is not recommended for new apps.

Platform support

gRPC C-core and gRPC for .NET have different platform support:

- **gRPC C-core**: A C++ gRPC implementation with its own TLS and HTTP/2 stacks. The `Grpc.Core` package is a .NET wrapper around gRPC C-core and contains a gRPC client and server. It supports .NET Framework, .NET Core, and .NET 5 or later.
- **gRPC for .NET**: Designed for .NET Core 3.x and .NET 5 or later. It uses TLS and HTTP/2 stacks built into modern .NET releases. The `Grpc.AspNetCore` package contains a gRPC server that is hosted in ASP.NET Core and requires .NET Core 3.x or .NET 5 or later. The `Grpc.Net.Client` package contains a gRPC client. The client in `Grpc.Net.Client` has limited support for .NET Framework using WinHttpHandler.

For more information, see gRPC on .NET supported platforms.

Configure server and channel

NuGet packages, configuration, and startup code must be modified when migrating from gRPC C-Core to gRPC for .NET.

gRPC for .NET has separate NuGet packages for its client and server. The packages added depend upon whether an app is hosting gRPC services or calling them:

- `Grpc.AspNetCore`: Services are hosted by ASP.NET Core. For server configuration information, see gRPC services with ASP.NET Core.
- `Grpc.Net.Client`: Clients use `GrpcChannel`, which internally uses networking functionality built into .NET. For client configuration information, see Call gRPC services with the .NET client.

When migration is complete, the `Grpc.Core` package should be removed from the app. `Grpc.Core` contains large native binaries, and removing the package reduces NuGet restore time and app size.

Code generated services and clients

gRPC C-Core and gRPC for .NET share many APIs, and code generated from `.proto` files is compatible with both gRPC implementations. Most clients and service can be migrated from C-Core to gRPC for .NET without changes.

gRPC service implementation lifetime

In the ASP.NET Core stack, gRPC services, by default, are created with a scoped lifetime. In contrast, gRPC C-core by default binds to a service with a singleton lifetime.

A scoped lifetime allows the service implementation to resolve other services with scoped lifetimes. For example, a scoped lifetime can also resolve `DbContext` from the DI container through constructor injection. Using scoped lifetime:

- A new instance of the service implementation is constructed for each request.
- It isn't possible to share state between requests via instance members on the implementation type.
- The expectation is to store shared states in a singleton service in the DI container. The stored shared states are resolved in the constructor of the gRPC service implementation.

For more information on service lifetimes, see Dependency injection in ASP.NET Core.

Add a singleton service

To facilitate the transition from a gRPC C-core implementation to ASP.NET Core, it's possible to change the service lifetime of the service implementation from scoped to singleton. This involves adding an instance of the service implementation to the DI container:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc();
    services.AddSingleton(new GreeterService());
}
```

However, a service implementation with a singleton lifetime is no longer able to resolve scoped services through constructor injection.

Configure gRPC services options

In C-core-based apps, settings such as `grpc.max_receive_message_length` and `grpc.max_send_message_length` are configured with `ChannelOption` when constructing the Server instance.

In ASP.NET Core, gRPC provides configuration through the `GrpcServiceOptions` type. For example, a gRPC service's the maximum incoming message size can be configured via `AddGrpc`. The following example changes the default `MaxReceiveMessageSize` of 4 MB to 16 MB:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    services.AddGrpc(options =>
    {
        options.MaxReceiveMessageSize = 16 * 1024 * 1024; // 16 MB
    });
}
```

For more information on configuration, see gRPC for .NET configuration.

Logging

C-core-based apps rely on the `GrpcEnvironment` to configure the logger for debugging purposes. The ASP.NET Core stack provides this functionality through the

Logging API. For example, a logger can be added to the gRPC service via constructor injection:

```
C#
```

```
public class GreeterService : Greeter.GreeterBase
{
    public GreeterService(ILogger<GreeterService> logger)
    {
    }
}
```

For more information on gRPC logging and diagnostics, see Logging and diagnostics in gRPC on .NET.

HTTPS

C-core-based apps configure HTTPS through the Server.Ports property. A similar concept is used to configure servers in ASP.NET Core. For example, Kestrel uses endpoint configuration for this functionality.

gRPC Interceptors

ASP.NET Core middleware offers similar functionalities compared to interceptors in C-core-based gRPC apps. Both are supported by ASP.NET Core gRPC apps, so there's no need to rewrite interceptors.

For more information on how these features compare to each other, see gRPC Interceptors versus Middleware.

Host gRPC in non-ASP.NET Core projects

A C-core-based server can be added to any project type. gRPC for .NET server requires ASP.NET Core. ASP.NET Core is usually available because the project file specifies `Microsoft.NET.SDK.Web` as the SDK.

A gRPC server can be hosted to non-ASP.NET Core projects by adding `<FrameworkReference Include="Microsoft.AspNetCore.App" />` to a project. The framework reference makes ASP.NET Core APIs available and they can be used to start an ASP.NET Core server.

For more information, see Host gRPC in non-ASP.NET Core projects.

gRPC for Windows Communication Foundation (WCF) developers

Article • 07/31/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article provides a summary of why ASP.NET Core gRPC is a good fit for Windows Communication Foundation (WCF) developers who want to migrate to modern architectures and platforms.

Comparison to WCF

Although the implementation and approach are different for gRPC, the experience of developing and consuming services with gRPC should be intuitive for WCF developers. WCF and gRPC are RPC (remote procedure call) frameworks with the same goals:

- Make it possible to code as though the client and server are on the same platform.
- Provide a simplified portable networking API.

Both platforms share the requirement of declaring and implementing an interface, although the process for declaring the interface is different. The many types of RPC calls that gRPC supports map well to the bindings available to WCF services. For more information and examples, see Migrate a WCF solution to gRPC.

Benefits of gRPC

gRPC provides a better framework than other approaches for the following reasons.

Performance

gRPC uses HTTP/2. In contrast to HTTP/1.1, HTTP/2:

- Is a smaller, faster binary protocol.

- Is more efficient for computers to parse.
- Supports multiplexing requests over a single connection. Multiplexing enables multiple requests to be sent over one connection without requests blocking each other. In HTTP/1.1, the blocking is known as "head-of-line (HOL) blocking."

gRPC uses Protobuf, an efficient binary format, to serialize messages. Protobuf messages are:

- Fast to serialize and deserialize.
- Use less bandwidth than text-based formats.

gRPC is a good solution for mobile devices and networks with bandwidth restrictions.

Interoperability

There are gRPC tools and libraries for all major programming languages and platforms, including .NET, Java, Python, Go, C++, Node.js, Swift, Dart, Ruby, and PHP. Thanks to the Protobuf binary wire format and the efficient code generation for each platform, developers can build cross-platform, performant apps.

Usability and productivity

gRPC is a comprehensive RPC solution. It works consistently across multiple languages and platforms. It also provides excellent tooling, with much of the boilerplate code automatically generated. Like WCF, gRPC automatically generates messages and a strongly typed client. Developer time is freed up to focus on business logic.

Streaming

gRPC has full bidirectional streaming, which provides similar functionality to WCF's full duplex services. gRPC streaming can operate over regular internet connections, load balancers, and service meshes.

Deadlines, timeouts, and cancellation

gRPC allows clients to specify a maximum time for an RPC to finish. If the specified deadline is exceeded, the server can cancel the operation independently of the client. Deadlines and cancellations can be propagated through subsequent gRPC calls to help enforce resource usage limits. Clients can stop operations when a deadline is exceeded, or earlier if necessary. For example, clients can stop operations because of a user interaction.

Security

gRPC can use TLS and HTTP/2 to provide an end-to-end encrypted connection between the client and the server. Support for client certificate authentication further increases security and trust between client and server.

gRPC as a migration path for WCF to .NET Core and .NET 5

.NET Core and .NET 5 marks a shift in the way that Microsoft delivers remote communication solutions to developers who want to deliver services across a range of platforms. .NET Core and .NET 5 support calling WCF services, but won't offer server-side support for hosting WCF.

There are two recommended paths for modernizing WCF apps:

- gRPC is built on modern technologies and has emerged as the most popular choice across the developer community for RPC apps. Starting with .NET Core 3.0, modern .NET platforms have excellent support for gRPC. Migrating WCF services to use gRPC helps provide the RPC features, performance, an interoperability needed in modern apps.
- CoreWCF is a community effort to bring support for hosting WCF services to .NET Core and .NET 5. A preview release is available and the project is working towards being production ready. CoreWCF only supports a subset of WCF's features, and .NET Framework apps that migrate to use it will need code changes and testing to be successful. CoreWCF is a good choice if an app has to maintain compatibility with existing clients that call WCF services.

Get started

Compare gRPC services with HTTP APIs

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By James Newton-King

This article explains how gRPC services compare to HTTP APIs with JSON (including ASP.NET Core web APIs). The technology used to provide an API for your app is an important choice, and gRPC offers unique benefits compared to HTTP APIs. This article discusses the strengths and weaknesses of gRPC and recommends scenarios for using gRPC over other technologies.

High-level comparison

The following table offers a high-level comparison of features between gRPC and HTTP APIs with JSON.

Expand table

Feature	gRPC	HTTP APIs with JSON
Contract	Required (`.proto`)	Optional (OpenAPI)
Protocol	HTTP/2	HTTP
Payload	Protobuf (small, binary)	JSON (large, human readable)
Prescriptiveness	Strict specification	Loose. Any HTTP is valid.
Streaming	Client, server, bi-directional	Client, server
Browser support	No (requires grpc-web)	Yes
Security	Transport (TLS)	Transport (TLS)
Client code-generation	Yes	OpenAPI + third-party tooling

gRPC strengths

Performance

gRPC messages are serialized using Protobuf, an efficient binary message format. Protobuf serializes very quickly on the server and client. Protobuf serialization results in small message payloads, important in limited bandwidth scenarios like mobile apps.

gRPC is designed for HTTP/2, a major revision of HTTP that provides significant performance benefits over HTTP 1.x:

- Binary framing and compression. HTTP/2 protocol is compact and efficient both in sending and receiving.
- Multiplexing of multiple HTTP/2 calls over a single TCP connection. Multiplexing eliminates head-of-line blocking.

HTTP/2 is not exclusive to gRPC. Many request types, including HTTP APIs with JSON, can use HTTP/2 and benefit from its performance improvements.

Code generation

All gRPC frameworks provide first-class support for code generation. A core file to gRPC development is the .proto file, which defines the contract of gRPC services and messages. From this file, gRPC frameworks generate a service base class, messages, and a complete client.

By sharing the `.proto` file between the server and client, messages and client code can be generated from end to end. Code generation of the client eliminates duplication of messages on the client and server, and creates a strongly-typed client for you. Not having to write a client saves significant development time in applications with many services.

Strict specification

A formal specification for HTTP API with JSON doesn't exist. Developers debate the best format of URLs, HTTP verbs, and response codes.

The gRPC specification is prescriptive about the format a gRPC service must follow. gRPC eliminates debate and saves developer time because gRPC is consistent across platforms and implementations.

Streaming

HTTP/2 provides a foundation for long-lived, real-time communication streams. gRPC provides first-class support for streaming through HTTP/2.

A gRPC service supports all streaming combinations:

- Unary (no streaming)
- Server to client streaming
- Client to server streaming
- Bi-directional streaming

Deadline/timeouts and cancellation

gRPC allows clients to specify how long they are willing to wait for an RPC to complete. The deadline is sent to the server, and the server can decide what action to take if it exceeds the deadline. For example, the server might cancel in-progress gRPC/HTTP/database requests on timeout.

Propagating the deadline and cancellation through child gRPC calls helps enforce resource usage limits.

gRPC recommended scenarios

gRPC is well suited to the following scenarios:

- **Microservices**: gRPC is designed for low latency and high throughput communication. gRPC is great for lightweight microservices where efficiency is critical.
- **Point-to-point real-time communication**: gRPC has excellent support for bi-directional streaming. gRPC services can push messages in real-time without polling.
- **Polyglot environments**: gRPC tooling supports all popular development languages, making gRPC a good choice for multi-language environments.
- **Network constrained environments**: gRPC messages are serialized with Protobuf, a lightweight message format. A gRPC message is always smaller than an equivalent JSON message.
- **Inter-process communication (IPC)**: IPC transports such as Unix domain sockets and named pipes can be used with gRPC to communicate between apps on the same machine. For more information, see Inter-process communication with gRPC.

gRPC weaknesses

Limited browser support

It's impossible to directly call a gRPC service from a browser today. gRPC heavily uses HTTP/2 features and no browser provides the level of control required over web requests to support a gRPC client. For example, browsers do not allow a caller to require that HTTP/2 be used, or provide access to underlying HTTP/2 frames.

gRPC on ASP.NET Core offers two browser-compatible solutions:

- **gRPC-Web** allows browser apps to call gRPC services with the gRPC-Web client and Protobuf. gRPC-Web requires the browser app to generate a gRPC client. gRPC-Web allows browser apps to benefit from the high-performance and low network usage of gRPC.

  .NET has built-in support for gRPC-Web. For more information, see gRPC-Web in ASP.NET Core gRPC apps.

- **gRPC JSON transcoding** allows browser apps to call gRPC services as if they were RESTful APIs with JSON. The browser app doesn't need to generate a gRPC client or know anything about gRPC. RESTful APIs can be automatically created from gRPC services by annotating the `.proto` file with HTTP metadata. Transcoding allows an app to support both gRPC and JSON web APIs without duplicating the effort of building separate services for both.

  .NET has built-in support for creating JSON web APIs from gRPC services. For more information, see gRPC JSON transcoding in ASP.NET Core gRPC apps.

> **Note**
>
> gRPC JSON transcoding requires .NET 7 or later.

Not human readable

HTTP API requests are sent as text and can be read and created by humans.

gRPC messages are encoded with Protobuf by default. While Protobuf is efficient to send and receive, its binary format isn't human readable. Protobuf requires the message's interface description specified in the `.proto` file to properly deserialize.

Additional tooling is required to analyze Protobuf payloads on the wire and to compose requests by hand.

Features such as server reflection and the gRPC command line tool exist to assist with binary Protobuf messages. Also, Protobuf messages support conversion to and from JSON. The built-in JSON conversion provides an efficient way to convert Protobuf messages to and from human readable form when debugging.

Alternative framework scenarios

Other frameworks are recommended over gRPC in the following scenarios:

- **Browser accessible APIs**: gRPC isn't fully supported in the browser. gRPC-Web can offer browser support, but it has limitations and introduces a server proxy.
- **Broadcast real-time communication**: gRPC supports real-time communication via streaming, but the concept of broadcasting a message out to registered connections doesn't exist. For example in a chat room scenario where new chat messages should be sent to all clients in the chat room, each gRPC call is required to individually stream new chat messages to the client. SignalR is a useful framework for this scenario. SignalR has the concept of persistent connections and built-in support for broadcasting messages.

ASP.NET Core Best Practices

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Mike Rousos

This article provides guidelines for maximizing performance and reliability of ASP.NET Core apps.

Cache aggressively

Caching is discussed in several parts of this article. For more information, see Overview of caching in ASP.NET Core.

Understand hot code paths

In this article, a *hot code path* is defined as a code path that is frequently called and where much of the execution time occurs. Hot code paths typically limit app scale-out and performance and are discussed in several parts of this article.

Avoid blocking calls

ASP.NET Core apps should be designed to process many requests simultaneously. Asynchronous APIs allow a small pool of threads to handle thousands of concurrent requests by not waiting on blocking calls. Rather than waiting on a long-running synchronous task to complete, the thread can work on another request.

A common performance problem in ASP.NET Core apps is blocking calls that could be asynchronous. Many synchronous blocking calls lead to Thread Pool starvation and degraded response times.

Do not block asynchronous execution by calling Task.Wait or Task<TResult>.Result. **Do not** acquire locks in common code paths. ASP.NET Core apps perform best when architected to run code in parallel. **Do not** call Task.Run and immediately await it. ASP.NET Core already runs app code on normal Thread Pool threads, so calling `Task.Run` only results in extra unnecessary Thread Pool scheduling. Even if the scheduled code would block a thread, `Task.Run` does not prevent that.

- **Do** make hot code paths asynchronous.
- **Do** call data access, I/O, and long-running operations APIs asynchronously if an asynchronous API is available.
- **Do not** use Task.Run to make a synchronous API asynchronous.
- **Do** make controller/Razor Page actions asynchronous. The entire call stack is asynchronous in order to benefit from async/await patterns.
- **Consider** using message brokers like Azure Service Bus to offload long-running calls

A profiler, such as PerfView, can be used to find threads frequently added to the Thread Pool. The `Microsoft-Windows-DotNETRuntime/ThreadPoolWorkerThread/Start` event indicates a thread added to the thread pool.

Return large collections across multiple smaller pages

A webpage shouldn't load large amounts of data all at once. When returning a collection of objects, consider whether it could lead to performance issues. Determine if the design could produce the following poor outcomes:

- OutOfMemoryException or high memory consumption
- Thread pool starvation (see the following remarks on IAsyncEnumerable<T>)
- Slow response times
- Frequent garbage collection

Do add pagination to mitigate the preceding scenarios. Using page size and page index parameters, developers should favor the design of returning a partial result. When an exhaustive result is required, pagination should be used to asynchronously populate batches of results to avoid locking server resources.

For more information on paging and limiting the number of returned records, see:

- Performance considerations
- Add paging to an ASP.NET Core app

Return `IEnumerable<T>` or `IAsyncEnumerable<T>`

Returning `IEnumerable<T>` from an action results in synchronous collection iteration by the serializer. The result is the blocking of calls and a potential for thread pool starvation. To avoid synchronous enumeration, use `ToListAsync` before returning the enumerable.

Beginning with ASP.NET Core 3.0, `IAsyncEnumerable<T>` can be used as an alternative to `IEnumerable<T>` that enumerates asynchronously. For more information, see Controller action return types.

Minimize large object allocations

The .NET Core garbage collector manages allocation and release of memory automatically in ASP.NET Core apps. Automatic garbage collection generally means that developers don't need to worry about how or when memory is freed. However, cleaning up unreferenced objects takes CPU time, so developers should minimize allocating objects in hot code paths. Garbage collection is especially expensive on large objects (>= 85,000 bytes). Large objects are stored on the large object heap and require a full (generation 2) garbage collection to clean up. Unlike generation 0 and generation 1 collections, a generation 2 collection requires a temporary suspension of app execution. Frequent allocation and de-allocation of large objects can cause inconsistent performance.

Recommendations:

- **Do** consider caching large objects that are frequently used. Caching large objects prevents expensive allocations.
- **Do** pool buffers by using an ArrayPool<T> to store large arrays.
- **Do not** allocate many, short-lived large objects on hot code paths.

Memory issues, such as the preceding, can be diagnosed by reviewing garbage collection (GC) stats in PerfView and examining:

- Garbage collection pause time.
- What percentage of the processor time is spent in garbage collection.
- How many garbage collections are generation 0, 1, and 2.

For more information, see Garbage Collection and Performance.

Optimize data access and I/O

Interactions with a data store and other remote services are often the slowest parts of an ASP.NET Core app. Reading and writing data efficiently is critical for good performance.

Recommendations:

- **Do** call all data access APIs asynchronously.
- **Do not** retrieve more data than is necessary. Write queries to return just the data that's necessary for the current HTTP request.
- **Do** consider caching frequently accessed data retrieved from a database or remote service if slightly out-of-date data is acceptable. Depending on the scenario, use a MemoryCache or a DistributedCache. For more information, see Response caching in ASP.NET Core.
- **Do** minimize network round trips. The goal is to retrieve the required data in a single call rather than several calls.
- **Do** use no-tracking queries in Entity Framework Core when accessing data for read-only purposes. EF Core can return the results of no-tracking queries more efficiently.
- **Do** filter and aggregate LINQ queries (with `.Where`, `.Select`, or `.Sum` statements, for example) so that the filtering is performed by the database.
- **Do** consider that EF Core resolves some query operators on the client, which may lead to inefficient query execution. For more information, see Client evaluation performance issues.
- **Do not** use projection queries on collections, which can result in executing "N + 1" SQL queries. For more information, see Optimization of correlated subqueries.

The following approaches may improve performance in high-scale apps:

- DbContext pooling
- Explicitly compiled queries

We recommend measuring the impact of the preceding high-performance approaches before committing the code base. The additional complexity of compiled queries may not justify the performance improvement.

Query issues can be detected by reviewing the time spent accessing data with Application Insights or with profiling tools. Most databases also make statistics available concerning frequently executed queries.

Pool HTTP connections with HttpClientFactory

Although HttpClient implements the `IDisposable` interface, it's designed for reuse. Closed `HttpClient` instances leave sockets open in the `TIME_WAIT` state for a short period of time. If a code path that creates and disposes of `HttpClient` objects is frequently used, the app may exhaust available sockets. `HttpClientFactory` was introduced in ASP.NET Core 2.1 as a solution to this problem. It handles pooling HTTP connections to optimize performance and reliability. For more information, see Use HttpClientFactory to implement resilient HTTP requests.

Recommendations:

- **Do not** create and dispose of `HttpClient` instances directly.
- **Do** use HttpClientFactory to retrieve `HttpClient` instances. For more information, see Use HttpClientFactory to implement resilient HTTP requests.

Keep common code paths fast

You want all of your code to be fast. Frequently-called code paths are the most critical to optimize. These include:

- Middleware components in the app's request processing pipeline, especially middleware run early in the pipeline. These components have a large impact on performance.
- Code that's executed for every request or multiple times per request. For example, custom logging, authorization handlers, or initialization of transient services.

Recommendations:

- **Do not** use custom middleware components with long-running tasks.
- **Do** use performance profiling tools, such as Visual Studio Diagnostic Tools or PerfView), to identify hot code paths.

Complete long-running Tasks outside of HTTP requests

Most requests to an ASP.NET Core app can be handled by a controller or page model calling necessary services and returning an HTTP response. For some requests that involve long-running tasks, it's better to make the entire request-response process asynchronous.

Recommendations:

- **Do not** wait for long-running tasks to complete as part of ordinary HTTP request processing.
- **Do** consider handling long-running requests with background services or out of process possibly with an Azure Function and/or using a message broker like Azure Service Bus. Completing work out-of-process is especially beneficial for CPU-intensive tasks.
- **Do** use real-time communication options, such as SignalR, to communicate with clients asynchronously.

Minify client assets

ASP.NET Core apps with complex front-ends frequently serve many JavaScript, CSS, or image files. Performance of initial load requests can be improved by:

- Bundling, which combines multiple files into one.
- Minifying, which reduces the size of files by removing whitespace and comments.

Recommendations:

- **Do** use the bundling and minification guidelines, which mention compatible tools and show how to use ASP.NET Core's `environment` tag to handle both `Development` and `Production` environments.
- **Do** consider other third-party tools, such as Webpack, for complex client asset management.

Compress responses

Reducing the size of the response usually increases the responsiveness of an app, often dramatically. One way to reduce payload sizes is to compress an app's responses. For more information, see Response compression.

Use the latest ASP.NET Core release

Each new release of ASP.NET Core includes performance improvements. Optimizations in .NET Core and ASP.NET Core mean that newer versions generally outperform older versions. For example, .NET Core 2.1 added support for compiled regular expressions and benefitted from Span<T>. ASP.NET Core 2.2 added support for HTTP/2. ASP.NET Core 3.0 adds many improvements that reduce memory usage and improve throughput. If performance is a priority, consider upgrading to the current version of ASP.NET Core.

Minimize exceptions

Exceptions should be rare. Throwing and catching exceptions is slow relative to other code flow patterns. Because of this, exceptions shouldn't be used to control normal program flow.

Recommendations:

- **Do not** use throwing or catching exceptions as a means of normal program flow, especially in hot code paths.
- **Do** include logic in the app to detect and handle conditions that would cause an exception.
- **Do** throw or catch exceptions for unusual or unexpected conditions.

App diagnostic tools, such as Application Insights, can help to identify common exceptions in an app that may affect performance.

Avoid synchronous read or write on HttpRequest/HttpResponse body

All I/O in ASP.NET Core is asynchronous. Servers implement the `Stream` interface, which has both synchronous and asynchronous overloads. The asynchronous ones should be preferred to avoid blocking thread pool threads. Blocking threads can lead to thread pool starvation.

Do not do this: The following example uses the ReadToEnd. It blocks the current thread to wait for the result. This is an example of sync over async.

C#

```
public class BadStreamReaderController : Controller
{
    [HttpGet("/contoso")]
    public ActionResult<ContosoData> Get()
    {
        var json = new StreamReader(Request.Body).ReadToEnd();

        return JsonSerializer.Deserialize<ContosoData>(json);
    }
}
```

In the preceding code, `Get` synchronously reads the entire HTTP request body into memory. If the client is slowly uploading, the app is doing sync over async. The app does sync over async because Kestrel does **NOT** support synchronous reads.

Do this: The following example uses ReadToEndAsync and does not block the thread while reading.

C#

```
public class GoodStreamReaderController : Controller
{
    [HttpGet("/contoso")]
    public async Task<ActionResult<ContosoData>> Get()
    {
        var json = await new StreamReader(Request.Body).ReadToEndAsync();

        return JsonSerializer.Deserialize<ContosoData>(json);
    }

}
```

The preceding code asynchronously reads the entire HTTP request body into memory.

> ⚠ **Warning**
>
> If the request is large, reading the entire HTTP request body into memory could lead to an out of memory (OOM) condition. OOM can result in a Denial Of Service. For more information, see Avoid reading large request bodies or response bodies into memory in this article.

Do this: The following example is fully asynchronous using a non-buffered request body:

C#

```
public class GoodStreamReaderController : Controller
{
    [HttpGet("/contoso")]
    public async Task<ActionResult<ContosoData>> Get()
    {
        return await JsonSerializer.DeserializeAsync<ContosoData>
(Request.Body);
    }
}
```

The preceding code asynchronously de-serializes the request body into a C# object.

Prefer ReadFormAsync over Request.Form

Use `HttpContext.Request.ReadFormAsync` instead of `HttpContext.Request.Form`. `HttpContext.Request.Form` can be safely read only with the following conditions:

- The form has been read by a call to `ReadFormAsync`, and
- The cached form value is being read using `HttpContext.Request.Form`

Do not do this: The following example uses `HttpContext.Request.Form`. `HttpContext.Request.Form` uses sync over async and can lead to thread pool starvation.

C#

```
public class BadReadController : Controller
{
    [HttpPost("/form-body")]
    public IActionResult Post()
    {
        var form =  HttpContext.Request.Form;

        Process(form["id"], form["name"]);

        return Accepted();
    }
```

Do this: The following example uses `HttpContext.Request.ReadFormAsync` to read the form body asynchronously.

C#

```
public class GoodReadController : Controller
{
    [HttpPost("/form-body")]
    public async Task<IActionResult> Post()
    {
       var form = await HttpContext.Request.ReadFormAsync();

        Process(form["id"], form["name"]);

        return Accepted();
    }
```

Avoid reading large request bodies or response bodies into memory

In .NET, every object allocation greater than or equal to 85,000 bytes ends up in the large object heap (LOH). Large objects are expensive in two ways:

- The allocation cost is high because the memory for a newly allocated large object has to be cleared. The CLR guarantees that memory for all newly allocated objects is cleared.
- LOH is collected with the rest of the heap. LOH requires a full garbage collection or Gen2 collection.

This blog post describes the problem succinctly:

> When a large object is allocated, it's marked as Gen 2 object. Not Gen 0 as for small objects. The consequences are that if you run out of memory in LOH, GC cleans up the whole managed heap, not only LOH. So it cleans up Gen 0, Gen 1 and Gen 2 including LOH. This is called full garbage collection and is the most time-consuming garbage collection. For many applications, it can be acceptable. But definitely not for high-performance web servers, where few big memory buffers are needed to handle an average web request (read from a socket, decompress, decode JSON, and more).

Storing a large request or response body into a single `byte[]` or `string`:

- May result in quickly running out of space in the LOH.
- May cause performance issues for the app because of full GCs running.

Working with a synchronous data processing API

When using a serializer/de-serializer that only supports synchronous reads and writes (for example, Json.NET):

- Buffer the data into memory asynchronously before passing it into the serializer/de-serializer.

> ⚠ **Warning**
>
> If the request is large, it could lead to an out of memory (OOM) condition. OOM can result in a Denial Of Service. For more information, see **Avoid reading large request bodies or response bodies into memory** in this article.

ASP.NET Core 3.0 uses System.Text.Json by default for JSON serialization. System.Text.Json:

- Reads and writes JSON asynchronously.
- Is optimized for UTF-8 text.
- Typically is higher performance than `Newtonsoft.Json`.

Do not store IHttpContextAccessor.HttpContext in a field

The IHttpContextAccessor.HttpContext returns the `HttpContext` of the active request when accessed from the request thread. The `IHttpContextAccessor.HttpContext` should **not** be stored in a field or variable.

Do not do this: The following example stores the `HttpContext` in a field and then attempts to use it later.

C#

```
public class MyBadType
{
    private readonly HttpContext _context;
    public MyBadType(IHttpContextAccessor accessor)
    {
        _context = accessor.HttpContext;
    }

    public void CheckAdmin()
    {
        if (!_context.User.IsInRole("admin"))
        {
            throw new UnauthorizedAccessException("The current user isn't an
admin");
        }
    }
}
```

The preceding code frequently captures a null or incorrect `HttpContext` in the constructor.

Do this: The following example:

- Stores the IHttpContextAccessor in a field.
- Uses the `HttpContext` field at the correct time and checks for `null`.

C#

```
public class MyGoodType
{
    private readonly IHttpContextAccessor _accessor;
    public MyGoodType(IHttpContextAccessor accessor)
    {
        _accessor = accessor;
    }

    public void CheckAdmin()
    {
        var context = _accessor.HttpContext;
        if (context != null && !context.User.IsInRole("admin"))
        {
            throw new UnauthorizedAccessException("The current user isn't an
admin");
        }
    }
}
```

Do not access HttpContext from multiple threads

`HttpContext` is **not** thread-safe. Accessing `HttpContext` from multiple threads in parallel can result in unexpected behavior such as the server to stop responding, crashes, and data corruption.

Do not do this: The following example makes three parallel requests and logs the incoming request path before and after the outgoing HTTP request. The request path is accessed from multiple threads, potentially in parallel.

C#

```
public class AsyncBadSearchController : Controller
{
    [HttpGet("/search")]
    public async Task<SearchResults> Get(string query)
    {
        var query1 = SearchAsync(SearchEngine.Google, query);
        var query2 = SearchAsync(SearchEngine.Bing, query);
        var query3 = SearchAsync(SearchEngine.DuckDuckGo, query);

        await Task.WhenAll(query1, query2, query3);

        var results1 = await query1;
        var results2 = await query2;
        var results3 = await query3;

        return SearchResults.Combine(results1, results2, results3);
```

```
    }

    private async Task<SearchResults> SearchAsync(SearchEngine engine,
string query)
    {
        var searchResults = _searchService.Empty();
        try
        {
            _logger.LogInformation("Starting search query from {path}.",
                                   HttpContext.Request.Path);
            searchResults = _searchService.Search(engine, query);
            _logger.LogInformation("Finishing search query from {path}.",
                                   HttpContext.Request.Path);
        }
        catch (Exception ex)
        {
            _logger.LogError(ex, "Failed query from {path}",
                             HttpContext.Request.Path);
        }

        return await searchResults;
    }
```

Do this: The following example copies all data from the incoming request before making the three parallel requests.

C#

```
public class AsyncGoodSearchController : Controller
{
    [HttpGet("/search")]
    public async Task<SearchResults> Get(string query)
    {
        string path = HttpContext.Request.Path;
        var query1 = SearchAsync(SearchEngine.Google, query,
                                 path);
        var query2 = SearchAsync(SearchEngine.Bing, query, path);
        var query3 = SearchAsync(SearchEngine.DuckDuckGo, query, path);

        await Task.WhenAll(query1, query2, query3);

        var results1 = await query1;
        var results2 = await query2;
        var results3 = await query3;

        return SearchResults.Combine(results1, results2, results3);
    }

    private async Task<SearchResults> SearchAsync(SearchEngine engine,
string query,
                                                  string path)
    {
        var searchResults = _searchService.Empty();
```

```
        try
        {
            _logger.LogInformation("Starting search query from {path}.",
                                   path);
            searchResults = await _searchService.SearchAsync(engine, query);
            _logger.LogInformation("Finishing search query from {path}.",
path);
        }
        catch (Exception ex)
        {
            _logger.LogError(ex, "Failed query from {path}", path);
        }

        return await searchResults;
    }
```

Do not use the HttpContext after the request is complete

`HttpContext` is only valid as long as there is an active HTTP request in the ASP.NET Core pipeline. The entire ASP.NET Core pipeline is an asynchronous chain of delegates that executes every request. When the `Task` returned from this chain completes, the `HttpContext` is recycled.

Do not do this: The following example uses `async void` which makes the HTTP request complete when the first `await` is reached:

- Using `async void` is **ALWAYS** a bad practice in ASP.NET Core apps.
- The example code accesses the `HttpResponse` after the HTTP request is complete.
- The late access crashes the process.

C#

```
public class AsyncBadVoidController : Controller
{
    [HttpGet("/async")]
    public async void Get()
    {
        await Task.Delay(1000);

        // The following line will crash the process because of writing
after the
        // response has completed on a background thread. Notice async void
Get()

        await Response.WriteAsync("Hello World");
```

```
    }
}
```

Do this: The following example returns a `Task` to the framework, so the HTTP request doesn't complete until the action completes.

C#

```
public class AsyncGoodTaskController : Controller
{
    [HttpGet("/async")]
    public async Task Get()
    {
        await Task.Delay(1000);

        await Response.WriteAsync("Hello World");
    }
}
```

Do not capture the HttpContext in background threads

Do not do this: The following example shows a closure is capturing the `HttpContext` from the `Controller` property. This is a bad practice because the work item could:

- Run outside of the request scope.
- Attempt to read the wrong `HttpContext`.

C#

```
[HttpGet("/fire-and-forget-1")]
public IActionResult BadFireAndForget()
{
    _ = Task.Run(async () =>
    {
        await Task.Delay(1000);

        var path = HttpContext.Request.Path;
        Log(path);
    });

    return Accepted();
}
```

Do this: The following example:

- Copies the data required in the background task during the request.
- Doesn't reference anything from the controller.

C#

```
[HttpGet("/fire-and-forget-3")]
public IActionResult GoodFireAndForget()
{
    string path = HttpContext.Request.Path;
    _ = Task.Run(async () =>
    {
        await Task.Delay(1000);

        Log(path);
    });

    return Accepted();
}
```

Background tasks should be implemented as hosted services. For more information, see Background tasks with hosted services.

Do not capture services injected into the controllers on background threads

Do not do this: The following example shows a closure that is capturing the `DbContext` from the `Controller` action parameter. This is a bad practice. The work item could run outside of the request scope. The `ContosoDbContext` is scoped to the request, resulting in an `ObjectDisposedException`.

C#

```
[HttpGet("/fire-and-forget-1")]
public IActionResult FireAndForget1([FromServices]ContosoDbContext context)
{
    _ = Task.Run(async () =>
    {
        await Task.Delay(1000);

        context.Contoso.Add(new Contoso());
        await context.SaveChangesAsync();
    });

    return Accepted();
}
```

Do this: The following example:

- Injects an IServiceScopeFactory in order to create a scope in the background work item. `IServiceScopeFactory` is a singleton.
- Creates a new dependency injection scope in the background thread.
- Doesn't reference anything from the controller.
- Doesn't capture the `ContosoDbContext` from the incoming request.

C#

```
[HttpGet("/fire-and-forget-3")]
public IActionResult FireAndForget3([FromServices]IServiceScopeFactory
                                    serviceScopeFactory)
{
    _ = Task.Run(async () =>
    {
        await Task.Delay(1000);

        await using (var scope = serviceScopeFactory.CreateAsyncScope())
        {
            var context =
scope.ServiceProvider.GetRequiredService<ContosoDbContext>();

            context.Contoso.Add(new Contoso());

            await context.SaveChangesAsync();
        }
    });

    return Accepted();
}
```

The following highlighted code:

- Creates a scope for the lifetime of the background operation and resolves services from it.
- Uses `ContosoDbContext` from the correct scope.

C#

```
[HttpGet("/fire-and-forget-3")]
public IActionResult FireAndForget3([FromServices]IServiceScopeFactory
                                    serviceScopeFactory)
{
    _ = Task.Run(async () =>
    {
        await Task.Delay(1000);
```

```
        await using (var scope = serviceScopeFactory.CreateAsyncScope())
        {
            var context =
scope.ServiceProvider.GetRequiredService<ContosoDbContext>();

            context.Contoso.Add(new Contoso());

            await context.SaveChangesAsync();
        }
    });

    return Accepted();
}
```

Do not modify the status code or headers after the response body has started

ASP.NET Core does not buffer the HTTP response body. The first time the response is written:

- The headers are sent along with that chunk of the body to the client.
- It's no longer possible to change response headers.

Do not do this: The following code tries to add response headers after the response has already started:

C#

```
app.Use(async (context, next) =>
{
    await next();

    context.Response.Headers["test"] = "test value";
});
```

In the preceding code, `context.Response.Headers["test"] = "test value";` will throw an exception if `next()` has written to the response.

Do this: The following example checks if the HTTP response has started before modifying the headers.

C#

```
app.Use(async (context, next) =>
{
    await next();
```

```
    if (!context.Response.HasStarted)
    {
        context.Response.Headers["test"] = "test value";
    }
});
```

Do this: The following example uses `HttpResponse.OnStarting` to set the headers before the response headers are flushed to the client.

Checking if the response has not started allows registering a callback that will be invoked just before response headers are written. Checking if the response has not started:

- Provides the ability to append or override headers just in time.
- Doesn't require knowledge of the next middleware in the pipeline.

C#

```
app.Use(async (context, next) =>
{
    context.Response.OnStarting(() =>
    {
        context.Response.Headers["someheader"] = "somevalue";
        return Task.CompletedTask;
    });

    await next();
});
```

Do not call next() if you have already started writing to the response body

Components only expect to be called if it's possible for them to handle and manipulate the response.

Use In-process hosting with IIS

Using in-process hosting, an ASP.NET Core app runs in the same process as its IIS worker process. In-process hosting provides improved performance over out-of-process hosting because requests aren't proxied over the loopback adapter. The loopback adapter is a network interface that returns outgoing network traffic back to the same machine. IIS handles process management with the Windows Process Activation Service (WAS).

Projects default to the in-process hosting model in ASP.NET Core 3.0 and later.

For more information, see Host ASP.NET Core on Windows with IIS

Don't assume that HttpRequest.ContentLength is not null

`HttpRequest.ContentLength` is null if the `Content-Length` header is not received. Null in that case means the length of the request body is not known; it doesn't mean the length is zero. Because all comparisons with null (except `==`) return false, the comparison `Request.ContentLength > 1024`, for example, might return `false` when the request body size is more than 1024. Not knowing this can lead to security holes in apps. You might think you're protecting against too-large requests when you aren't.

For more information, see this StackOverflow answer.

Reliable web app patterns

See *The Reliable Web App Pattern for.NET* YouTube videos and article for guidance on creating a modern, reliable, performant, testable, cost-efficient, and scalable ASP.NET Core app, whether from scratch or refactoring an existing app.

Web server implementations in ASP.NET Core

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Tom Dykstra, Steve Smith, Stephen Halter, and Chris Ross

An ASP.NET Core app runs with an in-process HTTP server implementation. The server implementation listens for HTTP requests and surfaces them to the app as a set of request features composed into an HttpContext.

Windows

ASP.NET Core ships with the following:

- Kestrel server is the default, cross-platform HTTP server implementation. Kestrel provides the best performance and memory utilization, but it doesn't have some of the advanced features in HTTP.sys. For more information, see Kestrel vs. HTTP.sys in the Windows tab.
- IIS HTTP Server is an in-process server for IIS.
- HTTP.sys server is a Windows-only HTTP server based on the HTTP.sys kernel driver and HTTP Server API.

When using IIS or IIS Express, the app either runs:

- In the same process as the IIS worker process (the in-process hosting model) with the IIS HTTP Server. *In-process* is the recommended configuration.
- In a process separate from the IIS worker process (the out-of-process hosting model) with the Kestrel server.

The ASP.NET Core Module is a native IIS module that handles native IIS requests between IIS and the in-process IIS HTTP Server or Kestrel. For more information, see ASP.NET Core Module (ANCM) for IIS.

Kestrel vs. HTTP.sys

Kestrel has the following advantages over HTTP.sys:

- Better performance and memory utilization.
- Cross platform
- Agility, it's developed and patched independent of the OS.
- Programmatic port and TLS configuration
- Extensibility that allows for protocols like PPv2 and alternate transports.

Http.Sys operates as a shared kernel mode component with the following features that kestrel does not have:

- Port sharing
- Kernel mode windows authentication. Kestrel supports only user-mode authentication.
- Fast proxying via queue transfers
- Direct file transmission
- Response caching

Hosting models

Several hosting models are available:

- Kestrel self-hosting: The Kestrel web server runs without requiring any other external web server such as IIS or HTTP.sys.

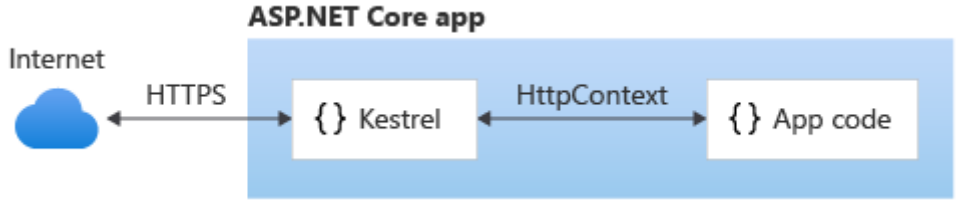
- HTTP.sys self-hosting is an alternative to Kestrel. Kestrel is recommended over HTTP.sys unless the app requires features not available in Kestrel.

- IIS in-process hosting: An ASP.NET Core app runs in the same process as its IIS worker process. IIS in-process hosting provides improved performance over IIS out-of-process hosting because requests aren't proxied over the loopback adapter, a network interface that returns outgoing network traffic back to the same machine. IIS handles process management with the Windows Process Activation Service (WAS).

- IIS out-of-process hosting: ASP.NET Core apps run in a process separate from the IIS worker process, and the module handles process management. The module starts the process for the ASP.NET Core app when the first request arrives and restarts the app if it shuts down or crashes. This is essentially the same behavior as seen with apps that run in-process that are managed by the

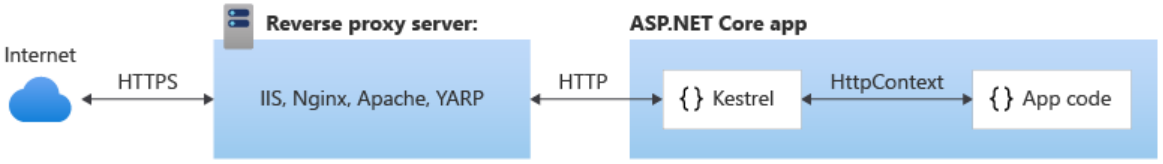
Windows Process Activation Service (WAS). Using a separate process also enables hosting more than one app from the same app pool.

For more information, see the following:



- Kestrel vs. HTTP.sys
- Host ASP.NET Core on Windows with IIS
- ASP.NET Core Module (ANCM) for IIS

Kestrel



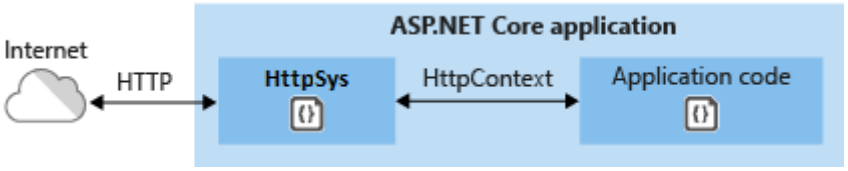
Kestrel server is the default, cross-platform HTTP server implementation. Kestrel provides the best performance and memory utilization, but it doesn't have some of the advanced features in HTTP.sys. For more information, see Kestrel vs. HTTP.sys in this document.

Use Kestrel:

- By itself as an edge server processing requests directly from a network, including the Internet.

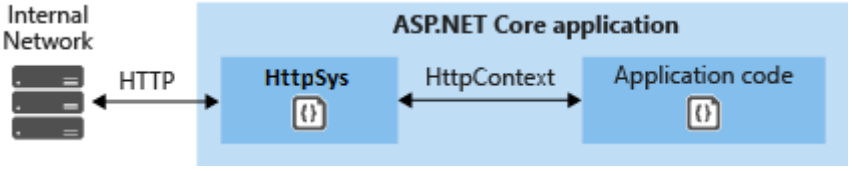
- With a *reverse proxy server*, such as Internet Information Services (IIS), Nginx, or Apache. A reverse proxy server receives HTTP requests from the Internet and forwards them to Kestrel.

Either hosting configuration—with or without a reverse proxy server—is supported.



For Kestrel configuration guidance and information on when to use Kestrel in a reverse proxy configuration, see Kestrel web server in ASP.NET Core.

Nginx with Kestrel



For information on how to use Nginx on Linux as a reverse proxy server for Kestrel, see Host ASP.NET Core on Linux with Nginx.

HTTP.sys

If ASP.NET Core apps are run on Windows, HTTP.sys is an alternative to Kestrel. Kestrel is recommended over HTTP.sys unless the app requires features not available in Kestrel. For more information, see HTTP.sys web server implementation in ASP.NET Core.

HTTP.sys can also be used for apps that are only exposed to an internal network.

For HTTP.sys configuration guidance, see HTTP.sys web server implementation in ASP.NET Core.

ASP.NET Core server infrastructure

The IApplicationBuilder available in the `Startup.Configure` method exposes the ServerFeatures property of type IFeatureCollection. Kestrel and HTTP.sys only expose a single feature each, IServerAddressesFeature, but different server implementations may expose additional functionality.

`IServerAddressesFeature` can be used to find out which port the server implementation has bound at runtime.

Custom servers

If the built-in servers don't meet the app's requirements, a custom server implementation can be created. The Open Web Interface for .NET (OWIN) guide demonstrates how to write a Nowin -based IServer implementation. Only the feature interfaces that the app uses require implementation, though at a minimum IHttpRequestFeature and IHttpResponseFeature must be supported.

Server startup

The server is launched when the Integrated Development Environment (IDE) or editor starts the app:

- Visual Studio: Launch profiles can be used to start the app and server with either IIS Express/ASP.NET Core Module or the console.
- Visual Studio Code: The app and server are started by Omnisharp, which activates the CoreCLR debugger.
- Visual Studio for Mac: The app and server are started by the Mono Soft-Mode Debugger.

When launching the app from a command prompt in the project's folder, dotnet run launches the app and server (Kestrel and HTTP.sys only). The configuration is specified by the `-c|--configuration` option, which is set to either `Debug` (default) or `Release`.

A `launchSettings.json` file provides configuration when launching an app with `dotnet run` or with a debugger built into tooling, such as Visual Studio. If launch profiles are present in a `launchSettings.json` file, use the `--launch-profile {PROFILE NAME}` option with the `dotnet run` command or select the profile in Visual Studio. For more information, see dotnet run and .NET Core distribution packaging.

HTTP/2 support

HTTP/2 is supported with ASP.NET Core in the following deployment scenarios:

- Kestrel
  - Operating system
    - Windows Server 2016/Windows 10 or later†
    - Linux with OpenSSL 1.0.2 or later (for example, Ubuntu 16.04 or later)
    - macOS 10.15 or later
  - Target framework: .NET Core 2.2 or later
- HTTP.sys
  - Windows Server 2016/Windows 10 or later
  - Target framework: Not applicable to HTTP.sys deployments.
- IIS (in-process)
  - Windows Server 2016/Windows 10 or later; IIS 10 or later
  - Target framework: .NET Core 2.2 or later
- IIS (out-of-process)
  - Windows Server 2016/Windows 10 or later; IIS 10 or later

- Public-facing edge server connections use HTTP/2, but the reverse proxy connection to Kestrel uses HTTP/1.1.
- Target framework: Not applicable to IIS out-of-process deployments.

†Kestrel has limited support for HTTP/2 on Windows Server 2012 R2 and Windows 8.1. Support is limited because the list of supported TLS cipher suites available on these operating systems is limited. A certificate generated using an Elliptic Curve Digital Signature Algorithm (ECDSA) may be required to secure TLS connections.

An HTTP/2 connection must use Application-Layer Protocol Negotiation (ALPN) and TLS 1.2 or later. For more information, see the topics that pertain to your server deployment scenarios.

Kestrel web server in ASP.NET Core

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Tom Dykstra, Chris Ross, and Stephen Halter

Kestrel is a cross-platform web server for ASP.NET Core. Kestrel is the recommended server for ASP.NET Core, and it's configured by default in ASP.NET Core project templates.

Kestrel's features include:

- **Cross-platform:** Kestrel is a cross-platform web server that runs on Windows, Linux, and macOS.
- **High performance:** Kestrel is optimized to handle a large number of concurrent connections efficiently.
- **Lightweight:** Optimized for running in resource-constrained environments, such as containers and edge devices.
- **Security hardened:** Kestrel supports HTTPS and is hardened against web server vulnerabilities.
- **Wide protocol support:** Kestrel supports common web protocols, including:
  - HTTP/1.1, HTTP/2 and HTTP/3
  - WebSockets
- **Integration with ASP.NET Core:** Seamless integration with other ASP.NET Core components, such as the middleware pipeline, dependency injection, and configuration system.
- **Flexible workloads**: Kestrel supports many workloads:
  - ASP.NET app frameworks such as Minimal APIs, MVC, Razor pages, SignalR, Blazor, and gRPC.
  - Building a reverse proxy with YARP.
- **Extensibility:** Customize Kestrel through configuration, middleware, and custom transports.

- **Performance diagnostics:** Kestrel provides built-in performance diagnostics features, such as logging and metrics.

Get started

ASP.NET Core project templates use Kestrel by default when not hosted with IIS. In the following template-generated `Program.cs`, the WebApplication.CreateBuilder method calls UseKestrel internally:

```
C#

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

For more information on configuring `WebApplication` and `WebApplicationBuilder`, see Minimal APIs quick reference.

Optional client certificates

For information on apps that must protect a subset of the app with a certificate, see Optional client certificates.

Behavior with debugger attached

The following timeouts and rate limits aren't enforced when a debugger is attached to a Kestrel process:

- KestrelServerLimits.KeepAliveTimeout
- KestrelServerLimits.RequestHeadersTimeout
- KestrelServerLimits.MinRequestBodyDataRate
- KestrelServerLimits.MinResponseDataRate
- IConnectionTimeoutFeature
- IHttpMinRequestBodyDataRateFeature
- IHttpMinResponseDataRateFeature

- RFC 9110: HTTP Semantics (Section 7.2: Host and :authority)
- When using UNIX sockets on Linux, the socket isn't automatically deleted on app shutdown. For more information, see this GitHub issue.

> **Note**
>
> As of ASP.NET Core 5.0, Kestrel's libuv transport is obsolete. The libuv transport doesn't receive updates to support new OS platforms, such as Windows ARM64, and will be removed in a future release. Remove any calls to the obsolete **UseLibuv** method and use Kestrel's default Socket transport instead.

Configure endpoints for the ASP.NET Core Kestrel web server

Article • 07/26/2024

Kestrel endpoints provide the infrastructure for listening to incoming requests and routing them to the appropriate middleware. The combination of an address and a protocol defines an endpoint.

- The address specifies the network interface that the server listens on for incoming requests, such as a TCP port.
- The protocol specifies the communication between the client and server, such as HTTP/1.1, HTTP/2, or HTTP/3.
- An endpoint can be secured using the `https` URL scheme or `UseHttps` method.

Endpoints can be configured using URLs, JSON in `appsettings.json`, and code. This article discusses how to use each option to configure an endpoint:

- Configure endpoints
- Configure HTTPS
- Configure HTTP protocols

Default endpoint

New ASP.NET Core projects are configured to bind to a random HTTP port between 5000-5300 and a random HTTPS port between 7000-7300. The selected ports are stored in the generated `Properties/launchSettings.json` file and can be modified by the developer. The `launchSetting.json` file is only used in local development.

If there's no endpoint configuration, then Kestrel binds to `http://localhost:5000`.

Configure endpoints

Kestrel endpoints listen for incoming connections. When an endpoint is created, it must be configured with the address it will listen to. Usually, this is a TCP address and port number.

There are several options for configuring endpoints:

- Configure endpoints with URLs
- Specify ports only
- Configure endpoints in appsettings.json
- Configure endpoints in code

Configure endpoints with URLs

The following sections explain how to configure endpoints using the:

- `ASPNETCORE_URLS` environment variable.
- `--urls` command-line argument.
- `urls` host configuration key.
- UseUrls extension method.
- WebApplication.Urls property.

URL formats

The URLs indicate the IP or host addresses with ports and protocols the server should listen on. The port can be omitted if it's the default for the protocol (typically 80 and 443). URLs can be in any of the following formats.

- IPv4 address with port number

```
http://65.55.39.10:80/
```

`0.0.0.0` is a special case that binds to all IPv4 addresses.

- IPv6 address with port number

  ```
  http://[0:0:0:0:0:ffff:4137:270a]:80/
  ```

  `[::]` is the IPv6 equivalent of IPv4 `0.0.0.0`.

- Wildcard host with port number

  ```
  http://contoso.com:80/
  http://*:80/
  ```

  Anything not recognized as a valid IP address or `localhost` is treated as a wildcard that binds to all IPv4 and IPv6 addresses. Some people like to use `*` or `+` to be more explicit. To bind different host names to different ASP.NET Core apps on the same port, use HTTP.sys or a reverse proxy server.

  Reverse proxy server examples include IIS, YARP, Nginx, and Apache.

- Host name `localhost` with port number or loopback IP with port number

  ```
  http://localhost:5000/
  http://127.0.0.1:5000/
  http://[::1]:5000/
  ```

  When `localhost` is specified, Kestrel attempts to bind to both IPv4 and IPv6 loopback interfaces. If the requested port is in use by another service on either loopback interface, Kestrel fails to start. If either loopback interface is unavailable for any other reason (most commonly because IPv6 isn't supported), Kestrel logs a warning.

Multiple URL prefixes can be specified by using a semicolon (`;`) delimiter:

```
http://*:5000;http://localhost:5001;https://hostname:5002
```

For more information, see Override configuration.

HTTPS URL prefixes

HTTPS URL prefixes can be used to define endpoints only if a default certificate is provided in the HTTPS endpoint configuration. For example, use KestrelServerOptions configuration or a configuration file, as shown later in this article.

For more information, see Configure HTTPS.

Specify ports only

Apps and containers are often given only a port to listen on, like port 80, without additional constraints like host or path. HTTP_PORTS and HTTPS_PORTS are config keys that specify the listening ports for the Kestrel and HTTP.sys servers. These keys may be specified as environment variables defined with the `DOTNET_` or `ASPNETCORE_` prefixes, or specified directly through any other config input, such as `appsettings.json`. Each is a semicolon-delimited list of port values, as shown in the following example:

```
ASPNETCORE_HTTP_PORTS=80;8080
ASPNETCORE_HTTPS_PORTS=443;8081
```

The preceding example is shorthand for the following configuration, which specifies the scheme (HTTP or HTTPS) and any host or IP.

```
ASPNETCORE_URLS=http://*:80/;http://*:8080/;https://*:443/;https://*:8081/
```

The HTTP_PORTS and HTTPS_PORTS configuration keys are lower priority and are overridden by URLS or values provided directly in code. Certificates still need to be configured separately via server-specific mechanics for HTTPS.

Configure endpoints in appsettings.json

Kestrel can load endpoints from an IConfiguration instance. By default, Kestrel configuration is loaded from the `Kestrel` section and endpoints are configured in `Kestrel:Endpoints`:

JSON

```
{
  "Kestrel": {
    "Endpoints": {
      "MyHttpEndpoint": {
        "Url": "http://localhost:8080"
      }
    }
  }
}
```

The preceding example:

- Uses `appsettings.json` as the configuration source. However, any `IConfiguration` source can be used.
- Adds an endpoint named `MyHttpEndpoint` on port 8080.

For more information about configuring endpoints with JSON, see later sections in this article that discuss configuring HTTPS and configuring HTTP protocols in appsettings.json.

Reloading endpoints from configuration

Reloading endpoint configuration when the configuration source changes is enabled by default. It can be disabled using KestrelServerOptions.Configure(IConfiguration, Boolean).

If a change is signaled, the following steps are taken:

- The new configuration is compared to the old one, and any endpoint without configuration changes isn't modified.
- Removed or modified endpoints are given 5 seconds to complete processing requests and shut down.
- New or modified endpoints are started.

Clients connecting to a modified endpoint may be disconnected or refused while the endpoint is restarted.

ConfigurationLoader

KestrelServerOptions.Configure returns a KestrelConfigurationLoader. The loader's Endpoint(String, Action<EndpointConfiguration>) method that can be used to supplement a configured endpoint's settings:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel((context, serverOptions) =>
{
    var kestrelSection = context.Configuration.GetSection("Kestrel");

    serverOptions.Configure(kestrelSection)
        .Endpoint("HTTPS", listenOptions =>
        {
            // ...
        });
});
```

`KestrelServerOptions.ConfigurationLoader` can be directly accessed to continue iterating on the existing loader, such as the one provided by WebApplicationBuilder.WebHost.

- The configuration section for each endpoint is available on the options in the Endpoint method so that custom settings may be read.
- KestrelServerOptions.Configure(IConfiguration) can be called multiple times, but only the last configuration is used unless `Load` is explicitly called on prior instances. The default host doesn't call `Load` so that its default configuration section may be replaced.
- `KestrelConfigurationLoader` mirrors the `Listen` family of APIs from `KestrelServerOptions` as `Endpoint` overloads, so code and config endpoints can be configured in the same place. These overloads don't use names and only consume default settings from configuration.

Configure endpoints in code

KestrelServerOptions provides methods for configuring endpoints in code:

- Listen
- ListenLocalhost
- ListenAnyIP
- ListenUnixSocket
- ListenNamedPipe

When both the `Listen` and UseUrls APIs are used simultaneously, the `Listen` endpoints override the `UseUrls` endpoints.

Bind to a TCP socket

The Listen, ListenLocalhost, and ListenAnyIP methods bind to a TCP socket:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
    });
});
```

The preceding example:

- Configures endpoints that listen on port 5000 and 5001.
- Configures HTTPS for an endpoint with the UseHttps extension method on ListenOptions. For more information, see Configure HTTPS in code.

On Windows, self-signed certificates can be created using the New-SelfSignedCertificate PowerShell cmdlet. For an unsupported example, see UpdateIISExpressSSLForChrome.ps1.

On macOS, Linux, and Windows, certificates can be created using OpenSSL.

Bind to a Unix socket

Listen on a Unix socket with ListenUnixSocket for improved performance with Nginx, as shown in this example:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.ListenUnixSocket("/tmp/kestrel-test.sock");
});
```

- In the Nginx configuration file, set the `server` > `location` > `proxy_pass` entry to `http://unix:/tmp/{KESTREL SOCKET}:/;`. `{KESTREL SOCKET}` is the name of the socket provided to ListenUnixSocket (for example, `kestrel-test.sock` in the preceding example).

- Ensure that the socket is writeable by Nginx (for example, `chmod go+w /tmp/kestrel-test.sock`).

Configure endpoint defaults

ConfigureEndpointDefaults(Action<ListenOptions>) specifies configuration that runs for each specified endpoint. Calling `ConfigureEndpointDefaults` multiple times replaces previous configuration.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ConfigureEndpointDefaults(listenOptions =>
    {
        // ...
    });
});
```

> ⓘ Note
>
> Endpoints created by calling Listen **before** calling ConfigureEndpointDefaults won't have the defaults applied.

Dynamic port binding

When port number `0` is specified, Kestrel dynamically binds to an available port. The following example shows how to determine which port Kestrel bound at runtime:

C#

```
app.Run(async (context) =>
{
    var serverAddressFeature = context.Features.Get<IServerAddressesFeature>
();

    if (serverAddressFeature is not null)
    {
        var listenAddresses = string.Join(", ",
serverAddressFeature.Addresses);

        // ...
```

```
    }
});
```

Dynamically binding a port isn't available in some situations:

- KestrelServerOptions.ListenLocalhost
- Binding TCP-based HTTP/1.1 or HTTP/2, and QUIC-based HTTP/3 together.

Configure HTTPS

Kestrel supports securing endpoints with HTTPS. Data sent over HTTPS is encrypted using Transport Layer Security (TLS) to increase the security of data transferred between the client and server.

HTTPS requires a TLS certificate. The TLS certificate is stored on the server, and Kestrel is configured to use it. An app can use the ASP.NET Core HTTPS development certificate in a local development environment. The development certificate isn't installed in nondevelopment environments. In production, a TLS certificate must be explicitly configured. At a minimum, a default certificate must be provided.

The way HTTPS and the TLS certificate is configured depends on how endpoints are configured:

- If URL prefixes or specify ports only are used to define endpoints, HTTPS can be used only if a default certificate is provided in HTTPS endpoint configuration. A default certificate can be configured with one of the following options:
- Configure HTTPS in appsettings.json
- Configure HTTPS in code

Configure HTTPS in appsettings.json

A default HTTPS app settings configuration schema is available for Kestrel. Configure multiple endpoints, including the URLs and the certificates to use, either from a file on disk or from a certificate store.

Any HTTPS endpoint that doesn't specify a certificate (`HttpsDefaultCert` in the example that follows) falls back to the certificate defined under `Certificates:Default` or the development certificate.

The following example is for `appsettings.json`, but any configuration source can be used:

```
JSON
```

```
{
  "Kestrel": {
    "Endpoints": {
      "Http": {
        "Url": "http://localhost:5000"
      },
      "HttpsInlineCertFile": {
        "Url": "https://localhost:5001",
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "$CREDENTIAL_PLACEHOLDER$"
        }
      },
      "HttpsInlineCertAndKeyFile": {
        "Url": "https://localhost:5002",
        "Certificate": {
          "Path": "<path to .pem/.crt file>",
          "KeyPath": "<path to .key file>",
          "Password": "$CREDENTIAL_PLACEHOLDER$"
        }
      },
      "HttpsInlineCertStore": {
        "Url": "https://localhost:5003",
        "Certificate": {
          "Subject": "<subject; required>",
          "Store": "<certificate store; required>",
          "Location": "<location; defaults to CurrentUser>",
          "AllowInvalid": "<true or false; defaults to false>"
        }
      },
      "HttpsDefaultCert": {
        "Url": "https://localhost:5004"
      }
    },
    "Certificates": {
      "Default": {
        "Path": "<path to .pfx file>",
        "Password": "$CREDENTIAL_PLACEHOLDER$"
      }
    }
  }
}
```

> **⚠ Warning**
>
> In the preceding example, the certificate password is stored in plain-text in `appsettings.json`. The `$CREDENTIAL_PLACEHOLDER$` token is used as a placeholder for the certificate's password. To store certificate passwords securely in development environments, see Protect secrets in development. To store certificate passwords

securely in production environments, see Azure Key Vault configuration provider. Development secrets shouldn't be used for production or test.

Schema notes

- Endpoint names are case-insensitive. For example, `HTTPS` and `Https` are equivalent.
- The `Url` parameter is required for each endpoint. The format for this parameter is the same as the top-level `Urls` configuration parameter except that it's limited to a single value. See URL formats earlier in this article.
- These endpoints replace the ones defined in the top-level `Urls` configuration rather than adding to them. Endpoints defined in code via `Listen` are cumulative with the endpoints defined in the configuration section.
- The `Certificate` section is optional. If the `Certificate` section isn't specified, the defaults defined in `Certificates:Default` are used. If no defaults are available, the development certificate is used. If there are no defaults and the development certificate isn't present, the server throws an exception and fails to start.
- The `Certificate` section supports multiple certificate sources.
- Any number of endpoints may be defined in `Configuration`, as long as they don't cause port conflicts.

Certificate sources

Certificate nodes can be configured to load certificates from a number of sources:

- `Path` and `Password` to load *.pfx* files.
- `Path`, `KeyPath` and `Password` to load *.pem*/*.crt* and *.key* files.
- `Subject` and `Store` to load from the certificate store.

For example, the `Certificates:Default` certificate can be specified as:

JSON

```
"Default": {
  "Subject": "<subject; required>",
  "Store": "<cert store; required>",
  "Location": "<location; defaults to CurrentUser>",
  "AllowInvalid": "<true or false; defaults to false>"
}
```

Configure client certificates in appsettings.json

ClientCertificateMode is used to configure client certificate behavior.

JSON

```
{
  "Kestrel": {
    "Endpoints": {
      "MyHttpsEndpoint": {
        "Url": "https://localhost:5001",
        "ClientCertificateMode": "AllowCertificate",
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "$CREDENTIAL_PLACEHOLDER$"
        }
      }
    }
  }
}
```

> ⚠ **Warning**
>
> In the preceding example, the certificate password is stored in plain-text in `appsettings.json`. The `$CREDENTIAL_PLACEHOLDER$` token is used as a placeholder for the certificate's password. To store certificate passwords securely in development environments, see Protect secrets in development. To store certificate passwords securely in production environments, see Azure Key Vault configuration provider. Development secrets shouldn't be used for production or test.

The default value is `ClientCertificateMode.NoCertificate`, where Kestrel doesn't request or require a certificate from the client.

For more information, see Configure certificate authentication in ASP.NET Core.

Configure SSL/TLS protocols in appsettings.json

SSL Protocols are protocols used for encrypting and decrypting traffic between two peers, traditionally a client and a server.

JSON

```
{
  "Kestrel": {
    "Endpoints": {
      "MyHttpsEndpoint": {
        "Url": "https://localhost:5001",
        "SslProtocols": ["Tls12", "Tls13"],
```

```
        "Certificate": {
          "Path": "<path to .pfx file>",
          "Password": "$CREDENTIAL_PLACEHOLDER$"
        }
      }
    }
  }
}
```

> ⚠ **Warning**
>
> In the preceding example, the certificate password is stored in plain-text in `appsettings.json`. The `$CREDENTIAL_PLACEHOLDER$` token is used as a placeholder for the certificate's password. To store certificate passwords securely in development environments, see Protect secrets in development. To store certificate passwords securely in production environments, see Azure Key Vault configuration provider. Development secrets shouldn't be used for production or test.

The default value, `SslProtocols.None`, causes Kestrel to use the operating system defaults to choose the best protocol. Unless you have a specific reason to select a protocol, use the default.

Configure HTTPS in code

When using the `Listen` API, the UseHttps extension method on ListenOptions is available to configure HTTPS.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Listen(IPAddress.Loopback, 5000);
    serverOptions.Listen(IPAddress.Loopback, 5001, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
    });
});
```

`ListenOptions.UseHttps` parameters:

- `filename` is the path and file name of a certificate file, relative to the directory that contains the app's content files.

- `password` is the password required to access the X.509 certificate data.
- `configureOptions` is an `Action` to configure the `HttpsConnectionAdapterOptions`. Returns the `ListenOptions`.
- `storeName` is the certificate store from which to load the certificate.
- `subject` is the subject name for the certificate.
- `allowInvalid` indicates if invalid certificates should be considered, such as self-signed certificates.
- `location` is the store location to load the certificate from.
- `serverCertificate` is the X.509 certificate.

For a complete list of `UseHttps` overloads, see UseHttps.

Configure client certificates in code

ClientCertificateMode configures the client certificate requirements.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ConfigureHttpsDefaults(listenOptions =>
    {
        listenOptions.ClientCertificateMode =
ClientCertificateMode.AllowCertificate;
    });
});
```

The default value is NoCertificate, where Kestrel doesn't request or require a certificate from the client.

For more information, see Configure certificate authentication in ASP.NET Core.

Configure HTTPS defaults in code

ConfigureHttpsDefaults(Action<HttpsConnectionAdapterOptions>) specifies a configuration `Action` to run for each HTTPS endpoint. Calling `ConfigureHttpsDefaults` multiple times replaces prior `Action` instances with the last `Action` specified.

C#

```
var builder = WebApplication.CreateBuilder(args);
```

```
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ConfigureHttpsDefaults(listenOptions =>
    {
        // ...
    });
});
```

> ⓘ **Note**
>
> Endpoints created by calling **Listen** **before** calling **ConfigureHttpsDefaults** won't have the defaults applied.

Configure SSL/TLS protocols in code

SSL protocols are protocols used for encrypting and decrypting traffic between two peers, traditionally a client and a server.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ConfigureHttpsDefaults(listenOptions =>
    {
        listenOptions.SslProtocols = SslProtocols.Tls13;
    });
});
```

Configure TLS cipher suites filter in code

On Linux, CipherSuitesPolicy can be used to filter TLS handshakes on a per-connection basis:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.ConfigureHttpsDefaults(listenOptions =>
    {
        listenOptions.OnAuthenticate = (context, sslOptions) =>
        {
            sslOptions.CipherSuitesPolicy = new CipherSuitesPolicy(
```

```
                new[]
                {
                    TlsCipherSuite.TLS_ECDHE_ECDSA_WITH_AES_128_GCM_SHA256,
                    TlsCipherSuite.TLS_ECDHE_ECDSA_WITH_AES_256_GCM_SHA384,
                    // ...
                });
        };
    });
});
```

Configure Server Name Indication

Server Name Indication (SNI) can be used to host multiple domains on the same IP address and port. SNI can be used to conserve resources by serving multiple sites from one server.

For SNI to function, the client sends the host name for the secure session to the server during the TLS handshake so that the server can provide the correct certificate. The client uses the furnished certificate for encrypted communication with the server during the secure session that follows the TLS handshake.

All websites must run on the same Kestrel instance. Kestrel doesn't support sharing an IP address and port across multiple instances without a reverse proxy.

SNI can be configured in two ways:

- Configure a mapping between host names and HTTPS options in Configuration. For example, JSON in the `appsettings.json` file.
- Create an endpoint in code and select a certificate using the host name with the ServerCertificateSelector callback.

Configure SNI in appsettings.json

Kestrel supports SNI defined in configuration. An endpoint can be configured with an `Sni` object that contains a mapping between host names and HTTPS options. The connection host name is matched to the options and they're used for that connection.

The following configuration adds an endpoint named `MySniEndpoint` that uses SNI to select HTTPS options based on the host name:

JSON

```
{
  "Kestrel": {
    "Endpoints": {
```

```
      "MySniEndpoint": {
        "Url": "https://*",
        "SslProtocols": ["Tls11", "Tls12"],
        "Sni": {
          "a.example.org": {
            "Protocols": "Http1AndHttp2",
            "SslProtocols": ["Tls11", "Tls12", "Tls13"],
            "Certificate": {
              "Subject": "<subject; required>",
              "Store": "<certificate store; required>",
            },
            "ClientCertificateMode" : "NoCertificate"
          },
          "*.example.org": {
            "Certificate": {
              "Path": "<path to .pfx file>",
              "Password": "$CREDENTIAL_PLACEHOLDER$"
            }
          },
          "*": {
            // At least one subproperty needs to exist per SNI section or it
            // cannot be discovered via IConfiguration
            "Protocols": "Http1",
          }
        }
      }
    },
    "Certificates": {
      "Default": {
        "Path": "<path to .pfx file>",
        "Password": "$CREDENTIAL_PLACEHOLDER$"
      }
    }
  }
}
```

> ⚠ **Warning**
>
> In the preceding example, the certificate password is stored in plain-text in `appsettings.json`. The `$CREDENTIAL_PLACEHOLDER$` token is used as a placeholder for the certificate's password. To store certificate passwords securely in development environments, see Protect secrets in development. To store certificate passwords securely in production environments, see Azure Key Vault configuration provider. Development secrets shouldn't be used for production or test.

HTTPS options that can be overridden by SNI:

- `Certificate` configures the certificate source.
- `Protocols` configures the allowed HTTP protocols.

- `SslProtocols` configures the allowed SSL protocols.
- `ClientCertificateMode` configures the client certificate requirements.

The host name supports wildcard matching:

- Exact match. For example, `a.example.org` matches `a.example.org`.
- Wildcard prefix. If there are multiple wildcard matches, then the longest pattern is chosen. For example, `*.example.org` matches `b.example.org` and `c.example.org`.
- Full wildcard. `*` matches everything else, including clients that aren't using SNI and don't send a host name.

The matched SNI configuration is applied to the endpoint for the connection, overriding values on the endpoint. If a connection doesn't match a configured SNI host name, then the connection is refused.

Configure SNI with code

Kestrel supports SNI with several callback APIs:

- `ServerCertificateSelector`
- `ServerOptionsSelectionCallback`
- `TlsHandshakeCallbackOptions`

SNI with `ServerCertificateSelector`

Kestrel supports SNI via the `ServerCertificateSelector` callback. The callback is invoked once per connection to allow the app to inspect the host name and select the appropriate certificate:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ListenAnyIP(5005, listenOptions =>
    {
        listenOptions.UseHttps(httpsOptions =>
        {
            var localhostCert = CertificateLoader.LoadFromStoreCert(
                "localhost", "My", StoreLocation.CurrentUser,
                allowInvalid: true);
            var exampleCert = CertificateLoader.LoadFromStoreCert(
                "example.com", "My", StoreLocation.CurrentUser,
                allowInvalid: true);
            var subExampleCert = CertificateLoader.LoadFromStoreCert(
```

```
                "sub.example.com", "My", StoreLocation.CurrentUser,
                allowInvalid: true);
            var certs = new Dictionary<string, X509Certificate2>(
                StringComparer.OrdinalIgnoreCase)
            {
                ["localhost"] = localhostCert,
                ["example.com"] = exampleCert,
                ["sub.example.com"] = subExampleCert
            };

            httpsOptions.ServerCertificateSelector = (connectionContext,
name) =>
            {
                if (name is not null && certs.TryGetValue(name, out var
cert))
                {
                    return cert;
                }

                return exampleCert;
            };
        });
    });
});
```

SNI with `ServerOptionsSelectionCallback`

Kestrel supports additional dynamic TLS configuration via the `ServerOptionsSelectionCallback` callback. The callback is invoked once per connection to allow the app to inspect the host name and select the appropriate certificate and TLS configuration. Default certificates and `ConfigureHttpsDefaults` aren't used with this callback.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ListenAnyIP(5005, listenOptions =>
    {
        listenOptions.UseHttps(httpsOptions =>
        {
            var localhostCert = CertificateLoader.LoadFromStoreCert(
                "localhost", "My", StoreLocation.CurrentUser,
                allowInvalid: true);
            var exampleCert = CertificateLoader.LoadFromStoreCert(
                "example.com", "My", StoreLocation.CurrentUser,
                allowInvalid: true);
```

```
            listenOptions.UseHttps((stream, clientHelloInfo, state,
cancellationToken) =>
            {
                if (string.Equals(clientHelloInfo.ServerName, "localhost",
                    StringComparison.OrdinalIgnoreCase))
                {
                    return new ValueTask<SslServerAuthenticationOptions>(
                        new SslServerAuthenticationOptions
                        {
                            ServerCertificate = localhostCert,
                            // Different TLS requirements for this host
                            ClientCertificateRequired = true
                        });
                }

                return new ValueTask<SslServerAuthenticationOptions>(
                    new SslServerAuthenticationOptions
                    {
                        ServerCertificate = exampleCert
                    });
            }, state: null!);
        });
    });
});
```

SNI with `TlsHandshakeCallbackOptions`

Kestrel supports additional dynamic TLS configuration via the `TlsHandshakeCallbackOptions.OnConnection` callback. The callback is invoked once per connection to allow the app to inspect the host name and select the appropriate certificate, TLS configuration, and other server options. Default certificates and `ConfigureHttpsDefaults` aren't used with this callback.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.ListenAnyIP(5005, listenOptions =>
    {
        listenOptions.UseHttps(httpsOptions =>
        {
            var localhostCert = CertificateLoader.LoadFromStoreCert(
                "localhost", "My", StoreLocation.CurrentUser,
                allowInvalid: true);
            var exampleCert = CertificateLoader.LoadFromStoreCert(
                "example.com", "My", StoreLocation.CurrentUser,
                allowInvalid: true);
```

```
            listenOptions.UseHttps(new TlsHandshakeCallbackOptions
            {
                OnConnection = context =>
                {
                    if (string.Equals(context.ClientHelloInfo.ServerName,
"localhost",
                        StringComparison.OrdinalIgnoreCase))
                    {
                        // Different TLS requirements for this host
                        context.AllowDelayedClientCertificateNegotation =
true;

                        return new ValueTask<SslServerAuthenticationOptions>
(
                            new SslServerAuthenticationOptions
                            {
                                ServerCertificate = localhostCert
                            });
                    }

                    return new ValueTask<SslServerAuthenticationOptions>(
                        new SslServerAuthenticationOptions
                        {
                            ServerCertificate = exampleCert
                        });
                }
            });
        });
    });
});
```

Configure HTTP protocols

Kestrel supports all commonly used HTTP versions. Endpoints can be configured to support different HTTP versions using the HttpProtocols enum, which specifies available HTTP version options.

TLS is required to support more than one HTTP version. The TLS Application-Layer Protocol Negotiation (ALPN) handshake is used to negotiate the connection protocol between the client and the server when an endpoint supports multiple protocols.

Expand table

`HttpProtocols` value	Connection protocol permitted
`Http1`	HTTP/1.1 only. Can be used with or without TLS.
`Http2`	HTTP/2 only. May be used without TLS only if the client supports a Prior Knowledge mode.

`HttpProtocols` value	Connection protocol permitted
`Http3`	HTTP/3 only. Requires TLS. The client may need to be configured to use HTTP/3 only.
`Http1AndHttp2`	HTTP/1.1 and HTTP/2. HTTP/2 requires the client to select HTTP/2 in the TLS Application-Layer Protocol Negotiation (ALPN) handshake; otherwise, the connection defaults to HTTP/1.1.
`Http1AndHttp2AndHttp3`	HTTP/1.1, HTTP/2 and HTTP/3. The first client request normally uses HTTP/1.1 or HTTP/2, and the alt-svc response header prompts the client to upgrade to HTTP/3. HTTP/2 and HTTP/3 requires TLS; otherwise, the connection defaults to HTTP/1.1.

The default protocol value for an endpoint is `HttpProtocols.Http1AndHttp2`.

TLS restrictions for HTTP/2:

- TLS version 1.2 or later
- Renegotiation disabled
- Compression disabled
- Minimum ephemeral key exchange sizes:
  - Elliptic curve Diffie-Hellman (ECDHE) [RFC4492]: 224 bits minimum
  - Finite field Diffie-Hellman (DHE) [`TLS12`]: 2048 bits minimum
- Cipher suite not prohibited.

`TLS_ECDHE_RSA_WITH_AES_128_GCM_SHA256` [`TLS-ECDHE`] with the P-256 elliptic curve [`FIPS186`] is supported by default.

Configure HTTP protocols in appsettings.json

The following `appsettings.json` example establishes the HTTP/1.1 connection protocol for a specific endpoint:

JSON

```
{
  "Kestrel": {
    "Endpoints": {
      "HttpsDefaultCert": {
        "Url": "https://localhost:5001",
        "Protocols": "Http1"
      }
    }
  }
}
```

A default protocol can be configured in the `Kestrel:EndpointDefaults` section. The following `appsettings.json` example establishes HTTP/1.1 as the default connection protocol for all endpoints:

JSON

```
{
  "Kestrel": {
    "EndpointDefaults": {
      "Protocols": "Http1"
    }
  }
}
```

Protocols specified in code override values set by configuration.

Configure HTTP protocols in code

ListenOptions.Protocols is used to specify protocols with the HttpProtocols enum.

The following example configures an endpoint for HTTP/1.1, HTTP/2, and HTTP/3 connections on port 8000. Connections are secured by TLS with a supplied certificate:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");
        listenOptions.Protocols = HttpProtocols.Http1AndHttp2AndHttp3;
    });
});
```

Configure options for the ASP.NET Core Kestrel web server

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

The Kestrel web server has constraint configuration options that are especially useful in Internet-facing deployments. To configure Kestrel configuration options, call ConfigureKestrel in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    // ...
});
```

Set constraints on the KestrelServerOptions.Limits property. This property holds an instance of the KestrelServerLimits class.

General limits

Keep-alive timeout

KeepAliveTimeout gets or sets the keep-alive timeout:

C#

```
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.KeepAliveTimeout = TimeSpan.FromMinutes(2);
});
```

This timeout is not enforced when a debugger is attached to the Kestrel process.

Maximum client connections

MaxConcurrentConnections gets or sets the maximum number of open connections:

```
C#

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.MaxConcurrentConnections = 100;
});
```

MaxConcurrentUpgradedConnections gets or sets the maximum number of open, upgraded connections:

```
C#

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.MaxConcurrentUpgradedConnections = 100;
});
```

An upgraded connection is one that has been switched from HTTP to another protocol, such as WebSockets. After a connection is upgraded, it isn't counted against the `MaxConcurrentConnections` limit.

Maximum request body size

MaxRequestBodySize gets or sets the maximum allowed size of any request body in bytes.

The recommended approach to override the limit in an ASP.NET Core MVC app is to use the RequestSizeLimitAttribute attribute on an action method:

```
C#

[RequestSizeLimit(100_000_000)]
public IActionResult Get()
```

The following example configures `MaxRequestBodySize` for all requests:

```
C#
```

```
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.MaxRequestBodySize = 100_000_000;
});
```

The following example configures `MaxRequestBodySize` for a specific request using IHttpMaxRequestBodySizeFeature in a custom middleware:

C#

```
app.Use(async (context, next) =>
{
    var httpMaxRequestBodySizeFeature =
context.Features.Get<IHttpMaxRequestBodySizeFeature>();

    if (httpMaxRequestBodySizeFeature is not null)
        httpMaxRequestBodySizeFeature.MaxRequestBodySize = 10 * 1024;

    // ...

    await next(context);
});
```

If the app attempts to configure the limit on a request after it starts to read the request, an exception is thrown. Ue the IHttpMaxRequestBodySizeFeature.IsReadOnly property to check if it's safe to set the `MaxRequestBodySize` property.

When an app runs out-of-process behind the ASP.NET Core Module, IIS sets the limit and Kestrel's request body size limit is disabled.

Minimum request body data rate

Kestrel checks every second if data is arriving at the specified rate in bytes/second. If the rate drops below the minimum, the connection is timed out. The grace period is the amount of time Kestrel allows the client to increase its send rate up to the minimum. The rate isn't checked during that time. The grace period helps avoid dropping connections that are initially sending data at a slow rate because of TCP slow-start. A minimum rate also applies to the response.

MinRequestBodyDataRate gets or sets the request body minimum data rate in bytes/second. MinResponseDataRate gets or sets the response minimum data rate in bytes/second.

The following example configures `MinRequestBodyDataRate` and `MinResponseDataRate` for all requests:

C#

```
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.MinRequestBodyDataRate = new MinDataRate(
        bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    serverOptions.Limits.MinResponseDataRate = new MinDataRate(
        bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
});
```

The following example configures `MinRequestBodyDataRate` and `MinResponseDataRate` for a specific request using IHttpMinRequestBodyDataRateFeature and IHttpMinResponseDataRateFeature in a custom middleware:

C#

```
app.Use(async (context, next) =>
{
    var httpMinRequestBodyDataRateFeature = context.Features
        .Get<IHttpMinRequestBodyDataRateFeature>();

    if (httpMinRequestBodyDataRateFeature is not null)
    {
        httpMinRequestBodyDataRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }

    var httpMinResponseDataRateFeature = context.Features
        .Get<IHttpMinResponseDataRateFeature>();

    if (httpMinResponseDataRateFeature is not null)
    {
        httpMinResponseDataRateFeature.MinDataRate = new MinDataRate(
            bytesPerSecond: 100, gracePeriod: TimeSpan.FromSeconds(10));
    }

    // ...

    await next(context);
});
```

`IHttpMinResponseDataRateFeature` isn't present in HttpContext.Features for HTTP/2 requests. Modifying rate limits on a per-request basis isn't generally supported for HTTP/2 because of the protocol's support for request multiplexing. However, `IHttpMinRequestBodyDataRateFeature` is still present in `HttpContext.Features` for HTTP/2 requests, because the read rate limit can still be *disabled entirely* on a per-request basis by setting IHttpMinResponseDataRateFeature.MinDataRate to `null`, even for an HTTP/2 request. Attempts to read `IHttpMinRequestBodyDataRateFeature.MinDataRate` or attempts

to set it to a value other than `null` result in a NotSupportedException for HTTP/2 requests.

Server-wide rate limits configured via KestrelServerOptions.Limits still apply to both HTTP/1.x and HTTP/2 connections.

Request headers timeout

RequestHeadersTimeout gets or sets the maximum amount of time the server spends receiving request headers:

```
C#

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.RequestHeadersTimeout = TimeSpan.FromMinutes(1);
});
```

This timeout is not enforced when a debugger is attached to the Kestrel process.

HTTP/2 limits

The limits in this section are set on KestrelServerLimits.Http2.

Maximum streams per connection

MaxStreamsPerConnection limits the number of concurrent request streams per HTTP/2 connection. Excess streams are refused:

```
C#

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.MaxStreamsPerConnection = 100;
});
```

Header table size

HeaderTableSize limits the size of the header compression tables, in octets, the HPACK encoder and decoder on the server can use. The HPACK decoder decompresses HTTP headers for HTTP/2 connections:

```
```

C#

```
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.HeaderTableSize = 4096;
});
```

Maximum frame size

MaxFrameSize indicates the size of the largest frame payload that is allowed to be received, in octets:

C#

```
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.MaxFrameSize = 16_384;
});
```

Maximum request header size

MaxRequestHeaderFieldSize indicates the size of the maximum allowed size of a request header field sequence. This limit applies to both name and value sequences in their compressed and uncompressed representations:

C#

```
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.MaxRequestHeaderFieldSize = 8192;
});
```

Initial connection window size

InitialConnectionWindowSize indicates how much request body data the server is willing to receive and buffer at a time aggregated across all requests (streams) per connection:

C#

```
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.InitialConnectionWindowSize = 131_072;
});
```

Requests are also limited by InitialStreamWindowSize.

Initial stream window size

InitialStreamWindowSize indicates how much request body data the server is willing to receive and buffer at a time per stream:

```
C#

builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.Limits.Http2.InitialStreamWindowSize = 98_304;
});
```

Requests are also limited by InitialConnectionWindowSize.

HTTP/2 keep alive ping configuration

Kestrel can be configured to send HTTP/2 pings to connected clients. HTTP/2 pings serve multiple purposes:

- Keep idle connections alive. Some clients and proxy servers close connections that are idle. HTTP/2 pings are considered as activity on a connection and prevent the connection from being closed as idle.
- Close unhealthy connections. Connections where the client doesn't respond to the keep alive ping in the configured time are closed by the server.

There are two configuration options related to HTTP/2 keep alive pings:

- KeepAlivePingDelay is a TimeSpan that configures the ping interval. The server sends a keep alive ping to the client if it doesn't receive any frames for this period of time. Keep alive pings are disabled when this option is set to TimeSpan.MaxValue.
- KeepAlivePingTimeout is a TimeSpan that configures the ping timeout. If the server doesn't receive any frames, such as a response ping, during this timeout then the connection is closed. Keep alive timeout is disabled when this option is set to TimeSpan.MaxValue.

The following example sets `KeepAlivePingDelay` and `KeepAlivePingTimeout`:

```
C#

builder.WebHost.ConfigureKestrel(serverOptions =>
{
```

```
    serverOptions.Limits.Http2.KeepAlivePingDelay =
TimeSpan.FromSeconds(30);
    serverOptions.Limits.Http2.KeepAlivePingTimeout =
TimeSpan.FromMinutes(1);
});
```

Other options

Synchronous I/O

AllowSynchronousIO controls whether synchronous I/O is allowed for the request and response.

> **⚠ Warning**
>
> A large number of blocking synchronous I/O operations can lead to thread pool starvation, which makes the app unresponsive. Only enable `AllowSynchronousIO` when using a library that doesn't support asynchronous I/O.

The following example enables synchronous I/O:

C#

```
builder.WebHost.ConfigureKestrel(serverOptions =>
{
    serverOptions.AllowSynchronousIO = true;
});
```

For information about other Kestrel options and limits, see:

- KestrelServerOptions
- KestrelServerLimits
- ListenOptions

Behavior with debugger attached

Certain timeouts and rate limits aren't enforced when a debugger is attached to a Kestrel process. For more information, see Behavior with debugger attached.

Diagnostics in Kestrel

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Sourabh Shirhatti

This article provides guidance for gathering diagnostics from Kestrel to help troubleshoot issues. Topics covered include:

- **Logging**: Structured logs written to .NET Core logging. ILogger is used by app frameworks to write logs, and by users for their own logging in an app.
- **Metrics**: Representation of data measures over intervals of time, for example, requests per second. Metrics are emitted using `EventCounter` and can be observed using the dotnet-counters command line tool or with Application Insights.
- **DiagnosticSource**: `DiagnosticSource` is a mechanism for production-time logging with rich data payloads for consumption within the process. Unlike logging, which assumes data will leave the process and expects serializable data, `DiagnosticSource` works well with complex data.

Logging

Like most components in ASP.NET Core, Kestrel uses `Microsoft.Extensions.Logging` to emit log information. Kestrel employs the use of multiple categories which allows you to be selective on which logs you listen to.

Expand table

Logging Category Name	Logging Events
`Microsoft.AspNetCore.Server.Kestrel`	`ApplicationError`, `ConnectionHeadResponseBodyWrite`, `ApplicationNeverCompleted`, `RequestBodyStart`, `RequestBodyDone`, `RequestBodyNotEntirelyRead`,

Logging Category Name	Logging Events
	`RequestBodyDrainTimedOut`, `ResponseMinimumDataRateNotSatisfied`, `InvalidResponseHeaderRemoved`, `HeartbeatSlow`
`Microsoft.AspNetCore.Server.Kestrel.BadRequests`	`ConnectionBadRequest`, `RequestProcessingError`, `RequestBodyMinimumDataRateNotSatisfied`
`Microsoft.AspNetCore.Server.Kestrel.Connections`	`ConnectionAccepted`, `ConnectionStart`, `ConnectionStop`, `ConnectionPause`, `ConnectionResume`, `ConnectionKeepAlive`, `ConnectionRejected`, `ConnectionDisconnect`, `NotAllConnectionsClosedGracefully`, `NotAllConnectionsAborted`, `ApplicationAbortedConnection`
`Microsoft.AspNetCore.Server.Kestrel.Http2`	`Http2ConnectionError`, `Http2ConnectionClosing`, `Http2ConnectionClosed`, `Http2StreamError`, `Http2StreamResetAbort`, `HPackDecodingError`, `HPackEncodingError`, `Http2FrameReceived`, `Http2FrameSending`, `Http2MaxConcurrentStreamsReached`
`Microsoft.AspNetCore.Server.Kestrel.Http3`	`Http3ConnectionError`, `Http3ConnectionClosing`, `Http3ConnectionClosed`, `Http3StreamAbort`, `Http3FrameReceived`, `Http3FrameSending`

Connection logging

Kestrel also supports the ability to emit `Debug` level logs for byte-level communication and can be enabled on a per-endpoint basis. To enable connection logging, see configure endpoints for Kestrel

Metrics

Metrics is a representation of data measures over intervals of time, for example, requests per second. Metrics data allows observation of the state of an app at a high-level. Kestrel metrics are emitted using `EventCounter`.

> ⓘ **Note**

The `connections-per-second` and `tls-handshakes-per-second` counters are named incorrectly. The counters:

- Do ***not*** always contain the number of new connections or TLS handshakes per second
- Display the number of new connection or TLS handshakes in the last update interval as requested as the consumer of Events via the `EventCounterIntervalSec` argument in the `filterPayload` to `KestrelEventSource`.

We **recommend** consumers of these counters scale the metric value based on the `DisplayRateTimeScale` of one second.

Expand table

Name	Display Name	Description
`connections-per-second`	Connection Rate	The number of new incoming connections per update interval
`total-connections`	Total Connections	The total number of connections
`tls-handshakes-per-second`	TLS Handshake Rate	The number of new TLS handshakes per update interval
`total-tls-handshakes`	Total TLS Handshakes	The total number of TLS handshakes
`current-tls-handshakes`	Current TLS Handshakes	The number of TLS handshakes in process
`failed-tls-handshakes`	Failed TLS Handshakes	The total number of failed TLS handshakes
`current-connections`	Current Connections	The total number of connections, including idle connections
`connection-queue-length`	Connection Queue Length	The total number connections queued to the thread pool. In a healthy system at steady state, this number should always be close to zero
`request-queue-length`	Request Queue Length	The total number requests queued to the thread pool. In a healthy system at steady state, this number should

Name	Display Name	Description
		always be close to zero. This metric is unlike the IIS/Http.Sys request queue and cannot be compared
`current-upgraded-requests`	Current Upgraded Requests (WebSockets)	The number of active WebSocket requests

DiagnosticSource

Kestrel emits a `DiagnosticSource` event for HTTP requests rejected at server layer such as malformed requests and protocols violations. As such, these requests never make it into the hosting layer of ASP.NET Core.

Kestrel emits these events with the `Microsoft.AspNetCore.Server.Kestrel.BadRequest` event name and an `IFeatureCollection` as the object payload. The underlying exception can be retrieved by accessing the `IBadRequestExceptionFeature` on the feature collection.

Resolving these events is a two-step process. An observer for `DiagnosticListener` must be created:

C#

```
class BadRequestEventListener : IObserver<KeyValuePair<string, object>>,
IDisposable
{
    private readonly IDisposable _subscription;
    private readonly Action<IBadRequestExceptionFeature> _callback;

    public BadRequestEventListener(DiagnosticListener diagnosticListener,
Action<IBadRequestExceptionFeature> callback)
    {
        _subscription = diagnosticListener.Subscribe(this!, IsEnabled);
        _callback = callback;
    }
    private static readonly Predicate<string> IsEnabled = (provider) =>
provider switch
    {
        "Microsoft.AspNetCore.Server.Kestrel.BadRequest" => true,
        _ => false
    };
    public void OnNext(KeyValuePair<string, object> pair)
    {
        if (pair.Value is IFeatureCollection featureCollection)
        {
            var badRequestFeature =
```

```
featureCollection.Get<IBadRequestExceptionFeature>();

            if (badRequestFeature is not null)
            {
                _callback(badRequestFeature);
            }
        }
    }
    public void OnError(Exception error) { }
    public void OnCompleted() { }
    public virtual void Dispose() => _subscription.Dispose();
}
```

Subscribe to the ASP.NET Core `DiagnosticListener` with the observer. In this example, we create a callback that logs the underlying exception.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();
var diagnosticSource = app.Services.GetRequiredService<DiagnosticListener>
();
using var badRequestListener = new BadRequestEventListener(diagnosticSource,
(badRequestExceptionFeature) =>
{
    app.Logger.LogError(badRequestExceptionFeature.Error, "Bad request
received");
});
app.MapGet("/", () => "Hello world");
app.Run();
```

Behavior with debugger attached

Certain timeouts and rate limits aren't enforced when a debugger is attached to a Kestrel process. For more information, see Behavior with debugger attached.

Use HTTP/2 with the ASP.NET Core Kestrel web server

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

HTTP/2 is available for ASP.NET Core apps if the following base requirements are met:

- Operating system
  - Windows Server 2016/Windows 10 or later‡
  - Linux with OpenSSL 1.0.2 or later (for example, Ubuntu 16.04 or later)
  - macOS 10.15 or later
- Target framework: .NET Core 2.2 or later
- Application-Layer Protocol Negotiation (ALPN) connection
- TLS 1.2 or later connection

‡Kestrel has limited support for HTTP/2 on Windows Server 2012 R2 and Windows 8.1. Support is limited because the list of supported TLS cipher suites available on these operating systems is limited. A certificate generated using an Elliptic Curve Digital Signature Algorithm (ECDSA) may be required to secure TLS connections.

If an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`.

Starting with .NET Core 3.0, HTTP/2 is enabled by default. For more information on configuration, see the Kestrel HTTP/2 limits and ListenOptions.Protocols sections.

Advanced HTTP/2 features

Additional HTTP/2 features in Kestrel support gRPC, including support for response trailers and sending reset frames.

Trailers

HTTP Trailers are similar to HTTP Headers, except they are sent after the response body is sent. For IIS and HTTP.sys, only HTTP/2 response trailers are supported.

C#

```
if (httpContext.Response.SupportsTrailers())
{
    httpContext.Response.DeclareTrailer("trailername");

    // Write body
    httpContext.Response.WriteAsync("Hello world");

    httpContext.Response.AppendTrailer("trailername", "TrailerValue");
}
```

In the preceding example code:

- `SupportsTrailers` ensures that trailers are supported for the response.
- `DeclareTrailer` adds the given trailer name to the `Trailer` response header. Declaring a response's trailers is optional, but recommended. If `DeclareTrailer` is called, it must be before the response headers are sent.
- `AppendTrailer` appends the trailer.

Reset

Reset allows for the server to reset a HTTP/2 request with a specified error code. A reset request is considered aborted.

C#

```
var resetFeature = httpContext.Features.Get<IHttpResetFeature>();
resetFeature.Reset(errorCode: 2);
```

`Reset` in the preceding code example specifies the `INTERNAL_ERROR` error code. For more information about HTTP/2 error codes, visit the HTTP/2 specification error code section.

Use HTTP/3 with the ASP.NET Core Kestrel web server

Article • 03/14/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

HTTP/3 is an approved standard and the third major version of HTTP. This article discusses the requirements for HTTP/3. HTTP/3 is fully supported in ASP.NET Core 7.0 and later.

> **Important**
>
> Apps configured to take advantage of HTTP/3 should be designed to also support HTTP/1.1 and HTTP/2.

HTTP/3 requirements

HTTP/3 has different requirements depending on the operating system. If the platform that Kestrel is running on doesn't have all the requirements for HTTP/3, then it's disabled, and Kestrel will fall back to other HTTP protocols.

Windows

- Windows 11 Build 22000 or later OR Windows Server 2022.
- TLS 1.3 or later connection.

Linux

- `libmsquic` package installed.

`libmsquic` is published via Microsoft's official Linux package repository at `packages.microsoft.com`. To install this package:

1. Add the `packages.microsoft.com` repository. See Linux Software Repository for Microsoft Products for instructions.
2. Install the `libmsquic` package using the distro's package manager. For example, `apt install libmsquic=1.9*` on Ubuntu.

Note: .NET 6 is only compatible with the 1.9.x versions of libmsquic. Libmsquic 2.x is not compatible due to breaking changes. Libmsquic receives updates to 1.9.x when needed to incorporate security fixes.

macOS

HTTP/3 isn't currently supported on macOS and may be available in a future release.

Getting started

HTTP/3 is not enabled by default. Add configuration to `Program.cs` to enable HTTP/3.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel((context, options) =>
{
    options.ListenAnyIP(5001, listenOptions =>
    {
        listenOptions.Protocols = HttpProtocols.Http1AndHttp2AndHttp3;
        listenOptions.UseHttps();
    });
});
```

The preceding code configures port 5001 to:

- Use HTTP/3 alongside HTTP/1.1 and HTTP/2 by specifying `HttpProtocols.Http1AndHttp2AndHttp3`.
- Enable HTTPS with `UseHttps`. HTTP/3 requires HTTPS.

Because not all routers, firewalls, and proxies properly support HTTP/3, HTTP/3 should be configured together with HTTP/1.1 and HTTP/2. This can be done by specifying HttpProtocols.Http1AndHttp2AndHttp3 as an endpoint's supported protocols.

For more information, see Configure endpoints for the ASP.NET Core Kestrel web server.

Alt-svc

HTTP/3 is discovered as an upgrade from HTTP/1.1 or HTTP/2 via the alt-svc header. That means the first request will normally use HTTP/1.1 or HTTP/2 before switching to HTTP/3. Kestrel automatically adds the `alt-svc` header if HTTP/3 is enabled.

Localhost testing

- Browsers don't allow self-signed certificates on HTTP/3, such as the Kestrel development certificate.
- `HttpClient` can be used for localhost/loopback testing in .NET 6 or later. Extra configuration is required when using `HttpClient` to make an HTTP/3 request:
  - Set HttpRequestMessage.Version to 3.0, or
  - Set HttpRequestMessage.VersionPolicy to HttpVersionPolicy.RequestVersionOrHigher.

HTTP/3 benefits

HTTP/3 uses the same semantics as HTTP/1.1 and HTTP/2: the same request methods, status codes, and message fields apply to all versions. The differences are in the underlying transport. Both HTTP/1.1 and HTTP/2 use TCP as their transport. HTTP/3 uses a new transport technology developed alongside HTTP/3 called QUIC.

HTTP/3 and QUIC have a number of benefits compared to HTTP/1.1 and HTTP/2:

- Faster response time of the first request. QUIC and HTTP/3 negotiates the connection in fewer round-trips between the client and the server. The first request reaches the server faster.
- Improved experience when there is connection packet loss. HTTP/2 multiplexes multiple requests via one TCP connection. Packet loss on the connection affects all requests. This problem is called "head-of-line blocking". Because QUIC provides native multiplexing, lost packets only impact the requests where data has been lost.
- Supports transitioning between networks. This feature is useful for mobile devices where it is common to switch between WIFI and cellular networks as a mobile device changes location. Currently, HTTP/1.1 and HTTP/2 connections fail with an error when switching networks. An app or web browsers must retry any failed HTTP requests. HTTP/3 allows the app or web browser to seamlessly continue when a network changes. Kestrel doesn't support network transitions in .NET 8. It may be available in a future release.

Connection middleware

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Kestrel supports connection middleware. Connection middleware is software that is assembled into a connection pipeline and runs when Kestrel receives a new connection. Each component:

- Chooses whether to pass the request to the next component in the pipeline.
- Can perform work before and after the next component in the pipeline.

Connection delegates are used to build the connection pipeline. Connection delegates are configured with the ListenOptions.Use method.

Connection middleware is different from ASP.NET Core Middleware. Connection middleware runs per-connection instead of per-request.

Connection logging

Connection logging is connection middleware that is included with ASP.NET Core. Call UseConnectionLogging to emit Debug level logs for byte-level communication on a connection.

Connection logging is helpful for troubleshooting problems in low-level communication, such as during TLS encryption and behind proxies. If `UseConnectionLogging` is placed before `UseHttps`, encrypted traffic is logged. If `UseConnectionLogging` is placed after `UseHttps`, decrypted traffic is logged.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
```

```
    {
        listenOptions.UseConnectionLogging();
    });
});
```

Create custom connection middleware

The following example shows a custom connection middleware that can filter TLS handshakes on a per-connection basis for specific ciphers if necessary. The middleware throws NotSupportedException for any cipher algorithm that the app doesn't support. Alternatively, define and compare ITlsHandshakeFeature.CipherAlgorithm to a list of acceptable cipher suites.

No encryption is used with a CipherAlgorithmType.Null cipher algorithm.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel((context, serverOptions) =>
{
    serverOptions.Listen(IPAddress.Any, 8000, listenOptions =>
    {
        listenOptions.UseHttps("testCert.pfx", "testPassword");

        listenOptions.Use((context, next) =>
        {
            var tlsFeature = context.Features.Get<ITlsHandshakeFeature>()!;

            if (tlsFeature.CipherAlgorithm == CipherAlgorithmType.Null)
            {
                throw new NotSupportedException(
                    $"Prohibited cipher: {tlsFeature.CipherAlgorithm}");
            }

            return next();
        });
    });
});
```

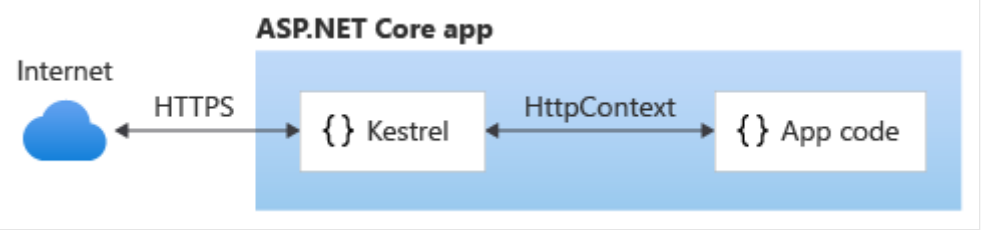
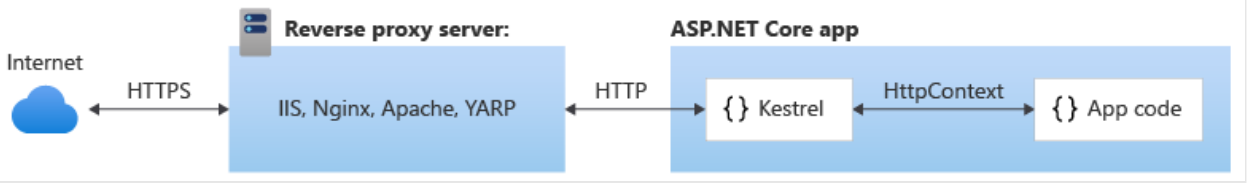
When to use Kestrel with a reverse proxy



Article • 09/27/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.



Kestrel can be used by itself or with a *reverse proxy server*. A reverse proxy server receives HTTP requests from the network and forwards them to Kestrel. Examples of a reverse proxy server include:

- Internet Information Services (IIS)
- Nginx
- Apache
- YARP: Yet Another Reverse Proxy

Kestrel used as an edge (Internet-facing) web server:

Kestrel used in a reverse proxy configuration:

Either configuration, with or without a reverse proxy server, is a supported hosting configuration.

When Kestrel is used as an edge server without a reverse proxy server, sharing of the same IP address and port among multiple processes is unsupported. When Kestrel is configured to listen on a port, Kestrel handles all traffic for that port regardless of

requests' `Host` headers. A reverse proxy that can share ports can forward requests to Kestrel on a unique IP and port.

Even if a reverse proxy server isn't required, using a reverse proxy server might be a good choice.

A reverse proxy:

- Can limit the exposed public surface area of the apps that it hosts.
- Provides an additional layer of configuration and defense-in-depth cybersecurity.
- Might integrate better with existing infrastructure.
- Simplifies load balancing and secure communication (HTTPS) configuration. Only the reverse proxy server requires the X.509 certificate for the public domain(s). That server can communicate with the app's servers on the internal network using plain HTTP or HTTPS with locally managed certificates. Internal HTTPS increases security but adds significant overhead.

> **⚠ Warning**
>
> Hosting in a reverse proxy configuration requires **host filtering**.

Host filtering with ASP.NET Core Kestrel web server

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

While Kestrel supports configuration based on prefixes such as `http://example.com:5000`, Kestrel largely ignores the host name. Host `localhost` is a special case used for binding to loopback addresses. Any host other than an explicit IP address binds to all public IP addresses. `Host` headers aren't validated.

As a workaround, use Host Filtering Middleware. The middleware is added by CreateDefaultBuilder, which calls AddHostFiltering:

C#

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateWebHostBuilder(args).Build().Run();
    }

    public static IWebHostBuilder CreateWebHostBuilder(string[] args) =>
        WebHost.CreateDefaultBuilder(args)
            .UseStartup<Startup>();
}
```

Host Filtering Middleware is disabled by default. To enable the middleware, define an `AllowedHosts` key in `appsettings.json`/`appsettings.{Environment}.json`. The value is a semicolon-delimited list of host names without port numbers:

`appsettings.json`:

JSON

```
{
  "AllowedHosts": "example.com;localhost"
}
```

> **Note**
>
> Forwarded Headers Middleware also has an AllowedHosts option. Forwarded Headers Middleware and Host Filtering Middleware have similar functionality for different scenarios. Setting `AllowedHosts` with Forwarded Headers Middleware is appropriate when the `Host` header isn't preserved while forwarding requests with a reverse proxy server or load balancer. Setting `AllowedHosts` with Host Filtering Middleware is appropriate when Kestrel is used as a public-facing edge server or when the `Host` header is directly forwarded.
>
> For more information on Forwarded Headers Middleware, see Configure ASP.NET Core to work with proxy servers and load balancers.

Request draining with ASP.NET Core Kestrel web server

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Opening HTTP connections is time consuming. For HTTPS, it's also resource intensive. Therefore, Kestrel tries to reuse connections per the HTTP/1.1 protocol. A request body must be fully consumed to allow the connection to be reused. The app doesn't always consume the request body, such as HTTP POST requests where the server returns a redirect or 404 response. In the HTTP POST redirect case:

- The client may already have sent part of the POST data.
- The server writes the 301 response.
- The connection can't be used for a new request until the POST data from the previous request body has been fully read.
- Kestrel tries to drain the request body. Draining the request body means reading and discarding the data without processing it.

The draining process makes a tradeoff between allowing the connection to be reused and the time it takes to drain any remaining data:

- Draining has a timeout of five seconds, which isn't configurable.
- If all of the data specified by the `Content-Length` or `Transfer-Encoding` header hasn't been read before the timeout, the connection is closed.

Sometimes you may want to terminate the request immediately, before or after writing the response. For example, clients may have restrictive data caps. Limiting uploaded data might be a priority. In such cases to terminate a request, call HttpContext.Abort from a controller, Razor Page, or middleware.

There are caveats to calling `Abort`:

- Creating new connections can be slow and expensive.

- There's no guarantee that the client has read the response before the connection closes.
- Calling `Abort` should be rare and reserved for severe error cases, not common errors.
  - Only call `Abort` when a specific problem needs to be solved. For example, call `Abort` if malicious clients are trying to POST data or when there's a bug in client code that causes large or several requests.
  - Don't call `Abort` for common error situations, such as HTTP 404 (Not Found).

Calling HttpResponse.CompleteAsync before calling `Abort` ensures that the server has completed writing the response. However, client behavior isn't predictable and they may not read the response before the connection is aborted.

This process is different for HTTP/2 because the protocol supports aborting individual request streams without closing the connection. The five-second drain timeout doesn't apply. If there's any unread request body data after completing a response, then the server sends an HTTP/2 RST frame. Additional request body data frames are ignored.

If possible, it's better for clients to use the Expect: 100-continue request header and wait for the server to respond before starting to send the request body. That gives the client an opportunity to examine the response and abort before sending unneeded data.

Host ASP.NET Core on Windows with IIS

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Internet Information Services (IIS) is a flexible, secure and manageable Web Server for hosting web apps, including ASP.NET Core.

Supported platforms

The following operating systems are supported:

- Windows 7 or later
- Windows Server 2012 R2 or later

Apps published for 32-bit (x86) or 64-bit (x64) deployment are supported. Deploy a 32-bit app with a 32-bit (x86) .NET Core SDK unless the app:

- Requires the larger virtual memory address space available to a 64-bit app.
- Requires the larger IIS stack size.
- Has 64-bit native dependencies.

Install the ASP.NET Core Module/Hosting Bundle

Download the latest installer using the following link:

Current .NET Core Hosting Bundle installer (direct download)

For more details instructions on how to install the ASP.NET Core Module, or installing different versions, see Install the .NET Core Hosting Bundle.

To download previous versions of the hosting bundle, see this GitHub issue.

Get started

For getting started with hosting a website on IIS, see our getting started guide.

For getting started with hosting a website on Azure App Services, see our deploying to Azure App Service guide.

Configuration

For configuration guidance, see Advanced configuration.

Deployment resources for IIS administrators

- IIS documentation
- Getting Started with the IIS Manager in IIS
- .NET Core application deployment
- ASP.NET Core Module (ANCM) for IIS
- ASP.NET Core directory structure
- IIS modules with ASP.NET Core
- Troubleshoot ASP.NET Core on Azure App Service and IIS
- Common error troubleshooting for Azure App Service and IIS with ASP.NET Core

Overlapped recycle

In general, we recommend using a pattern like blue-green deployments for zero-downtime deployments. Features like Overlapped Recycle help, but don't guarantee that you can do a zero-downtime deployment. For more information, see this GitHub issue.

Optional client certificates

For information on apps that must protect a subset of the app with a certificate, see Optional client certificates.

ASP.NET Core Module (ANCM) for IIS

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

The ASP.NET Core Module (ANCM) is a native IIS module that plugs into the IIS pipeline, allowing ASP.NET Core applications to work with IIS. Run ASP.NET Core apps with IIS by either:

- Hosting an ASP.NET Core app inside of the IIS worker process (`w3wp.exe`), called the in-process hosting model.
- Forwarding web requests to a backend ASP.NET Core app running the Kestrel server, called the out-of-process hosting model.

There are trade-offs between each of the hosting models. By default, the in-process hosting model is used due to better performance and diagnostics.

For more information and configuration guidance, see the following topics:

- Web server implementations in ASP.NET Core

Install ASP.NET Core Module (ANCM)

The ASP.NET Core Module (ANCM) is installed with the .NET Core Runtime from the .NET Core Hosting Bundle. The ASP.NET Core Module is forward and backward compatible with in-support releases of .NET.

Breaking changes and security advisories are reported on the Announcements repo. Announcements can be limited to a specific version by selecting a **Label** filter.

Download the installer using the following link:

Current .NET Core Hosting Bundle installer (direct download)

For more information, including installing an earlier version of the module, see Hosting Bundle.

For a tutorial experience on publishing an ASP.NET Core app to an IIS server, see Publish an ASP.NET Core app to IIS.

Additional resources

In-process hosting with IIS and ASP.NET Core

Article • 07/31/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

In-process hosting runs an ASP.NET Core app in the same process as its IIS worker process. In-process hosting provides improved performance over out-of-process hosting because requests aren't proxied over the loopback adapter, a network interface that returns outgoing network traffic back to the same machine.

The following diagram illustrates the relationship between IIS, the ASP.NET Core Module, and an app hosted in-process:

Enable in-process hosting

Since ASP.NET Core 3.0, in-process hosting has been enabled by default for all app deployed to IIS.

To explicitly configure an app for in-process hosting, set the value of the `<AspNetCoreHostingModel>` property to `InProcess` in the project file (`.csproj`):

XML

```xml
<PropertyGroup>
  <AspNetCoreHostingModel>InProcess</AspNetCoreHostingModel>
</PropertyGroup>
```

General architecture

The general flow of a request is as follows:

1. A request arrives from the web to the kernel-mode HTTP.sys driver.
2. The driver routes the native request to IIS on the website's configured port, usually 80 (HTTP) or 443 (HTTPS).
3. The ASP.NET Core Module receives the native request and passes it to IIS HTTP Server (`IISHttpServer`). IIS HTTP Server is an in-process server implementation for IIS that converts the request from native to managed.

After the IIS HTTP Server processes the request:

1. The request is sent to the ASP.NET Core middleware pipeline.
2. The middleware pipeline handles the request and passes it on as an `HttpContext` instance to the app's logic.
3. The app's response is passed back to IIS through IIS HTTP Server.
4. IIS sends the response to the client that initiated the request.

`CreateDefaultBuilder` adds an IServer instance by calling the UseIIS method to boot the CoreCLR and host the app inside of the IIS worker process (`w3wp.exe` or `iisexpress.exe`). Performance tests indicate that hosting a .NET Core app in-process delivers significantly higher request throughput compared to hosting the app out-of-process and proxying requests to Kestrel.

Apps published as a single file executable can't be loaded by the in-process hosting model.

Application configuration

To configure IIS options, include a service configuration for IISServerOptions in `Program.cs`. The following example disables AutomaticAuthentication:

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Server.IIS;
using Microsoft.EntityFrameworkCore;
using RPauth.Data;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
```

```
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();

builder.Services.Configure<IISServerOptions>(options =>
{
    options.AutomaticAuthentication = false;
});

builder.Services.AddTransient<IClaimsTransformation, MyClaimsTransformation>
();
builder.Services.AddAuthentication(IISServerDefaults.AuthenticationScheme);

builder.Services.AddRazorPages();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Expand table

Option	Default	Setting
`AutomaticAuthentication`	`true`	If `true`, IIS Server sets the `HttpContext.User` authenticated by Windows Authentication. If `false`, the server only provides an identity for `HttpContext.User` and responds to challenges when explicitly requested by the `AuthenticationScheme`. Windows Authentication

Option	Default	Setting
		must be enabled in IIS for `AutomaticAuthentication` to function. For more information, see Windows Authentication.
`AuthenticationDisplayName`	`null`	Sets the display name shown to users on login pages.
`AllowSynchronousIO`	`false`	Whether synchronous I/O is allowed for the `HttpContext.Request` and the `HttpContext.Response`.
`MaxRequestBodySize`	`30000000`	Gets or sets the max request body size for the `HttpRequest`. Note that IIS itself has the limit `maxAllowedContentLength` which will be processed before the `MaxRequestBodySize` set in the `IISServerOptions`. Changing the `MaxRequestBodySize` won't affect the `maxAllowedContentLength`. To increase `maxAllowedContentLength`, add an entry in the `web.config` to set `maxAllowedContentLength` to a higher value. For more details, see Configuration.

Differences between in-process and out-of-process hosting

The following characteristics apply when hosting in-process:

- IIS HTTP Server (`IISHttpServer`) is used instead of Kestrel server. For in-process, CreateDefaultBuilder calls UseIIS to:
  - Register the `IISHttpServer`.
  - Configure the port and base path the server should listen on when running behind the ASP.NET Core Module.
  - Configure the host to capture startup errors.
- The requestTimeout attribute doesn't apply to in-process hosting.
- Sharing an app pool among apps isn't supported. Use one app pool per app.
- The architecture (bitness) of the app and installed runtime (x64 or x86) must match the architecture of the app pool. For example, apps published for 32-bit (x86) must have 32-bit enabled for their IIS Application Pools. For more information, see the Create the IIS site section.
- Client disconnects are detected. The HttpContext.RequestAborted cancellation token is cancelled when the client disconnects.

- When hosting in-process, AuthenticateAsync isn't called internally to initialize a user. Therefore, an IClaimsTransformation implementation used to transform claims after every authentication isn't activated by default. When transforming claims with an IClaimsTransformation implementation, call AddAuthentication to add authentication services:

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Identity;
using Microsoft.AspNetCore.Server.IIS;
using Microsoft.EntityFrameworkCore;
using RPauth.Data;

var builder = WebApplication.CreateBuilder(args);

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();

builder.Services.Configure<IISServerOptions>(options =>
{
    options.AutomaticAuthentication = false;
});

builder.Services.AddTransient<IClaimsTransformation, MyClaimsTransformation>
();
builder.Services.AddAuthentication(IISServerDefaults.AuthenticationScheme);

builder.Services.AddRazorPages();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseMigrationsEndPoint();
}
else
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();
```

```
app.UseAuthentication();
app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

- Web Package (single-file) deployments aren't supported.

Out-of-process hosting with IIS and ASP.NET Core

Article • 07/31/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Because ASP.NET Core apps run in a process separate from the IIS worker process, the ASP.NET Core Module handles process management. The module starts the process for the ASP.NET Core app when the first request arrives and restarts the app if it shuts down or crashes. This is essentially the same behavior as seen with apps that run in-process that are managed by the Windows Process Activation Service (WAS).

The following diagram illustrates the relationship between IIS, the ASP.NET Core Module, and an app hosted out-of-process:

1. Requests arrive from the web to the kernel-mode HTTP.sys driver.
2. The driver routes the requests to IIS on the website's configured port. The configured port is usually 80 (HTTP) or 443 (HTTPS).
3. The module forwards the requests to Kestrel on a random port for the app. The random port isn't 80 or 443.

The ASP.NET Core Module specifies the port via an environment variable at startup. The UseIISIntegration extension configures the server to listen on `http://localhost:{PORT}`. Additional checks are performed, and requests that don't originate from the module are rejected. The module doesn't support HTTPS forwarding. Requests are forwarded over HTTP even if received by IIS over HTTPS.

After Kestrel picks up the request from the module, the request is forwarded into the ASP.NET Core middleware pipeline. The middleware pipeline handles the request and

passes it on as an `HttpContext` instance to the app's logic. Middleware added by IIS Integration updates the scheme, remote IP, and pathbase to account for forwarding the request to Kestrel. The app's response is passed back to IIS, which forwards it back to the HTTP client that initiated the request.

For ASP.NET Core Module configuration guidance, see ASP.NET Core Module (ANCM) for IIS.

For more information on hosting, see Host in ASP.NET Core.

Application configuration

Enable the IISIntegration components

When building a host in `CreateHostBuilder` (`Program.cs`), call CreateDefaultBuilder to enable IIS integration:

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        ...
```

For more information on `CreateDefaultBuilder`, see .NET Generic Host in ASP.NET Core.

Out-of-process hosting model

To configure IIS options, include a service configuration for IISOptions in ConfigureServices. The following example prevents the app from populating `HttpContext.Connection.ClientCertificate`:

C#

```
services.Configure<IISOptions>(options =>
{
    options.ForwardClientCertificate = false;
});
```

Expand table

Option	Default	Setting
`AutomaticAuthentication`	`true`	If `true`, IIS Integration Middleware sets the `HttpContext.User` authenticated by Windows

Option	Default	Setting
		Authentication. If `false`, the middleware only provides an identity for `HttpContext.User` and responds to challenges when explicitly requested by the `AuthenticationScheme`. Windows Authentication must be enabled in IIS for `AutomaticAuthentication` to function. For more information, see the Windows Authentication topic.
`AuthenticationDisplayName`	`null`	Sets the display name shown to users on login pages.
`ForwardClientCertificate`	`true`	If `true` and the `MS-ASPNETCORE-CLIENTCERT` request header is present, the `HttpContext.Connection.ClientCertificate` is populated.

Proxy server and load balancer scenarios

The IIS Integration Middleware and the ASP.NET Core Module are configured to forward the:

- Scheme (HTTP/HTTPS).
- Remote IP address where the request originated.

The IIS Integration Middleware configures Forwarded Headers Middleware.

Additional configuration might be required for apps hosted behind additional proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Out-of-process hosting model

To configure an app for out-of-process hosting, set the value of the `<AspNetCoreHostingModel>` property to `OutOfProcess` in the project file (`.csproj`):

XML

```
<PropertyGroup>
  <AspNetCoreHostingModel>OutOfProcess</AspNetCoreHostingModel>
</PropertyGroup>
```

In-process hosting is set with `InProcess`, which is the default value.

The value of `<AspNetCoreHostingModel>` is case insensitive, so `inprocess` and `outofprocess` are valid values.

Kestrel server is used instead of IIS HTTP Server (`IISHttpServer`).

For out-of-process, CreateDefaultBuilder calls UseIISIntegration to:

- Configure the port and base path the server should listen on when running behind the ASP.NET Core Module.
- Configure the host to capture startup errors.

Process name

`Process.GetCurrentProcess().ProcessName` reports `w3wp`/`iisexpress` (in-process) or `dotnet` (out-of-process).

Many native modules, such as Windows Authentication, remain active. To learn more about IIS modules active with the ASP.NET Core Module, see IIS modules with ASP.NET Core.

The ASP.NET Core Module can also:

- Set environment variables for the worker process.
- Log stdout output to file storage for troubleshooting startup issues.
- Forward Windows authentication tokens.

The .NET Core Hosting Bundle

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

The .NET Core Hosting bundle is an installer for the .NET Core Runtime and the ASP.NET Core Module. The bundle allows ASP.NET Core apps to run with IIS.

Install the .NET Core Hosting Bundle

> **Important**
>
> If the Hosting Bundle is installed before IIS, the bundle installation must be repaired. Run the Hosting Bundle installer again after installing IIS.
>
> If the Hosting Bundle is installed after installing the 64-bit (x64) version of .NET Core, SDKs might appear to be missing (**No .NET Core SDKs were detected**). To resolve the problem, see **Troubleshoot and debug ASP.NET Core projects**.

Breaking changes and security advisories are reported on the Announcements repo. Announcements can be limited to a specific version by selecting a **Label** filter.

Direct download

Download the installer using the following links:

- Current version:.NET Core Hosting Bundle installer (direct download)
- Previous and pre-release versions

Visual C++ Redistributable Requirement

On older versions of Windows, for example Windows Server 2012 R2, install the Visual Studio C++ 2015, 2017, 2019 Redistributable. Otherwise, a confusing error message in the Windows Event Log reports that `The data is the error.`

Current x64 VS C++ redistributable Current x86 VS C++ redistributable

Earlier versions of the installer

To obtain an earlier version of the installer:

1. Navigate to the Download .NET Core page.
2. Select the desired .NET Core version.
3. In the **Run apps - Runtime** column, find the row of the .NET Core runtime version desired.
4. Download the installer using the **Hosting Bundle** link.

> ⚠ **Warning**
>
> Some installers contain release versions that have reached their end of life (EOL) and are no longer supported by Microsoft. For more information, see the **support policy**.
>
> The **ASP.NET Core Module** is forward and backward compatible with **in-support releases of .NET**.

Options

1. The following parameters are available when running the installer from an administrator command shell:

   - `OPT_NO_ANCM=1`: Skip installing the ASP.NET Core Module.
   - `OPT_NO_RUNTIME=1`: Skip installing the .NET Core runtime. Used when the server only hosts self-contained deployments (SCD).
   - `OPT_NO_SHAREDFX=1`: Skip installing the ASP.NET Shared Framework (ASP.NET runtime). Used when the server only hosts self-contained deployments (SCD).
   - `OPT_NO_X86=1`: Skip installing x86 runtimes. Use this parameter when you know that you won't be hosting 32-bit apps. If there's any chance that you will host both 32-bit and 64-bit apps in the future, don't use this parameter and install both runtimes.

- `OPT_NO_SHARED_CONFIG_CHECK=1`: Disable the check for using an IIS Shared Configuration when the shared configuration (`applicationHost.config`) is on the same machine as the IIS installation. *Only available for ASP.NET Core 2.2 or later Hosting Bundler installers.* For more information, see Advanced configuration.

> **Note**
>
> For information on IIS Shared Configuration, see **ASP.NET Core Module with IIS Shared Configuration**.

> **Note**
>
> When running the Hosting Bundle installer with options set, the value for each option is saved in the registry. Subsequent installs from the same Major.Minor version band use the same options, unless another set of options is explicitly passed from the command line. If the first install of the hosting bundle has no options passed, each option gets a default value of `0` written in to the registry. A value of `0` implies that the option is off, meaning the user is not opting out of the given component.

Restart IIS

After the Hosting Bundle is installed, a manual IIS restart may be required. For example, the `dotnet` CLI tooling (command) might not exist on the PATH for running IIS worker processes.

To manually restart IIS, stop the Windows Process Activation Service (WAS) and then restart the World Wide Web Publishing Service (W3SVC) and any dependent services. Execute the following commands in an elevated command shell:

Console

```
net stop was /y
net start w3svc
```

Module version and Hosting Bundle installer logs

To determine the version of the installed ASP.NET Core Module:

1. On the hosting system, navigate to `%PROGRAMFILES%\IIS\Asp.Net Core Module\V2`.
2. Locate the `aspnetcorev2.dll` file.
3. Right-click the file and select **Properties** from the contextual menu.
4. Select the **Details** tab. The **File version** and **Product version** represent the installed version of the module.

The Hosting Bundle installer logs for the module are found at `C:\Users\%UserName%\AppData\Local\Temp`. The file is named `dd_DotNetCoreWinSvrHosting__{TIMESTAMP}_000_AspNetCoreModule_x64.log`, where the placeholder `{TIMESTAMP}` is the timestamp of the file.

`web.config` file

Article • 07/31/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

The `web.config` is a file that is read by IIS and the ASP.NET Core Module to configure an app hosted with IIS.

`web.config` file location

In order to set up the ASP.NET Core Module correctly, the `web.config` file must be present at the content root path (typically the app base path) of the deployed app. This is the same location as the website physical path provided to IIS. The `web.config` file is required at the root of the app to enable the publishing of multiple apps using Web Deploy.

Sensitive files exist on the app's physical path, such as `{ASSEMBLY}.runtimeconfig.json`, `{ASSEMBLY}.xml` (XML Documentation comments), and `{ASSEMBLY}.deps.json`, where the placeholder `{ASSEMBLY}` is the assembly name. When the `web.config` file is present and the site starts normally, IIS doesn't serve these sensitive files if they're requested. If the `web.config` file is missing, incorrectly named, or unable to configure the site for normal startup, IIS may serve sensitive files publicly.

The `web.config` file must be present in the deployment at all times, correctly named, and able to configure the site for normal start up. Never remove the `web.config` file from a production deployment.

If a `web.config` file isn't present in the project, the file is created with the correct `processPath` and `arguments` to configure the ASP.NET Core Module and moved to published output.

If a `web.config` file is present in the project, the file is transformed with the correct `processPath` and `arguments` to configure the ASP.NET Core Module and moved to

published output. The transformation doesn't modify IIS configuration settings in the file.

The `web.config` file may provide additional IIS configuration settings that control active IIS modules. For information on IIS modules that are capable of processing requests with ASP.NET Core apps, see the IIS modules topic.

Creating, transforming, and publishing the `web.config` file is handled by an MSBuild target (`_TransformWebConfig`) when the project is published. This target is present in the Web SDK targets (`Microsoft.NET.Sdk.Web`). The SDK is set at the top of the project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

To prevent the Web SDK from transforming the `web.config` file, use the `<IsTransformWebConfigDisabled>` property in the project file:

XML

```
<PropertyGroup>
  <IsTransformWebConfigDisabled>true</IsTransformWebConfigDisabled>
</PropertyGroup>
```

When disabling the Web SDK from transforming the file, the `processPath` and `arguments` should be manually set by the developer. For more information, see ASP.NET Core Module (ANCM) for IIS.

Configuration of ASP.NET Core Module with `web.config`

The ASP.NET Core Module is configured with the `aspNetCore` section of the `system.webServer` node in the site's `web.config` file.

The following `web.config` file is published for a framework-dependent deployment and configures the ASP.NET Core Module to handle site requests:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
```

```
      <handlers>
        <add name="aspNetCore" path="*" verb="*"
modules="AspNetCoreModuleV2" resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath="dotnet"
                  arguments=".\MyApp.dll"
                  stdoutLogEnabled="false"
                  stdoutLogFile=".\logs\stdout"
                  hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

The following `web.config` is published for a self-contained deployment:

XML

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <handlers>
        <add name="aspNetCore" path="*" verb="*"
modules="AspNetCoreModuleV2" resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath=".\MyApp.exe"
                  stdoutLogEnabled="false"
                  stdoutLogFile=".\logs\stdout"
                  hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

The InheritInChildApplications property is set to `false` to indicate that the settings specified within the <location> element aren't inherited by apps that reside in a subdirectory of the app.

When an app is deployed to Azure App Service, the `stdoutLogFile` path is set to `\\?\%home%\LogFiles\stdout`. The path saves stdout logs to the `LogFiles` folder, which is a location automatically created by the service.

For information on IIS sub-application configuration, see Advanced configuration.

Attributes of the `aspNetCore` element

Expand table

Attribute	Description	Default
`arguments`	Optional string attribute. Arguments to the executable specified in `processPath`.	
`disableStartUpErrorPage`	Optional Boolean attribute. If true, the **502.5 - Process Failure** page is suppressed, and the 502 status code page configured in the `web.config` takes precedence.	`false`
`forwardWindowsAuthToken`	Optional Boolean attribute. If true, the token is forwarded to the child process listening on `%ASPNETCORE_PORT%` as a header 'MS-ASPNETCORE-WINAUTHTOKEN' per request. It's the responsibility of that process to call CloseHandle on this token per request.	`true`
`hostingModel`	Optional string attribute. Specifies the hosting model as in-process (`InProcess`/`inprocess`) or out-of-process (`OutOfProcess`/`outofprocess`).	`OutOfProcess`/`outofprocess` when not present
`processesPerApplication`	Optional integer attribute. Specifies the number of instances of the process specified in the `processPath` setting that can be spun up per app. †For in-process hosting, the value is limited to `1`. Setting `processesPerApplication` is discouraged. This attribute will be removed in a future release.	Default: `1` Min: `1` Max: `100`†
`processPath`	Required string attribute. Path to the executable that launches a process listening for HTTP requests. Relative paths are supported. If the path begins with `.`, the path is	

Attribute	Description	Default
	considered to be relative to the site root.	
`rapidFailsPerMinute`	Optional integer attribute. Specifies the number of times the process specified in `processPath` is allowed to crash per minute. If this limit is exceeded, the module stops launching the process for the remainder of the minute. Not supported with in-process hosting.	Default: `10` Min: `0` Max: `100`
`requestTimeout`	Optional timespan attribute. Specifies the duration for which the ASP.NET Core Module waits for a response from the process listening on %ASPNETCORE_PORT%. In versions of the ASP.NET Core Module that shipped with the release of ASP.NET Core 2.1 or later, the `requestTimeout` is specified in hours, minutes, and seconds. Doesn't apply to in-process hosting. For in-process hosting, the module waits for the app to process the request. Valid values for minutes and seconds segments of the string are in the range 0-59. Use of `60` in the value for minutes or seconds results in a *500 - Internal Server Error*.	Default: `00:02:00` Min: `00:00:00` Max: `360:00:00`
`shutdownTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to gracefully shutdown when the `app_offline.htm` file is detected.	Default: `10` Min: `0` Max: `600`
`startupTimeLimit`	Optional integer attribute. Duration in seconds that the module waits for the executable to start a process listening on the port. If this	Default: `120` Min: `0` Max: `3600`

Attribute	Description	Default
	time limit is exceeded, the module kills the process. When hosting *in-process*: The process is **not** restarted and does **not** use the `rapidFailsPerMinute` setting. When hosting *out-of-process*: The module attempts to relaunch the process when it receives a new request and continues to attempt to restart the process on subsequent incoming requests unless the app fails to start `rapidFailsPerMinute` number of times in the last rolling minute. A value of 0 (zero) is **not** considered an infinite timeout.	
`stdoutLogEnabled`	Optional Boolean attribute. If true, `stdout` and `stderr` for the process specified in `processPath` are redirected to the file specified in `stdoutLogFile`.	`false`
`stdoutLogFile`	Optional string attribute. Specifies the relative or absolute file path for which `stdout` and `stderr` from the process specified in `processPath` are logged. Relative paths are relative to the root of the site. Any path starting with `.` are relative to the site root and all other paths are treated as absolute paths. Any folders provided in the path are created by the module when the log file is created. Using underscore delimiters, a timestamp, process ID, and file extension (`.log`) are added to the last segment of the `stdoutLogFile` path. If `.\logs\stdout` is supplied as a value, an example stdout log is saved as `stdout_20180205194132_1934.log` in the `logs` folder when saved on February 5, 2018 at 19:41:32 with a process ID of 1934.	`aspnetcore-stdout`

Set environment variables

Environment variables can be specified for the process in the `processPath` attribute. Specify an environment variable with the `<environmentVariable>` child element of an `<environmentVariables>` collection element. Environment variables set in this section take precedence over system environment variables.

The following example sets two environment variables in `web.config`. `ASPNETCORE_ENVIRONMENT` configures the app's environment to `Development`. A developer may temporarily set this value in the `web.config` file in order to force the Developer Exception Page to load when debugging an app exception. `CONFIG_DIR` is an example of a user-defined environment variable, where the developer has written code that reads the value on startup to form a path for loading the app's configuration file.

XML

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="inprocess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development"
/>
    <environmentVariable name="CONFIG_DIR" value="f:\application_config" />
  </environmentVariables>
</aspNetCore>
```

> **Note**
>
> An alternative to setting the environment directly in `web.config` is to include the `<EnvironmentName>` property in the publish profile (.pubxml) or project file. This approach sets the environment in `web.config` when the project is published:
>
> XML
>
> ```
> <PropertyGroup>
>   <EnvironmentName>Development</EnvironmentName>
> </PropertyGroup>
> ```

> **Warning**

> Only set the `ASPNETCORE_ENVIRONMENT` environment variable to `Development` on staging and testing servers that aren't accessible to untrusted networks, such as the Internet.

Configuration of IIS with `web.config`

IIS configuration is influenced by the `<system.webServer>` section of `web.config` for IIS scenarios that are functional for ASP.NET Core apps with the ASP.NET Core Module. For example, IIS configuration is functional for dynamic compression. If IIS is configured at the server level to use dynamic compression, the `<urlCompression>` element in the app's `web.config` file can disable it for an ASP.NET Core app.

For more information, see the following topics:

- Configuration reference for <system.webServer>
- ASP.NET Core Module (ANCM) for IIS
- IIS modules with ASP.NET Core

To set environment variables for individual apps running in isolated app pools (supported for IIS 10.0 or later), see the *`AppCmd.exe` command* section of the Environment Variables <environmentVariables> topic in the IIS reference documentation.

Configuration sections of `web.config`

Configuration sections of ASP.NET 4.x apps in `web.config` aren't used by ASP.NET Core apps for configuration:

- `<system.web>`
- `<appSettings>`
- `<connectionStrings>`
- `<location>`

ASP.NET Core apps are configured using other configuration providers. For more information, see Configuration.

Transform web.config

If you need to transform `web.config` on publish, see Transform web.config. You might need to transform `web.config` on publish to set environment variables based on the

configuration, profile, or environment.

Development-time IIS support in Visual Studio for ASP.NET Core

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Sourabh Shirhatti

This article describes Visual Studio support for debugging ASP.NET Core apps running with IIS on Windows Server. This topic walks through enabling this scenario and setting up a project.

Prerequisites

- Visual Studio for Windows
- **ASP.NET and web development** workload
- **.NET Core cross-platform development** workload
- X.509 security certificate (for HTTPS support)

Enable IIS

1. In Windows, navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Select the **Internet Information Services** checkbox. Select **OK**.

The IIS installation may require a system restart.

Configure IIS

IIS must have a website configured with the following:

- **Host name**: Typically, the **Default Web Site** is used with a **Host name** of `localhost`. However, any valid IIS website with a unique host name works.

- **Site Binding**
  - For apps that require HTTPS, create a binding to port 443 with a certificate. Typically, the **IIS Express Development Certificate** is used, but any valid certificate works.
  - For apps that use HTTP, confirm the existence of a binding to port 80 or create a binding to port 80 for a new site.
  - Use a single binding for either HTTP or HTTPS. **Binding to both HTTP and HTTPS ports simultaneously isn't supported.**

Configure the project

HTTPS redirection

For a new project that requires HTTPS, select the checkbox to **Configure for HTTPS** in the **Create a new ASP.NET Core Web Application** window. Selecting the checkbox adds HTTPS Redirection and HSTS Middleware to the app when it's created.

For an existing project that requires HTTPS, use HTTPS Redirection and HSTS Middleware in `Startup.Configure`. For more information, see Enforce HTTPS in ASP.NET Core.

For a project that uses HTTP, HTTPS Redirection and HSTS Middleware aren't added to the app. No app configuration is required.

IIS launch profile

Create a new launch profile to add development-time IIS support:

1. Right-click the project in **Solution Explorer**. Select **Properties**. Open the **Debug** tab.

2. For **Profile**, select the **New** button. Name the profile "IIS" in the popup window. Select **OK** to create the profile.

3. For the **Launch** setting, select **IIS** from the list.

4. Select the checkbox for **Launch browser** and provide the endpoint URL.

   When the app requires HTTPS, use an HTTPS endpoint (`https://`). For HTTP, use an HTTP (`http://`) endpoint.

Provide the same host name and port as the IIS configuration specified earlier uses, typically `localhost`.

Provide the name of the app at the end of the URL.

For example, `https://localhost/WebApplication1` (HTTPS) or `http://localhost/WebApplication1` (HTTP) are valid endpoint URLs.

5. In the **Environment variables** section, select the **Add** button. Provide an environment variable with a **Name** of `ASPNETCORE_ENVIRONMENT` and a **Value** of `Development`.

6. In the **Web Server Settings** area, set the **App URL** to the same value used for the **Launch browser** endpoint URL.

7. For the **Hosting Model** setting in Visual Studio 2019 or later, select **Default** to use the hosting model used by the project. If the project sets the `<AspNetCoreHostingModel>` property in its project file, the value of the property (`InProcess` or `OutOfProcess`) is used. If the property isn't present, the default hosting model of the app is used, which is in-process. If the app requires an explicit hosting model setting different from the app's normal hosting model, set the **Hosting Model** to either `In Process` or `Out Of Process` as needed.

8. Save the profile.

When not using Visual Studio, manually add a launch profile to the launchSettings.json file in the *Properties* folder. The following example configures the profile to use the HTTPS protocol:

JSON

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iis": {
      "applicationUrl": "https://localhost/WebApplication1",
      "sslPort": 0
    }
  },
  "profiles": {
    "IIS": {
      "commandName": "IIS",
      "launchBrowser": true,
      "launchUrl": "https://localhost/WebApplication1",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development"
```

```
      }
    }
  }
}
```

Confirm that the `applicationUrl` and `launchUrl` endpoints match and use the same protocol as the IIS binding configuration, either HTTP or HTTPS.

Run the project

Run Visual Studio as an administrator:

- Confirm that the build configuration drop-down list is set to **Debug**.
- Set the Start Debugging button to the **IIS** profile and select the button to start the app.

Visual Studio may prompt a restart if not running as an administrator. If prompted, restart Visual Studio.

If an untrusted development certificate is used, the browser may require you to create an exception for the untrusted certificate.

> **Note**
>
> Debugging a Release build configuration with Just My Code and compiler optimizations results in a degraded experience. For example, break points aren't hit.

IIS modules with ASP.NET Core

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Some of the native IIS modules and all of the IIS managed modules aren't able to process requests for ASP.NET Core apps. In many cases, ASP.NET Core offers an alternative to the scenarios addressed by IIS native and managed modules.

Native modules

The table indicates native IIS modules that are functional with ASP.NET Core apps and the ASP.NET Core Module.

Expand table

Module	Functional with ASP.NET Core apps	ASP.NET Core Option
Anonymous Authentication `AnonymousAuthenticationModule`	Yes	
Basic Authentication `BasicAuthenticationModule`	Yes	
Client Certification Mapping Authentication `CertificateMappingAuthenticationModule`	Yes	
CGI `CgiModule`	No	
Configuration Validation `ConfigurationValidationModule`	Yes	
HTTP Errors `CustomErrorModule`	No	Status Code Pages Middleware

Module	Functional with ASP.NET Core apps	ASP.NET Core Option
Custom Logging `CustomLoggingModule`	Yes	
Default Document `DefaultDocumentModule`	No	Default Files Middleware
Digest Authentication `DigestAuthenticationModule`	Yes	
Directory Browsing `DirectoryListingModule`	No	Directory Browsing Middleware
Dynamic Compression `DynamicCompressionModule`	Yes	Response Compression Middleware
Failed Requests Tracing `FailedRequestsTracingModule`	Yes	ASP.NET Core Logging
File Caching `FileCacheModule`	No	Response Caching Middleware
HTTP Caching `HttpCacheModule`	No	Response Caching Middleware
HTTP Logging `HttpLoggingModule`	Yes	ASP.NET Core Logging
HTTP Redirection `HttpRedirectionModule`	Yes	URL Rewriting Middleware
HTTP Tracing `TracingModule`	Yes	
IIS Client Certificate Mapping Authentication `IISCertificateMappingAuthenticationModule`	Yes	
IP and Domain Restrictions `IpRestrictionModule`	Yes	
ISAPI Filters `IsapiFilterModule`	Yes	Middleware
ISAPI `IsapiModule`	Yes	Middleware
Protocol Support `ProtocolSupportModule`	Yes	

Module	Functional with ASP.NET Core apps	ASP.NET Core Option
Request Filtering `RequestFilteringModule`	Yes	URL Rewriting Middleware IRule
Request Monitor `RequestMonitorModule`	Yes	
URL Rewriting† `RewriteModule`	Yes	URL Rewriting Middleware
Server-Side Includes `ServerSideIncludeModule`	No	
Static Compression `StaticCompressionModule`	No	Response Compression Middleware
Static Content `StaticFileModule`	No	Static File Middleware
Token Caching `TokenCacheModule`	Yes	
URI Caching `UriCacheModule`	Yes	
URL Authorization `UrlAuthorizationModule`	Yes	ASP.NET Core Identity
WebDav `WebDAV`	No	
Windows Authentication `WindowsAuthenticationModule`	Yes	

†The URL Rewrite Module's `isFile` and `isDirectory` match types don't work with ASP.NET Core apps due to the changes in directory structure.

Managed modules

Managed modules are *not* functional with hosted ASP.NET Core apps when the app pool's .NET CLR version is set to **No Managed Code**. ASP.NET Core offers middleware alternatives in several cases.

Expand table

Module	ASP.NET Core Option
AnonymousIdentification	
DefaultAuthentication	
FileAuthorization	
FormsAuthentication	Cookie Authentication Middleware
OutputCache	Response Caching Middleware
Profile	
RoleManager	
ScriptModule-4.0	
Session	Session Middleware
UrlAuthorization	
UrlMappingsModule	URL Rewriting Middleware
UrlRoutingModule-4.0	ASP.NET Core Identity
WindowsAuthentication	

IIS Manager application changes

When using IIS Manager to configure settings, the *web.config* file of the app is changed. If deploying an app and including *web.config*, any changes made with IIS Manager are overwritten by the deployed *web.config* file. If changes are made to the server's *web.config* file, copy the updated *web.config* file on the server to the local project immediately.

Disabling IIS modules

If an IIS module is configured at the server level that must be disabled for an app, an addition to the app's *web.config* file can disable the module. Either leave the module in place and deactivate it using a configuration setting (if available) or remove the module from the app.

Module deactivation

Many modules offer a configuration setting that allows them to be disabled without removing the module from the app. This is the simplest and quickest way to deactivate a module. For example, the HTTP Redirection Module can be disabled with the `<httpRedirect>` element in *web.config*:

XML

```
<configuration>
  <system.webServer>
    <httpRedirect enabled="false" />
  </system.webServer>
</configuration>
```

For more information on disabling modules with configuration settings, follow the links in the *Child Elements* section of IIS <system.webServer>.

Module removal

If opting to remove a module with a setting in *web.config*, unlock the module and unlock the `<modules>` section of *web.config* first:

1. Unlock the module at the server level. Select the IIS server in the IIS Manager **Connections** sidebar. Open the **Modules** in the **IIS** area. Select the module in the list. In the **Actions** sidebar on the right, select **Unlock**. If the action entry for the module appears as **Lock**, the module is already unlocked, and no action is required. Unlock as many modules as you plan to remove from *web.config* later.

2. Deploy the app without a `<modules>` section in *web.config*. If an app is deployed with a *web.config* containing the `<modules>` section without having unlocked the section first in the IIS Manager, the Configuration Manager throws an exception when attempting to unlock the section. Therefore, deploy the app without a `<modules>` section.

3. Unlock the `<modules>` section of *web.config*. In the **Connections** sidebar, select the website in **Sites**. In the **Management** area, open the **Configuration Editor**. Use the navigation controls to select the `system.webServer/modules` section. In the **Actions** sidebar on the right, select to **Unlock** the section. If the action entry for the module section appears as **Lock Section**, the module section is already unlocked, and no action is required.

4. Add a `<modules>` section to the app's local *web.config* file with a `<remove>` element to remove the module from the app. Add multiple `<remove>` elements to remove multiple modules. If *web.config* changes are made on the server, immediately make

the same changes to the project's *web.config* file locally. Removing a module using this approach doesn't affect the use of the module with other apps on the server.

```
XML

<configuration>
 <system.webServer>
   <modules>
     <remove name="MODULE_NAME" />
   </modules>
 </system.webServer>
</configuration>
```

In order to add or remove modules for IIS Express using *web.config*, modify *applicationHost.config* to unlock the `<modules>` section:

1. Open *{APPLICATION ROOT}\.vs\config\applicationhost.config*.
2. Locate the `<section>` element for IIS modules and change `overrideModeDefault` from `Deny` to `Allow`:

   ```
   XML

   <section name="modules"
            allowDefinition="MachineToApplication"
            overrideModeDefault="Allow" />
   ```

3. Locate the `<location path="" overrideMode="Allow"><system.webServer><modules>` section. For any modules that you wish to remove, set `lockItem` from `true` to `false`. In the following example, the CGI Module is unlocked:

   ```
   XML

   <add name="CgiModule" lockItem="false" />
   ```

4. After the `<modules>` section and individual modules are unlocked, you're free to add or remove IIS modules using the app's *web.config* file for running the app on IIS Express.

An IIS module can also be removed with *Appcmd.exe*. Provide the `MODULE_NAME` and `APPLICATION_NAME` in the command:

```
Console
```

```
Appcmd.exe delete module MODULE_NAME /app.name:APPLICATION_NAME
```

For example, remove the `DynamicCompressionModule` from the Default Web Site:

Console

```
%windir%\system32\inetsrv\appcmd.exe delete module DynamicCompressionModule
/app.name:"Default Web Site"
```

Minimum module configuration

The only modules required to run an ASP.NET Core app are the Anonymous Authentication Module and the ASP.NET Core Module.

The URI Caching Module (`UriCacheModule`) allows IIS to cache website configuration at the URL level. Without this module, IIS must read and parse configuration on every request, even when the same URL is repeatedly requested. Parsing the configuration every request results in a significant performance penalty. *Although the URI Caching Module isn't strictly required for a hosted ASP.NET Core app to run, we recommend that the URI Caching Module be enabled for all ASP.NET Core deployments.*

The HTTP Caching Module (`HttpCacheModule`) implements the IIS output cache and also the logic for caching items in the HTTP.sys cache. Without this module, content is no longer cached in kernel mode, and cache profiles are ignored. Removing the HTTP Caching Module usually has adverse effects on performance and resource usage. *Although the HTTP Caching Module isn't strictly required for a hosted ASP.NET Core app to run, we recommend that the HTTP Caching Module be enabled for all ASP.NET Core deployments.*

IIS log creation and redirection

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

The ASP.NET Core Module redirects stdout and stderr console output to disk if the `stdoutLogEnabled` and `stdoutLogFile` attributes of the `aspNetCore` element are set. Any folders in the `stdoutLogFile` path are created by the module when the log file is created. The app pool must have write access to the location where the logs are written (use `IIS AppPool\{APP POOL NAME}` to provide write permission, where the placeholder `{APP POOL NAME}` is the app pool name).

Logs aren't rotated, unless process recycling/restart occurs. It's the responsibility of the hoster to limit the disk space the logs consume.

Using the stdout log is only recommended for troubleshooting app startup issues when hosting on IIS or when using development-time support for IIS with Visual Studio, not while debugging locally and running the app with IIS Express.

Don't use the stdout log for general app logging purposes. For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

A timestamp and file extension are added automatically when the log file is created. The log file name is composed by appending the timestamp, process ID, and file extension (`.log`) to the last segment of the `stdoutLogFile` path (typically `stdout`) delimited by underscores. If the `stdoutLogFile` path ends with `stdout`, a log for an app with a PID of 1934 created on 2/5/2018 at 19:42:32 has the file name `stdout_20180205194132_1934.log`.

If `stdoutLogEnabled` is false, errors that occur on app startup are captured and emitted to the event log up to 30 KB. After startup, all additional logs are discarded.

The following sample `aspNetCore` element configures stdout logging at the relative path `.\log\`. Confirm that the AppPool user identity has permission to write to the path

provided.

XML

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="true"
    stdoutLogFile=".\logs\stdout"
    hostingModel="inprocess">
</aspNetCore>
```

When publishing an app for Azure App Service deployment, the Web SDK sets the `stdoutLogFile` value to `\\?\%home%\LogFiles\stdout`. The `%home` environment variable is predefined for apps hosted by Azure App Service.

To create logging filter rules, see the Apply log filter rules in code section of the ASP.NET Core logging documentation.

For more information on path formats, see File path formats on Windows systems.

Enhanced diagnostic logs

The ASP.NET Core Module is configurable to provide enhanced diagnostics logs. Add the `<handlerSettings>` element to the `<aspNetCore>` element in `web.config`. Setting the `debugLevel` to `TRACE` exposes a higher fidelity of diagnostic information:

XML

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="false"
    stdoutLogFile="\\?\%home%\LogFiles\stdout"
    hostingModel="inprocess">
  <handlerSettings>
    <handlerSetting name="debugFile" value=".\logs\aspnetcore-debug.log" />
    <handlerSetting name="debugLevel" value="FILE,TRACE" />
  </handlerSettings>
</aspNetCore>
```

Any folders in the path (`logs` in the preceding example) are created by the module when the log file is created. The app pool must have write access to the location where the logs are written (use `IIS AppPool\{APP POOL NAME}` to provide write permission, where the placeholder `{APP POOL NAME}` is the app pool name).

Debug level (`debugLevel`) values can include both the level and the location.

Levels (in order from least to most verbose):

- ERROR
- WARNING
- INFO
- TRACE

Locations (multiple locations are permitted):

- CONSOLE
- EVENTLOG
- FILE

The handler settings can also be provided via environment variables:

- `ASPNETCORE_MODULE_DEBUG_FILE`: Path to the debug log file. (Default: `aspnetcore-debug.log`)
- `ASPNETCORE_MODULE_DEBUG`: Debug level setting.

> ⚠ **Warning**
>
> Do **not** leave debug logging enabled in the deployment for longer than required to troubleshoot an issue. The size of the log isn't limited. Leaving the debug log enabled can exhaust the available disk space and crash the server or app service.

See Configuration of ASP.NET Core Module with web.config for an example of the `aspNetCore` element in the `web.config` file.

Troubleshoot ASP.NET Core on Azure App Service and IIS

Article • 09/27/2024

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, the ASP.NET Core project default server is Kestrel. Visual studio can be configured to use IIS Express. A *502.5 - Process Failure* or a *500.30 - Start Failure* that occurs when debugging locally with IIS Express can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:

    - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
    - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.
    - When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.

3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module (ANCM) for IIS.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

This error also may occur when the .NET Core Hosting Bundle isn't installed or is corrupted. Installing or repairing the installation of the .NET Core Hosting Bundle (for IIS) or Visual Studio (for IIS Express) may fix the problem.

500.0 In-Process Handler Load Failure

The worker process fails. The app doesn't start.

An unknown error occurred loading ASP.NET Core Module components. Take one of the following actions:

- Contact Microsoft Support (select **Developer Tools** then **ASP.NET Core**).
- Ask a question on Stack Overflow.
- File an issue on our GitHub repository.

500.30 In-Process Startup Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core CLR in-process, but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

Common failure conditions:

- The app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine.
- Using Azure Key Vault, lack of permissions to the Key Vault. Check the access policies in the targeted Key Vault to ensure that the correct permissions are granted.

500.31 ANCM Failed to Find Native Dependencies

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core runtime in-process, but it fails to start. The most common cause of this startup failure is when the `Microsoft.NETCore.App` or `Microsoft.AspNetCore.App` runtime isn't installed. If the app is deployed to target ASP.NET Core 3.0 and that version doesn't exist on the machine, this error occurs. An example error message follows:

```
```

```
The specified framework 'Microsoft.NETCore.App', version '3.0.0' was not
found.
  - The following frameworks were found:
      2.2.1 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview5-27626-15 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27713-13 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27714-15 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27723-08 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
```

The error message lists all the installed .NET Core versions and the version requested by the app. To fix this error, either:

- Install the appropriate version of .NET Core on the machine.
- Change the app to target a version of .NET Core that's present on the machine.
- Publish the app as a self-contained deployment.

When running in development (the `ASPNETCORE_ENVIRONMENT` environment variable is set to `Development`), the specific error is written to the HTTP response. The cause of a process startup failure is also found in the Application Event Log.

500.32 ANCM Failed to Load dll

The worker process fails. The app doesn't start.

The most common cause for this error is that the app is published for an incompatible processor architecture. If the worker process is running as a 32-bit app and the app was published to target 64-bit, this error occurs.

To fix this error, either:

- Republish the app for the same processor architecture as the worker process.
- Publish the app as a framework-dependent deployment.

500.33 ANCM Request Handler Load Failure

The worker process fails. The app doesn't start.

The app didn't reference the `Microsoft.AspNetCore.App` framework. Only apps targeting the `Microsoft.AspNetCore.App` framework can be hosted by the ASP.NET Core Module.

To fix this error, confirm that the app is targeting the `Microsoft.AspNetCore.App` framework. Check the `.runtimeconfig.json` to verify the framework targeted by the app.

500.34 ANCM Mixed Hosting Models Not Supported

The worker process can't run both an in-process app and an out-of-process app in the same process.

To fix this error, run apps in separate IIS application pools.

500.35 ANCM Multiple In-Process Applications in same Process

The worker process can't run multiple in-process apps in the same process.

To fix this error, run apps in separate IIS application pools.

500.36 ANCM Out-Of-Process Handler Load Failure

The out-of-process request handler, *aspnetcorev2_outofprocess.dll*, isn't next to the *aspnetcorev2.dll* file. This indicates a corrupted installation of the ASP.NET Core Module.

To fix this error, repair the installation of the .NET Core Hosting Bundle (for IIS) or Visual Studio (for IIS Express).

500.37 ANCM Failed to Start Within Startup Time Limit

ANCM failed to start within the provided startup time limit. By default, the timeout is 120 seconds.

This error can occur when starting a large number of apps on the same machine. Check for CPU/Memory usage spikes on the server during startup. You may need to stagger the startup process of multiple apps.

500.38 ANCM Application DLL Not Found

ANCM failed to locate the application DLL, which should be next to the executable.

This error occurs when hosting an app packaged as a single-file executable using the in-process hosting model. The in-process model requires that the ANCM load the .NET Core app into the existing IIS process. This scenario isn't supported by the single-file

deployment model. Use **one** of the following approaches in the app's project file to fix this error:

1. Disable single-file publishing by setting the `PublishSingleFile` MSBuild property to `false`.
2. Switch to the out-of-process hosting model by setting the `AspNetCoreHostingModel` MSBuild property to `OutOfProcess`.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.

2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:

    - If deploying a 32-bit (x86) app, set the value to `True`.
    - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Failed to start application (ErrorCode '0x800701b1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/3/ROOT', ErrorCode '0x800701b1'.
```

The app failed to start because a Windows Service failed to load.

One common service that needs to be enabled is the "null" service. The following command enables the `null` Windows Service:

Windows Command Prompt

```
sc.exe start null
```

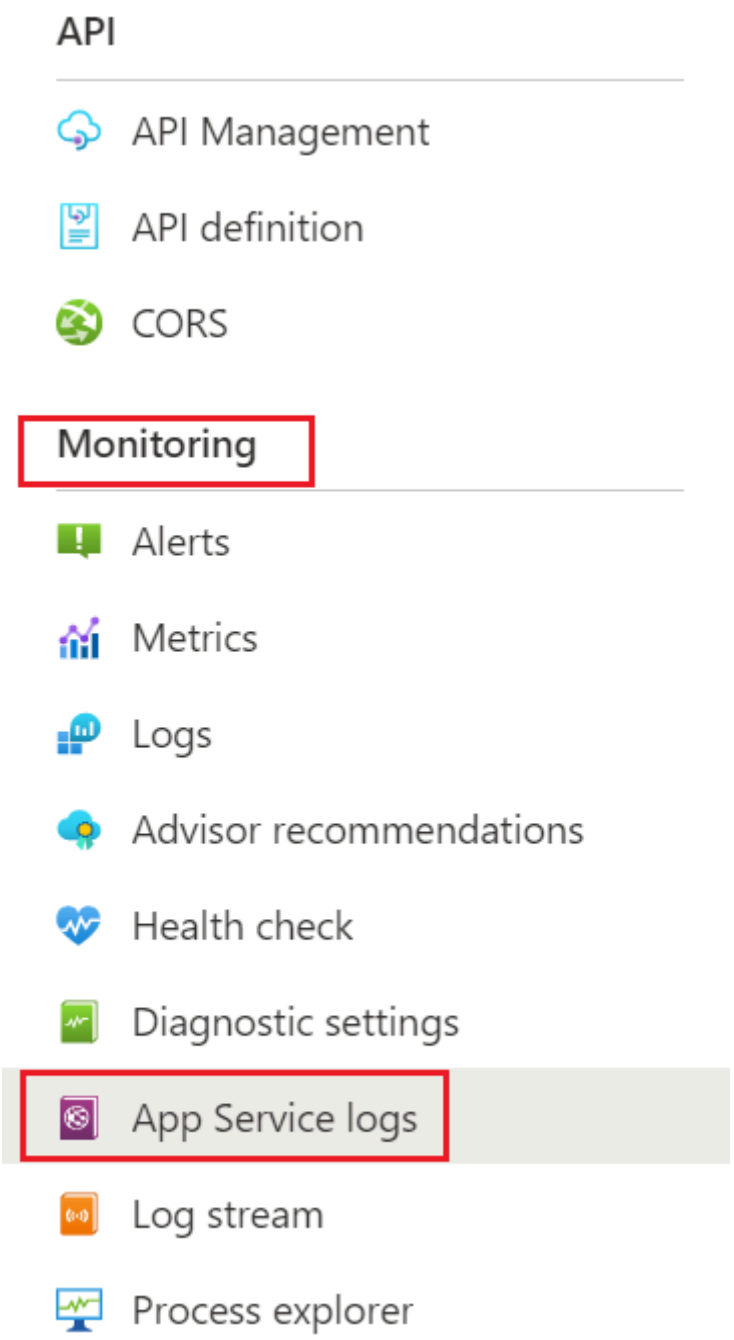
Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

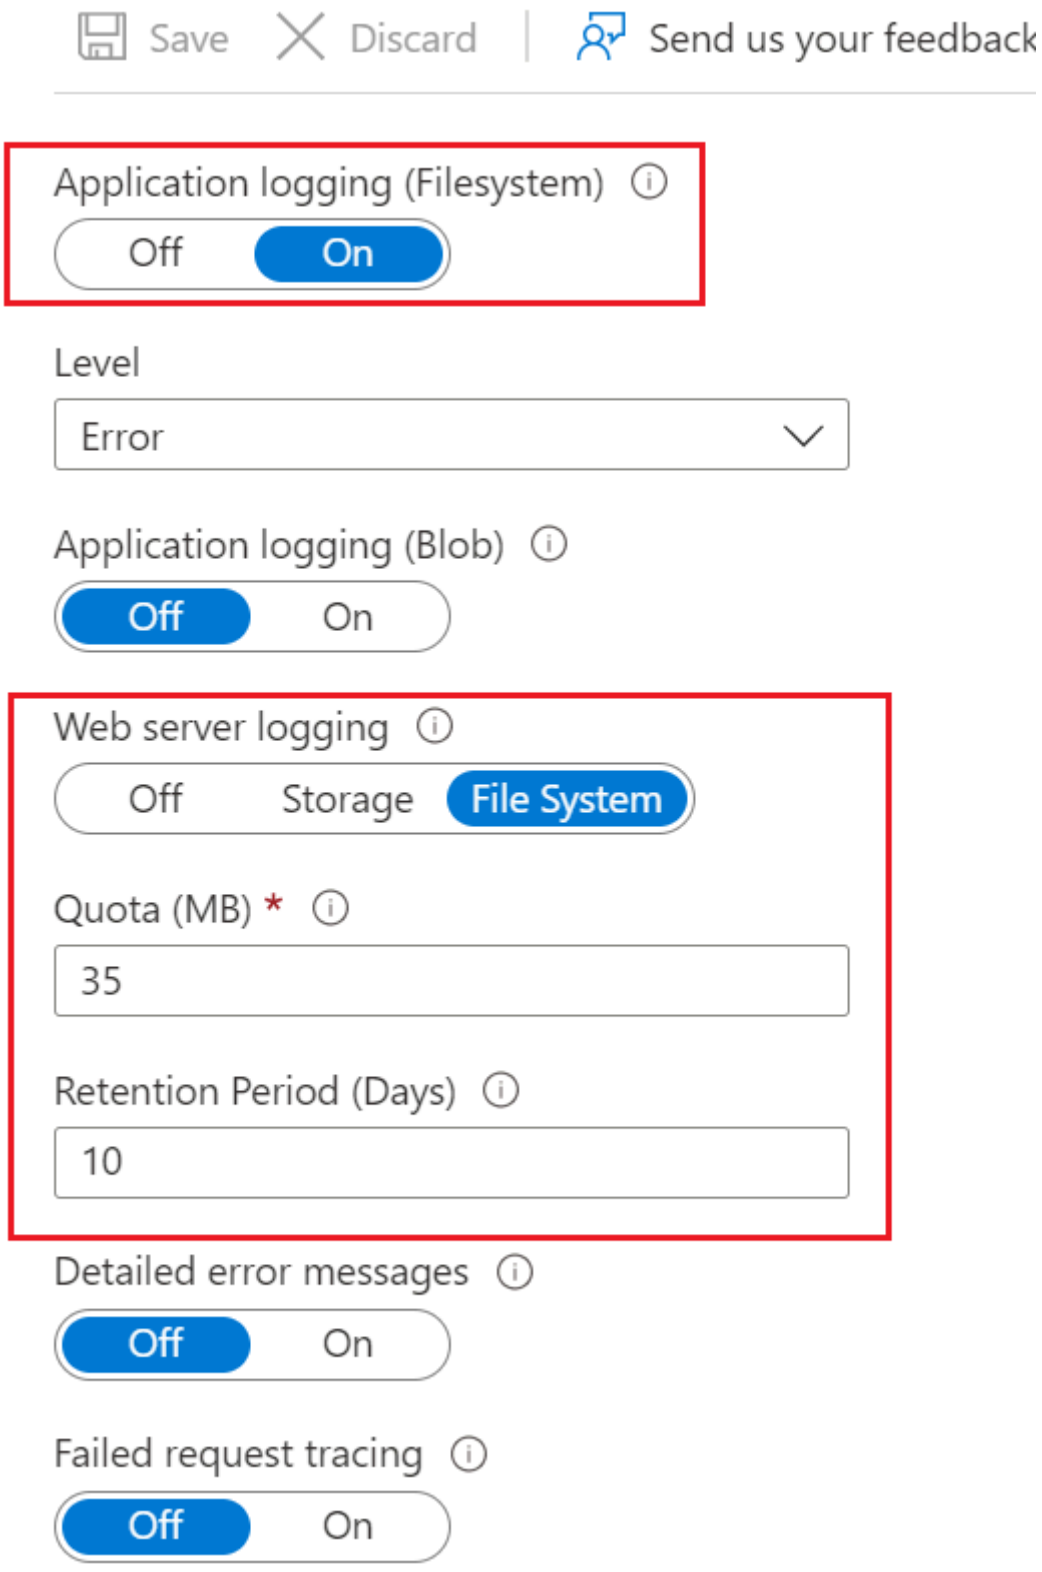
The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service



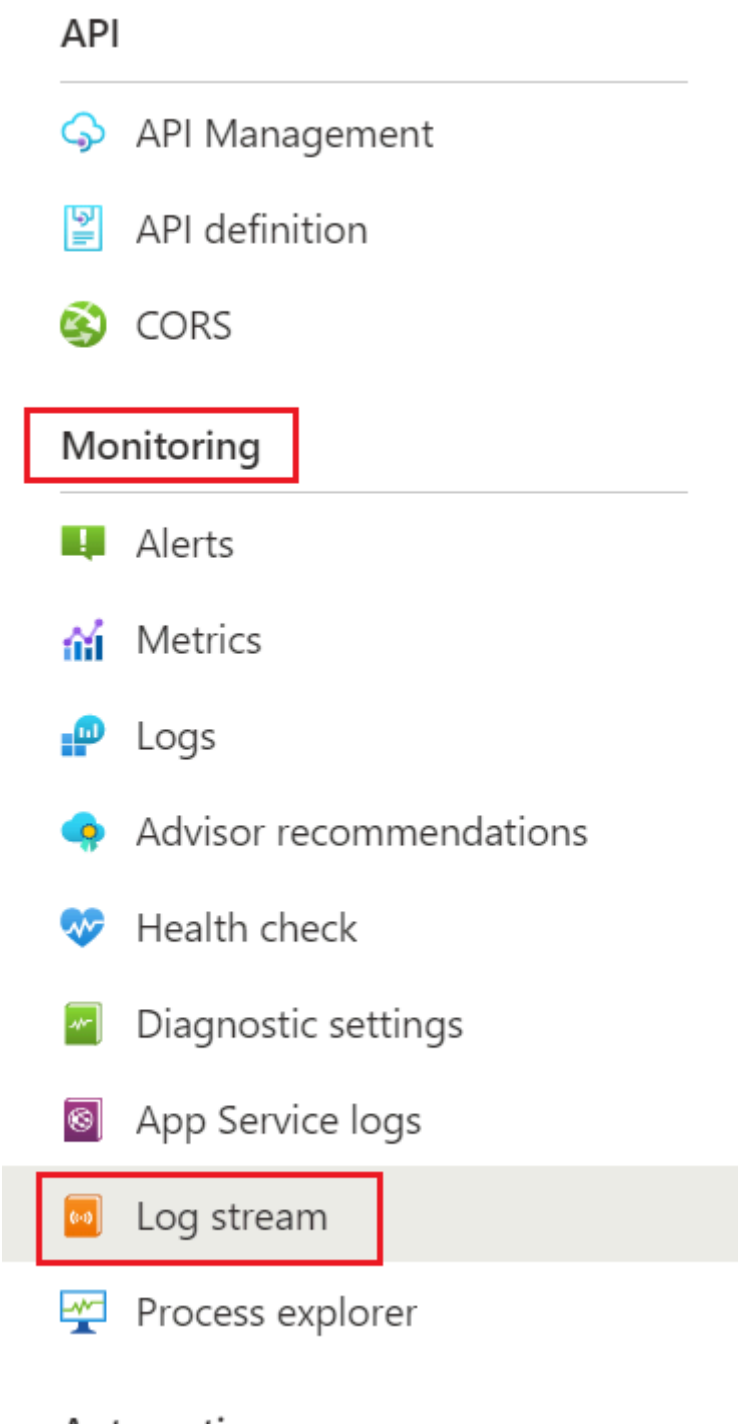
> **Important**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Azure App Services Log stream

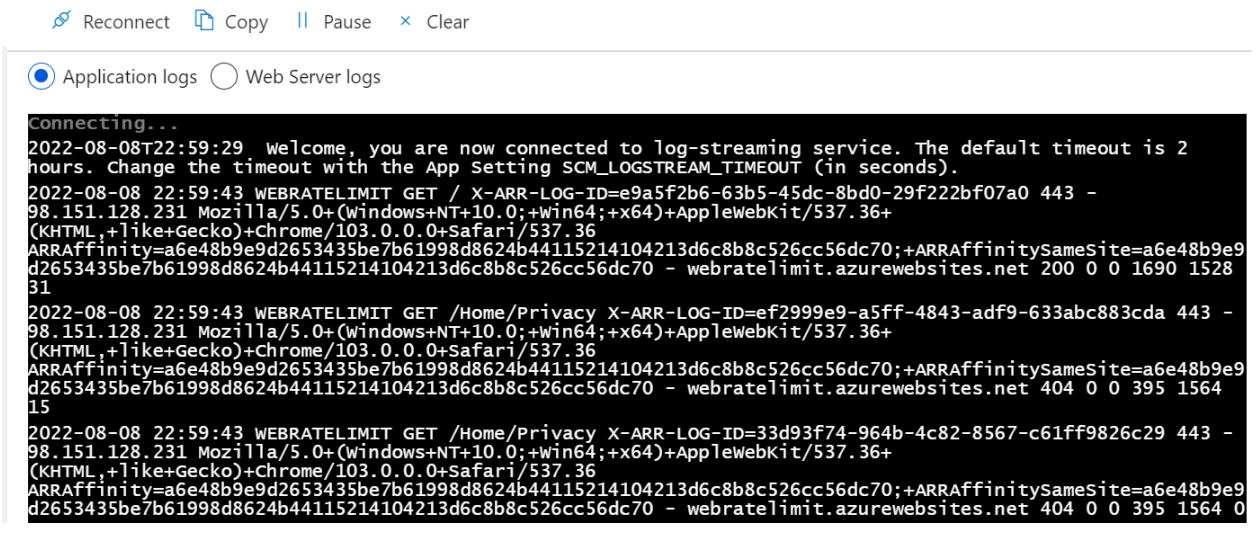


The Azure App Services Log streams logging information as it occurs. To view streaming logs:

1. In the Azure portal, open the app in **App Services**.



2. In the left pane, navigate to **Monitoring** > **App Service Logs**.



3. Select **File System** for **Web Server Logging**. Optionally enable **Application logging**.

4. In the left pane, navigate to **Monitoring** > **Log stream**, and then select **Application logs** or **Web Server Logs**.

The following images shows the application logs output:

Streaming logs have some latency and might not display immediately.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.
2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go** → button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the `eventlog.xml` file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go** → button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:

- If the app is a framework-dependent deployment:

  .NET CLI

  ```
  dotnet .\{ASSEMBLY NAME}.dll
  ```

- If the app is a self-contained deployment:

  Console

  ```
  {ASSEMBLY NAME}.exe
  ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:

  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

- If the app is a self-contained deployment:

  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

> ⚠ **Warning**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. In the Azure Portal, navigate to the web app.
2. In the **App Service** blade, enter **kudu** in the search box.
3. Select **Advanced Tools** > **Go**.
4. Select **Debug console** > **CMD**.
5. Navigate to *site/wwwroot*
6. Select the pencil icon to edit the *web.config* file.
7. In the `<aspNetCore />` element, set `stdoutLogEnabled="true"` and select **Save**.

Disable stdout logging when troubleshooting is complete by setting `stdoutLogEnabled="false"`.

For more information, see ASP.NET Core Module (ANCM) for IIS.

ASP.NET Core Module debug log (Azure App Service)

The ASP.NET Core Module debug log provides additional, deeper logging from the ASP.NET Core Module. To enable and view stdout logs:

1. To enable the enhanced diagnostic log, perform either of the following:

- Follow the instructions in Enhanced diagnostic logs to configure the app for an enhanced diagnostic logging. Redeploy the app.
- Add the `<handlerSettings>` shown in Enhanced diagnostic logs to the live app's *web.config* file using the Kudu console:
  a. Open **Advanced Tools** in the **Development Tools** area. Select the **Go**→ button. The Kudu console opens in a new browser tab or window.
  b. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
  c. Open the folders to the path **site** > **wwwroot**. Edit the *web.config* file by selecting the pencil button. Add the `<handlerSettings>` section as shown in Enhanced diagnostic logs. Select the **Save** button.

2. Open **Advanced Tools** in the **Development Tools** area. Select the **Go**→ button. The Kudu console opens in a new browser tab or window.
3. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
4. Open the folders to the path **site** > **wwwroot**. If you didn't supply a path for the *aspnetcore-debug.log* file, the file appears in the list. If you supplied a path, navigate to the location of the log file.
5. Open the log file with the pencil button next to the file name.

Disable debug logging when troubleshooting is complete:

To disable the enhanced debug log, perform either of the following:

- Remove the `<handlerSettings>` from the *web.config* file locally and redeploy the app.
- Use the Kudu console to edit the *web.config* file and remove the `<handlerSettings>` section. Save the file.

For more information, see Log creation and redirection with the ASP.NET Core Module.

> ⚠ **Warning**
>
> Failure to disable the debug log can lead to app or server failure. There's no limit on log file size. Only use debug logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or nonresponsive app (Azure App Service)

When an app responds slowly or doesn't respond to a request, see Troubleshoot slow web app performance issues in Azure App Service.

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.
2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.
4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go**→ button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.

5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> ⚠ **Warning**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`).

`stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.

4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.
3. Save the file.

For more information, see ASP.NET Core Module (ANCM) for IIS.

> ⚠ **Warning**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (IIS)

Add the following handler settings to the app's *web.config* file to enable ASP.NET Core Module debug log:

XML

```
<aspNetCore ...>
  <handlerSettings>
    <handlerSetting name="debugLevel" value="file" />
    <handlerSetting name="debugFile" value="c:\temp\ancm.log" />
  </handlerSettings>
</aspNetCore>
```

Confirm that the path specified for the log exists and that the app pool's identity has write permissions to the location.

For more information, see Log creation and redirection with the ASP.NET Core Module.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

XML

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="InProcess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development"
/>
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or non-responding app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.

2. Run the EnableDumps PowerShell script:

   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     Console

     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     Console

     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.

4. After the crash has occurred, run the DisableDumps PowerShell script:

   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     Console

     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     Console

     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> ⚠ **Warning**
>
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App doesn't respond, fails during startup, or runs normally

When an app stops responding but doesn't crash, fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

Common error troubleshooting for Azure App Service and IIS with ASP.NET Core

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This topic describes the most common errors and provides troubleshooting advice when hosting ASP.NET Core apps on Azure Apps Service and IIS.

See Troubleshoot ASP.NET Core on Azure App Service and IIS information on common app startup errors and instructions on how to diagnose errors.

Collect the following information:

- Browser behavior such as status code and error message.
- Application Event Log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS

    1. Select **Start** on the **Windows** menu, type *Event Viewer*, and press **Enter**.
    2. After the **Event Viewer** opens, expand **Windows Logs** > **Application** in the sidebar.

- ASP.NET Core Module stdout and debug log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS: Follow the instructions in the Log creation and redirection and Enhanced diagnostic logs sections of the ASP.NET Core Module topic.

Compare error information to the following common errors. If a match is found, follow the troubleshooting advice.

The list of errors in this topic isn't exhaustive. If you encounter an error not listed here, open a new issue using the **Content feedback** button at the bottom of this topic with detailed instructions on how to reproduce the error.

> ⓘ **Important**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

OS upgrade removed the 32-bit ASP.NET Core Module

Application Log: The Module DLL **C:\WINDOWS\system32\inetsrv\aspnetcore.dll** failed to load. The data is the error.

Troubleshooting:

Non-OS files in the **C:\Windows\SysWOW64\inetsrv** directory aren't preserved during an OS upgrade. If the ASP.NET Core Module is installed prior to an OS upgrade and then any app pool is run in 32-bit mode after an OS upgrade, this issue is encountered. After an OS upgrade, repair the ASP.NET Core Module. See Install the .NET Core Hosting bundle. Select **Repair** when the installer is run.

Missing site extension, 32-bit (x86) and 64-bit (x64) site extensions installed, or wrong process bitness set

Applies to apps hosted by Azure App Services.

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found. Failed to start application '/LM/W3SVC/1416782824/ROOT', ErrorCode '0x8000ffff'.

- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff. Could not find inprocess request handler. It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.

Troubleshooting:

- If running the app on a preview runtime, install either the 32-bit (x86) **or** 64-bit (x64) site extension that matches the bitness of the app and the app's runtime version. **Don't install both extensions or multiple runtime versions of the extension.**
  - ASP.NET Core {RUNTIME VERSION} (x86) Runtime
  - ASP.NET Core {RUNTIME VERSION} (x64) Runtime

  Restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and both the 32-bit (x86) and 64-bit (x64) site extensions are installed, uninstall the site extension that doesn't match the bitness of the app. After removing the site extension, restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and the site extension's bitness matches that of the app, confirm that the preview site extension's *runtime version* matches the app's runtime version.
- Confirm that the app's **Platform** in **Application Settings** matches the bitness of the app.

For more information, see Deploy ASP.NET Core apps to Azure App Service.

An x86 app is deployed but the app pool isn't enabled for 32-bit apps

- **Browser:** HTTP Error 500.30 - ANCM In-Process Start Failure

- **Application Log:** Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' hit unexpected managed exception, exception code = '0xe0434352'. Please check the stderr logs for more information. Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' failed to load clr and managed application. CLR worker thread exited prematurely

- **ASP.NET Core Module stdout Log:** The log file is created but empty.

- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8007023e

This scenario is trapped by the SDK when publishing a self-contained app. The SDK produces an error if the RID doesn't match the platform target (for example, `win10-x64` RID with `<PlatformTarget>x86</PlatformTarget>` in the project file).

Troubleshooting:

For an x86 framework-dependent deployment (`<PlatformTarget>x86</PlatformTarget>`), enable the IIS app pool for 32-bit apps. In IIS Manager, open the app pool's **Advanced Settings** and set **Enable 32-Bit Applications** to **True**.

Platform conflicts with RID

- **Browser:** HTTP Error 502.5 - Process Failure

- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ', ErrorCode = '0x80004005 : ff.

- **ASP.NET Core Module stdout Log:** Unhandled Exception: System.BadImageFormatException: Could not load file or assembly '{ASSEMBLY}.dll'. An attempt was made to load a program with an incorrect format.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

- If this exception occurs for an Azure Apps deployment when upgrading an app and deploying newer assemblies, manually delete all files from the prior deployment. Lingering incompatible assemblies can result in a `System.BadImageFormatException` exception when deploying an upgraded app.

URI endpoint wrong or stopped website

- **Browser:** ERR_CONNECTION_REFUSED **--OR--** Unable to connect
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm the correct URI endpoint for the app is in use. Check the bindings.
- Confirm that the IIS website isn't in the *Stopped* state.

CoreWebEngine or W3SVC server features disabled

OS Exception: The IIS 7.0 CoreWebEngine and W3SVC features must be installed to use the ASP.NET Core Module.

Troubleshooting:

Confirm that the proper role and features are enabled. See IIS Configuration.

Incorrect website physical path or app missing

- **Browser:** 403 Forbidden - Access is denied **--OR--** 403.14 Forbidden - The Web server is configured to not list the contents of this directory.
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Check the IIS website **Basic Settings** and the physical app folder. Confirm that the app is in the folder at the IIS website **Physical path**.

Incorrect role, ASP.NET Core Module not installed, or incorrect permissions

- **Browser:** 500.19 Internal Server Error - The requested page cannot be accessed because the related configuration data for the page is invalid. --**OR**-- This page can't be displayed
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm that the proper role is enabled. See IIS Configuration.
- Open **Programs & Features** or **Apps & features** and confirm that **Windows Server Hosting** is installed. If **Windows Server Hosting** isn't present in the list of installed programs, download and install the .NET Core Hosting Bundle.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.
- Make sure that the **Application Pool** > **Process Model** > **Identity** is set to **ApplicationPoolIdentity** or the custom identity has the correct permissions to access the app's deployment folder.
- If you uninstalled the ASP.NET Core Hosting Bundle and installed an earlier version of the hosting bundle, the *applicationHost.config* file doesn't include a section for the ASP.NET Core Module. Open *applicationHost.config* at *%windir%/System32/inetsrv/config* and find the `<configuration><configSections>` `<sectionGroup name="system.webServer">` section group. If the section for the ASP.NET Core Module is missing from the section group, add the section element:

  ```
  XML
  <section name="aspNetCore" overrideModeDefault="Allow" />
  ```

  Alternatively, install the latest version of the ASP.NET Core Hosting Bundle. The latest version is backwards-compatible with supported ASP.NET Core apps.

Incorrect processPath, missing PATH variable, Hosting Bundle not installed, system/IIS not restarted, VC++ Redistributable not installed, or dotnet.exe access violation

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"{...}" ', ErrorCode = '0x80070002 : 0. Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed to start application '/LM/W3SVC/2/ROOT', ErrorCode '0x8007023e'.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** Event Log: 'Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed HRESULT returned: 0x8007023e

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Check the *processPath* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's `dotnet` for a framework-dependent deployment (FDD) or `.\{ASSEMBLY}.exe` for a self-contained deployment (SCD).
- For an FDD, *dotnet.exe* might not be accessible via the PATH settings. Confirm that *C:\Program Files\dotnet* exists in the System PATH settings.
- For an FDD, *dotnet.exe* might not be accessible for the user identity of the app pool. Confirm that the app pool user identity has access to the *C:\Program Files\dotnet* directory. Confirm that there are no deny rules configured for the app pool user identity on the *C:\Program Files\dotnet* and app directories.
- An FDD may have been deployed and .NET Core installed without restarting IIS. Either restart the server or restart IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.
- An FDD may have been deployed without installing the .NET Core runtime on the hosting system. If the .NET Core runtime hasn't been installed, run the **.NET Core Hosting Bundle installer** on the system.

Current .NET Core Hosting Bundle installer (direct download)

For more information, see Install the .NET Core Hosting Bundle.

If a specific runtime is required, download the runtime from the .NET Downloads page and install it on the system. Complete the installation by restarting the system or restarting IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.

Incorrect arguments of <aspNetCore> element

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed to start application '/LM/W3SVC/3/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed HRESULT returned: 0x8000ffff

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

- Examine the *arguments* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's either (a) `.\{ASSEMBLY}.dll` for a framework-dependent deployment (FDD); or (b) not present, an empty string (`arguments=""`), or a list of the app's arguments (`arguments="{ARGUMENT_1}, {ARGUMENT_2}, ... {ARGUMENT_X}"`) for a self-contained deployment (SCD).

Missing .NET Core shared framework

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.

Failed to start application '/LM/W3SVC/5/ROOT', ErrorCode '0x8000ffff'.

- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.
- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8000ffff

Troubleshooting:

For a framework-dependent deployment (FDD), confirm that the correct runtime installed on the system.

Stopped Application Pool

- **Browser:** 503 Service Unavailable
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Confirm that the Application Pool isn't in the *Stopped* state.

Sub-application includes a <handlers> section

- **Browser:** HTTP Error 500.19 - Internal Server Error
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.
- **ASP.NET Core Module Debug Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.

Troubleshooting:

Confirm that the sub-app's *web.config* file doesn't include a `<handlers>` section or that the sub-app doesn't inherit the parent app's handlers.

The parent app's `<system.webServer>` section of *web.config* is placed inside of a `<location>` element. The InheritInChildApplications property is set to `false` to indicate that the settings specified within the <location> element aren't inherited by apps that reside in a subdirectory of the parent app. For more information, see ASP.NET Core Module (ANCM) for IIS.

stdout log path incorrect

- **Browser:** The app responds normally.
- **Application Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module debug Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core

Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.

Troubleshooting:

- The `stdoutLogFile` path specified in the `<aspNetCore>` element of *web.config* doesn't exist. For more information, see ASP.NET Core Module: Log creation and redirection.
- The app pool user doesn't have write access to the stdout log path.

Application configuration general issue

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure **--OR--** HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Variable
- **ASP.NET Core Module stdout Log:** The log file is created but empty or created with normal entries until the point of the app failing.
- **ASP.NET Core Module Debug Log:** Variable

Troubleshooting:

The process failed to start, most likely due to an app configuration or programming issue.

For more information, see the following topics:

- Troubleshoot ASP.NET Core on Azure App Service and IIS
- Troubleshoot and debug ASP.NET Core projects

Advanced configuration of the ASP.NET Core Module and IIS

Article • 09/27/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article covers advanced configuration options and scenarios for the ASP.NET Core Module and IIS.

Modify the stack size

Only applies when using the in-process hosting model.

Configure the managed stack size using the `stackSize` setting in bytes in the `web.config` file. The default size is 1,048,576 bytes (1 MB). The following example changes the stack size to 2 MB (2,097,152 bytes):

XML

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="false"
    stdoutLogFile="\\?\%home%\LogFiles\stdout"
    hostingModel="inprocess">
  <handlerSettings>
    <handlerSetting name="stackSize" value="2097152" />
  </handlerSettings>
</aspNetCore>
```

Disallow rotation on config

The `disallowRotationOnConfigChange` setting is intended for blue/green scenarios where a change to global config should not cause all sites to recycle. When this flag is true, only changes relevant to the site itself will cause it to recycle. For example, a site recycles

if its *web.config* changes or something changes that is relevant to the site's path from IIS's perspective. But a general change to *applicationHost.config* would not cause an app to recycle. The following example sets this setting to true:

XML

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="false"
    stdoutLogFile="\\?\%home%\LogFiles\stdout"
    hostingModel="inprocess">
  <handlerSettings>
    <handlerSetting name="disallowRotationOnConfigChange" value="true" />
  </handlerSettings>
</aspNetCore>
```

This setting corresponds to the API ApplicationPoolRecycling.DisallowRotationOnConfigChange

Reduce 503 likelihood during app recycle

By default, there is a one second delay between when IIS is notified of a recycle or shutdown and when ANCM tells the managed server to initiate shutdown. The delay is configurable via the `ANCM_shutdownDelay` environment variable or by setting the `shutdownDelay` handler setting. Both values are in milliseconds. The delay is primarily to reduce the likelihood of a race where:

- IIS hasn't started queuing requests to go to the new app.
- ANCM starts rejecting new requests that come into the old app.

This setting doesn't mean incoming requests will be delayed by this amount. The setting indicates that the old app instance will start shutting down after the timeout occurs. Slower machines or machines with heavier CPU usage might need to adjust this value to reduce 503 likelihood.

The following example sets the delay to 5 seconds:

XML

```
<aspNetCore processPath="dotnet"
    arguments=".\MyApp.dll"
    stdoutLogEnabled="false"
    stdoutLogFile="\\?\%home%\LogFiles\stdout"
    hostingModel="inprocess">
  <handlerSettings>
    <handlerSetting name="shutdownDelay" value="5000" />
```

```
  </handlerSettings>
</aspNetCore>
```

Proxy configuration uses HTTP protocol and a pairing token

Only applies to out-of-process hosting.

The proxy created between the ASP.NET Core Module and Kestrel uses the HTTP protocol. There's no risk of eavesdropping the traffic between the module and Kestrel from a location off of the server.

A pairing token is used to guarantee that the requests received by Kestrel were proxied by IIS and didn't come from some other source. The pairing token is created and set into an environment variable (`ASPNETCORE_TOKEN`) by the module. The pairing token is also set into a header (`MS-ASPNETCORE-TOKEN`) on every proxied request. IIS Middleware checks each request it receives to confirm that the pairing token header value matches the environment variable value. If the token values are mismatched, the request is logged and rejected. The pairing token environment variable and the traffic between the module and Kestrel aren't accessible from a location off of the server. Without knowing the pairing token value, a cyberattacker can't submit requests that bypass the check in the IIS Middleware.

ASP.NET Core Module with an IIS Shared Configuration

The ASP.NET Core Module installer runs with the privileges of the `TrustedInstaller` account. Because the local system account doesn't have modify permission for the share path used by the IIS Shared Configuration, the installer throws an access denied error when attempting to configure the module settings in the `applicationHost.config` file on the share.

When using an IIS Shared Configuration on the same machine as the IIS installation, run the ASP.NET Core Hosting Bundle installer with the `OPT_NO_SHARED_CONFIG_CHECK` parameter set to `1`:

Console

```
dotnet-hosting-{VERSION}.exe OPT_NO_SHARED_CONFIG_CHECK=1
```

When the path to the shared configuration isn't on the same machine as the IIS installation, follow these steps:

1. Disable the IIS Shared Configuration.
2. Run the installer.
3. Export the updated `applicationHost.config` file to the file share.
4. Re-enable the IIS Shared Configuration.

Data protection

The ASP.NET Core Data Protection stack is used by several ASP.NET Core middlewares, including middleware used in authentication. Even if Data Protection APIs aren't called by user code, data protection should be configured with a deployment script or in user code to create a persistent cryptographic key store. If data protection isn't configured, the keys are held in memory and discarded when the app restarts.

If the Data Protection key ring is stored in memory when the app restarts:

- All cookie-based authentication tokens are invalidated.
- Users are required to sign in again on their next request.
- Any data protected with the key ring can no longer be decrypted. This may include CSRF tokens and ASP.NET Core MVC TempData cookies.

To configure data protection under IIS to persist the key ring, use **one** of the following approaches:

- **Create Data Protection Registry keys**

  Data Protection keys used by ASP.NET Core apps are stored in the registry external to the apps. To persist the keys for a given app, create Registry keys for the app pool.

  For standalone, non-webfarm IIS installations, the Data Protection Provision-AutoGenKeys.ps1 PowerShell script can be used for each app pool used with an ASP.NET Core app. This script creates a Registry key in the HKLM registry that's accessible only to the worker process account of the app's app pool. Keys are encrypted at rest using DPAPI with a machine-wide key.

  In web farm scenarios, an app can be configured to use a UNC path to store its Data Protection key ring. By default, the keys aren't encrypted. Ensure that the file permissions for the network share are limited to the Windows account that the app runs under. An X509 certificate can be used to protect keys at rest. Consider a mechanism to allow users to upload certificates. Place certificates into the user's

trusted certificate store and ensure they're available on all machines where the user's app runs. For more information, see Configure ASP.NET Core Data Protection.

- **Configure the IIS Application Pool to load the user profile**

  This setting is in the **Process Model** section under the **Advanced Settings** for the app pool. Set **Load User Profile** to `True`. When set to `True`, keys are stored in the user profile directory and protected using DPAPI with a key specific to the user account. Keys are persisted to the `%LOCALAPPDATA%/ASP.NET/DataProtection-Keys` folder.

  The app pool's setProfileEnvironment attribute must also be enabled. The default value of `setProfileEnvironment` is `true`. In some scenarios (for example, Windows OS), `setProfileEnvironment` is set to `false`. If keys aren't stored in the user profile directory as expected:

  1. Navigate to the `%windir%/system32/inetsrv/config` folder.
  2. Open the `applicationHost.config` file.
  3. Locate the `<system.applicationHost><applicationPools><applicationPoolDefaults><processModel>` element.
  4. Confirm that the `setProfileEnvironment` attribute isn't present, which defaults the value to `true`, or explicitly set the attribute's value to `true`.

- **Use the file system as a key ring store**

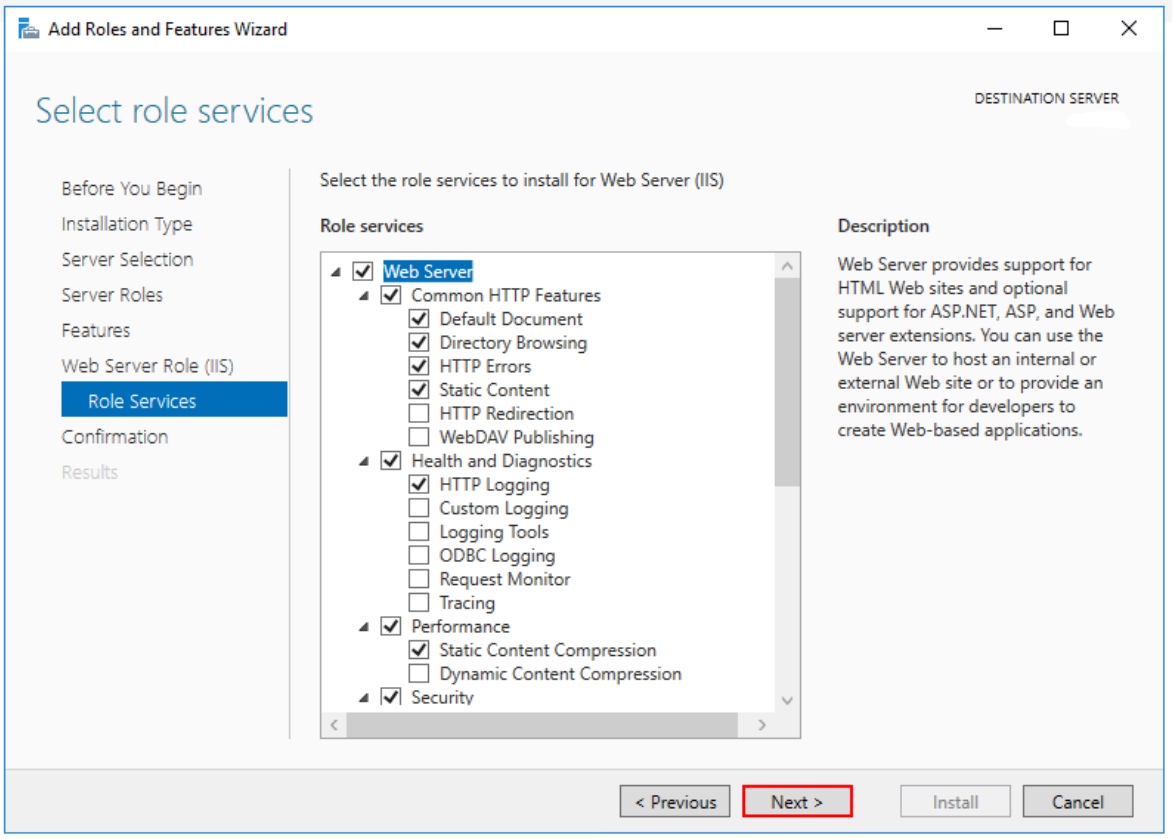
  Adjust the app code to use the file system as a key ring store. Use an X509 certificate to protect the key ring and ensure the certificate is a trusted certificate. If the certificate is self-signed, place the certificate in the Trusted Root store.

  When using IIS in a web farm:
  - Use a file share that all machines can access.
  - Deploy an X509 certificate to each machine. Configure Data Protection in code.

- **Set a machine-wide policy for Data Protection**

  The Data Protection system has limited support for setting a default machine-wide policy for all apps that consume the Data Protection APIs. For more information, see ASP.NET Core Data Protection Overview.

IIS configuration



Windows Server operating systems

Enable the **Web Server (IIS)** server role and establish role services.

1. Use the **Add Roles and Features** wizard from the **Manage** menu or the link in **Server Manager**. On the **Server Roles** step, check the box for **Web Server (IIS)**.

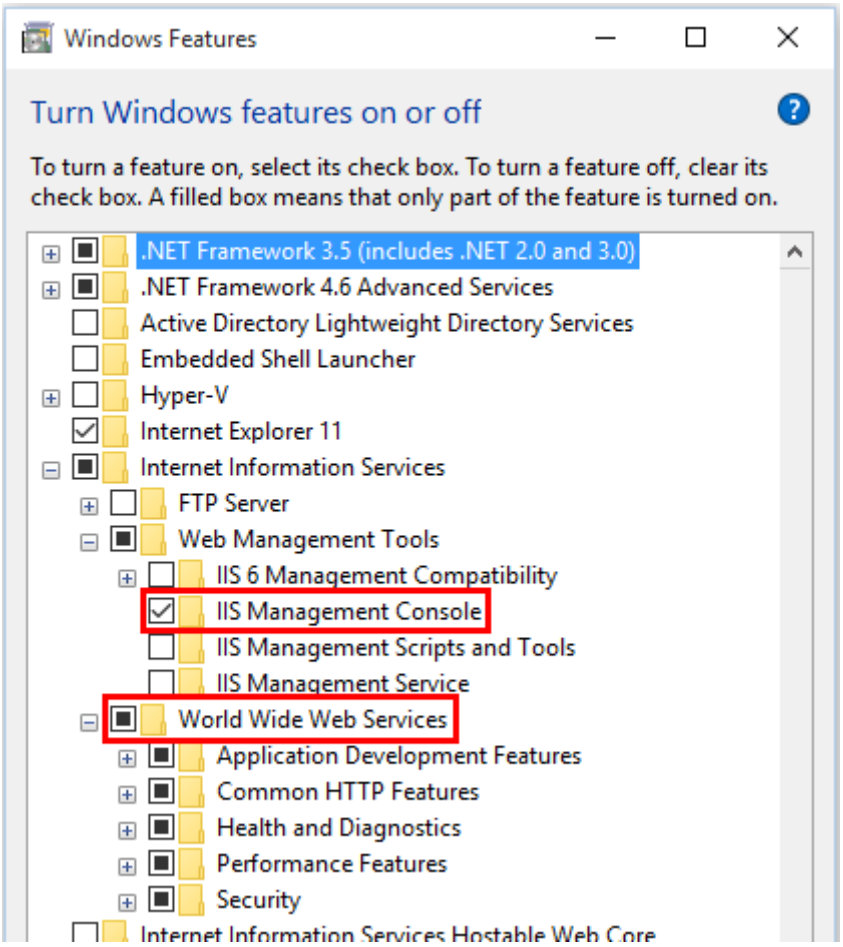
2. After the **Features** step, the **Role services** step loads for Web Server (IIS). Select the IIS role services desired or accept the default role services provided.

Windows Authentication (Optional)
To enable Windows Authentication, expand the following nodes: **Web Server** > **Security**. Select the **Windows Authentication** feature. For more information, see Windows Authentication <windowsAuthentication> and Configure Windows authentication.

WebSockets (Optional)
WebSockets is supported with ASP.NET Core 1.1 or later. To enable WebSockets, expand the following nodes: **Web Server** > **Application Development**. Select the **WebSocket Protocol** feature. For more information, see WebSockets.

3. Proceed through the **Confirmation** step to install the web server role and services. A server/IIS restart isn't required after installing the **Web Server (IIS)** role.

Windows desktop operating systems



Enable the **IIS Management Console** and **World Wide Web Services**.

1. Navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Open the **Internet Information Services** node. Open the **Web Management Tools** node.
3. Check the box for **IIS Management Console**.
4. Check the box for **World Wide Web Services**.
5. Accept the default features for **World Wide Web Services** or customize the IIS features.

   Windows Authentication (Optional)
   To enable Windows Authentication, expand the following nodes: **World Wide Web Services** > **Security**. Select the **Windows Authentication** feature. For more information, see Windows Authentication <windowsAuthentication> and Configure Windows authentication.

   WebSockets (Optional)
   WebSockets is supported with ASP.NET Core 1.1 or later. To enable WebSockets, expand the following nodes: **World Wide Web Services** > **Application Development Features**. Select the **WebSocket Protocol** feature. For more information, see WebSockets.

6. If the IIS installation requires a restart, restart the system.

Virtual Directories

IIS Virtual Directories aren't supported with ASP.NET Core apps. An app can be hosted as a sub-application.

Sub-applications

An ASP.NET Core app can be hosted as an IIS sub-application (sub-app). The sub-app's path becomes part of the root app's URL.

Static asset links within the sub-app should use tilde-slash (`~/`) notation in MVC and Razor Pages. Tilde-slash notation triggers a Tag Helper to prepend the sub-app's pathbase to the rendered relative link. For a sub-app at `/subapp_path`, an image linked with `src="~/image.png"` is rendered as `src="/subapp_path/image.png"`. The root app's Static File Middleware doesn't process the static file request. The request is processed by the sub-app's Static File Middleware.

> ⓘ Note

Razor components (`.razor`) shouldn't use tilde-slash notation. For more information, see the **Blazor app base path documentation**.

If a static asset's `src` attribute is set to an absolute path (for example, `src="/image.png"`), the link is rendered without the sub-app's pathbase. The root app's Static File Middleware attempts to serve the asset from the root app's web root, which results in a *404 - Not Found* response unless the static asset is available from the root app.

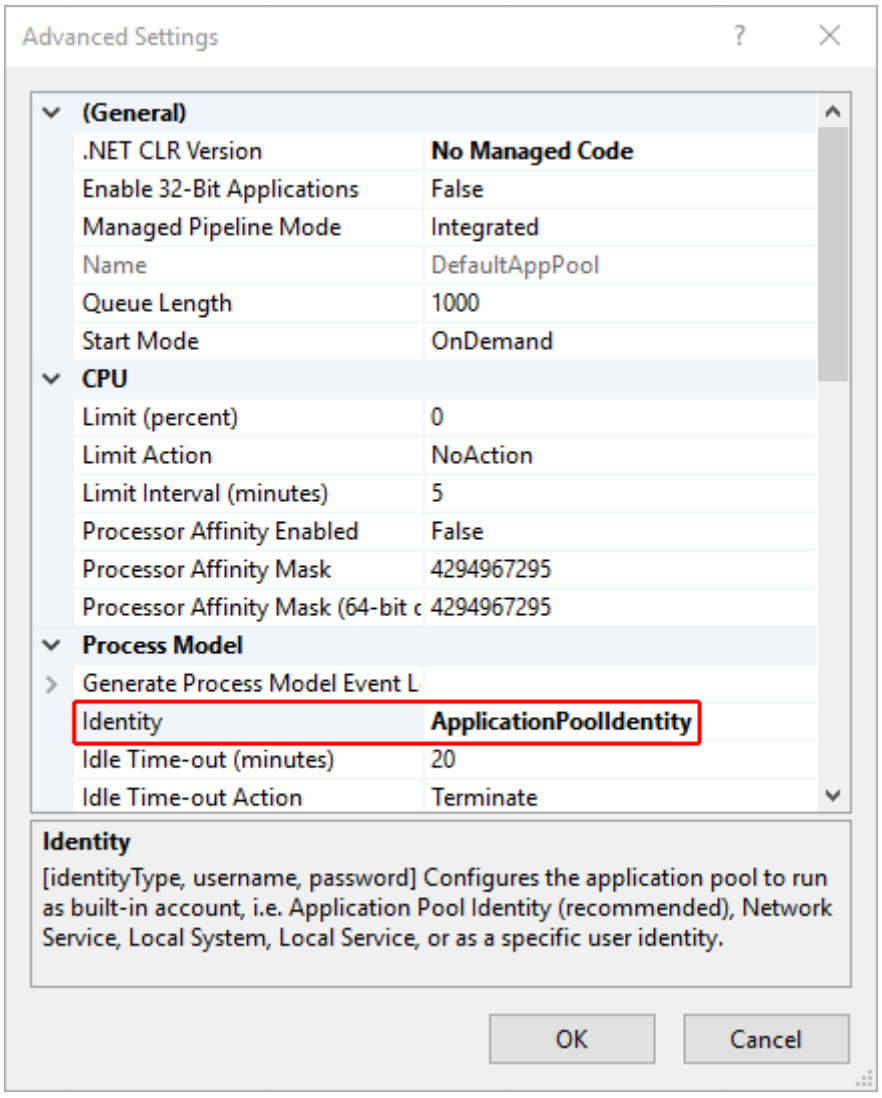
To host an ASP.NET Core app as a sub-app under another ASP.NET Core app:

1. Establish an app pool for the sub-app. Set the **.NET CLR Version** to **No Managed Code** because the Core Common Language Runtime (CoreCLR) for .NET Core is booted to host the app in the worker process, not the desktop CLR (.NET CLR).
2. Add the root site in IIS Manager with the sub-app in a folder under the root site.
3. Right-click the sub-app folder in IIS Manager and select **Convert to Application**.
4. In the **Add Application** dialog, use the **Select** button for the **Application Pool** to assign the app pool that you created for the sub-app. Select **OK**.

The assignment of a separate app pool to the sub-app is a requirement when using the in-process hosting model.

For more information on the in-process hosting model and configuring the ASP.NET Core Module, see ASP.NET Core Module (ANCM) for IIS.

Application Pools



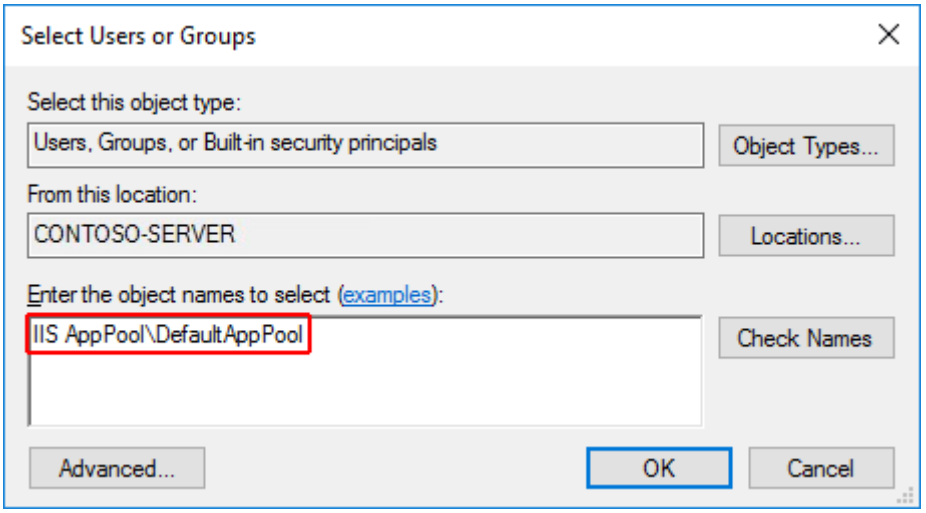
App pool isolation is determined by the hosting model:

- In-process hosting: Apps are required to run in separate app pools.
- Out-of-process hosting: We recommend isolating the apps from each other by running each app in its own app pool.

The IIS **Add Website** dialog defaults to a single app pool per app. When a **Site name** is provided, the text is automatically transferred to the **Application pool** textbox. A new app pool is created using the site name when the site is added.

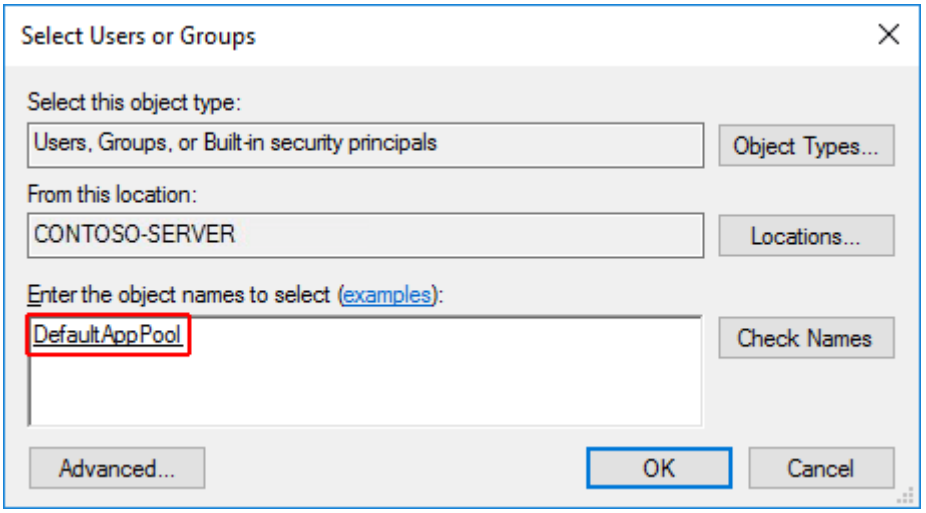
Application Pool Identity

An app pool identity account allows an app to run under a unique account without having to create and manage domains or local accounts. On IIS 8.0 or later, the IIS Admin Worker Process (WAS) creates a virtual account with the name of the new app pool and runs the app pool's worker processes under this account by default. In the IIS Management Console under **Advanced Settings** for the app pool, ensure that the **Identity** is set to use `ApplicationPoolIdentity`:



The IIS management process creates a secure identifier with the name of the app pool in the Windows Security System. Resources can be secured using this identity. However, this identity isn't a real user account and doesn't show up in the Windows User Management Console.

If the IIS worker process requires elevated access to the app, modify the Access Control List (ACL) for the directory containing the app:



1. Open Windows Explorer and navigate to the directory.
2. Right-click on the directory and select **Properties**.
3. Under the **Security** tab, select the **Edit** button and then the **Add** button.

4. Select the **Locations** button and make sure the system is selected.

5. Enter `IIS AppPool\{APP POOL NAME}` format, where the placeholder `{APP POOL NAME}` is the app pool name, in **Enter the object names to select** area. Select the **Check Names** button. For the *DefaultAppPool* check the names using `IIS AppPool\DefaultAppPool`. When the **Check Names** button is selected, a value of `DefaultAppPool` is indicated in the object names area. It isn't possible to enter the app pool name directly into the object names area. Use the `IIS AppPool\{APP POOL NAME}` format, where the placeholder `{APP POOL NAME}` is the app pool name, when checking for the object name.

6. Select **OK**.

7. Read & execute permissions should be granted by default. Provide additional permissions as needed.

Access can also be granted at a command prompt using the **ICACLS** tool. Using the *DefaultAppPool* as an example, the following command is used to grant read and execute permissions to the `MyWebApp` folder, subfolders, and files:

```
```

Console

```
ICACLS C:\sites\MyWebApp /grant "IIS AppPool\DefaultAppPool:(OI)(CI)RX"
```

For more information, see the icacls topic.

HTTP/2 support

HTTP/2 is supported with ASP.NET Core in the following IIS deployment scenarios:

- In-process
  - Windows Server 2016/Windows 10 or later; IIS 10 or later
  - TLS 1.2 or later connection
- Out-of-process
  - Windows Server 2016/Windows 10 or later; IIS 10 or later
  - Public-facing edge server connections use HTTP/2, but the reverse proxy connection to the Kestrel server uses HTTP/1.1.
  - TLS 1.2 or later connection

For an in-process deployment when an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`. For an out-of-process deployment when an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/1.1`.

For more information on the in-process and out-of-process hosting models, see ASP.NET Core Module (ANCM) for IIS.

HTTP/2 is enabled by default. Connections fall back to HTTP/1.1 if an HTTP/2 connection isn't established. For more information on HTTP/2 configuration with IIS deployments, see HTTP/2 on IIS.

CORS preflight requests

This section only applies to ASP.NET Core apps that target the .NET Framework.

For an ASP.NET Core app that targets the .NET Framework, OPTIONS requests aren't passed to the app by default in IIS. To learn how to configure the app's IIS handlers in `web.config` to pass OPTIONS requests, see Enable cross-origin requests in ASP.NET Web API 2: How CORS Works.

Application Initialization Module and Idle Timeout

When hosted in IIS by the ASP.NET Core Module version 2:

- Application Initialization Module: App's hosted in-process or out-of-process can be configured to start automatically on a worker process restart or server restart.
- Idle Timeout: App's hosted in-process can be configured not to time out during periods of inactivity.

Application Initialization Module

Applies to apps hosted in-process and out-of-process.

IIS Application Initialization is an IIS feature that sends an HTTP request to the app when the app pool starts or is recycled. The request triggers the app to start. By default, IIS issues a request to the app's root URL (`/`) to initialize the app (see the additional resources for more details on configuration).

Confirm that the IIS Application Initialization role feature in enabled:

On Windows 7 or later desktop systems when using IIS locally:

1. Navigate to **Control Panel** > **Programs** > **Programs and Features** > **Turn Windows features on or off** (left side of the screen).
2. Open **Internet Information Services** > **World Wide Web Services** > **Application Development Features**.
3. Select the checkbox for **Application Initialization**.

On Windows Server 2008 R2 or later:

1. Open the **Add Roles and Features Wizard**.
2. In the **Select role services** panel, open the **Application Development** node.
3. Select the checkbox for **Application Initialization**.

Use either of the following approaches to enable the Application Initialization Module for the site:

- Using IIS Manager:

    1. Select **Application Pools** in the **Connections** panel.
    2. Right-click the app's app pool in the list and select **Advanced Settings**.

3. The default **Start Mode** is `OnDemand`. Set the **Start Mode** to `AlwaysRunning`. Select **OK**.
4. Open the **Sites** node in the **Connections** panel.
5. Right-click the app and select **Manage Website** > **Advanced Settings**.
6. The default **Preload Enabled** setting is `False`. Set **Preload Enabled** to `True`. Select **OK**.

- Using `web.config`, add the `<applicationInitialization>` element with `doAppInitAfterRestart` set to `true` to the `<system.webServer>` elements in the app's `web.config` file:

```
XML
```

```xml
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <applicationInitialization doAppInitAfterRestart="true" />
    </system.webServer>
  </location>
</configuration>
```

Idle Timeout

Only applies to apps hosted in-process.

To prevent the app from idling, set the app pool's idle timeout using IIS Manager:

1. Select **Application Pools** in the **Connections** panel.
2. Right-click the app's app pool in the list and select **Advanced Settings**.
3. The default **Idle Time-out (minutes)** is `20` minutes. Set the **Idle Time-out (minutes)** to `0` (zero). Select **OK**.
4. Recycle the worker process.

To prevent apps hosted out-of-process from timing out, use either of the following approaches:

- Ping the app from an external service in order to keep it running.
- If the app only hosts background services, avoid IIS hosting and use a Windows Service to host the ASP.NET Core app.

Application Initialization Module and Idle Timeout additional resources

- IIS 8.0 Application Initialization
- Application Initialization <applicationInitialization>.
- Process Model Settings for an Application Pool <processModel>.

Module, schema, and configuration file locations

Module

IIS (x86/amd64):

- `%windir%\System32\inetsrv\aspnetcore.dll`
- `%windir%\SysWOW64\inetsrv\aspnetcore.dll`
- `%ProgramFiles%\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll`
- `%ProgramFiles(x86)%\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll`

IIS Express (x86/amd64):

- `%ProgramFiles%\IIS Express\aspnetcore.dll`
- `%ProgramFiles(x86)%\IIS Express\aspnetcore.dll`
- `%ProgramFiles%\IIS Express\Asp.Net Core Module\V2\aspnetcorev2.dll`
- `%ProgramFiles(x86)%\IIS Express\Asp.Net Core Module\V2\aspnetcorev2.dll`

Schema

IIS

- `%windir%\System32\inetsrv\config\schema\aspnetcore_schema.xml`
- `%windir%\System32\inetsrv\config\schema\aspnetcore_schema_v2.xml`

IIS Express

- `%ProgramFiles%\IIS Express\config\schema\aspnetcore_schema.xml`
- `%ProgramFiles%\IIS Express\config\schema\aspnetcore_schema_v2.xml`

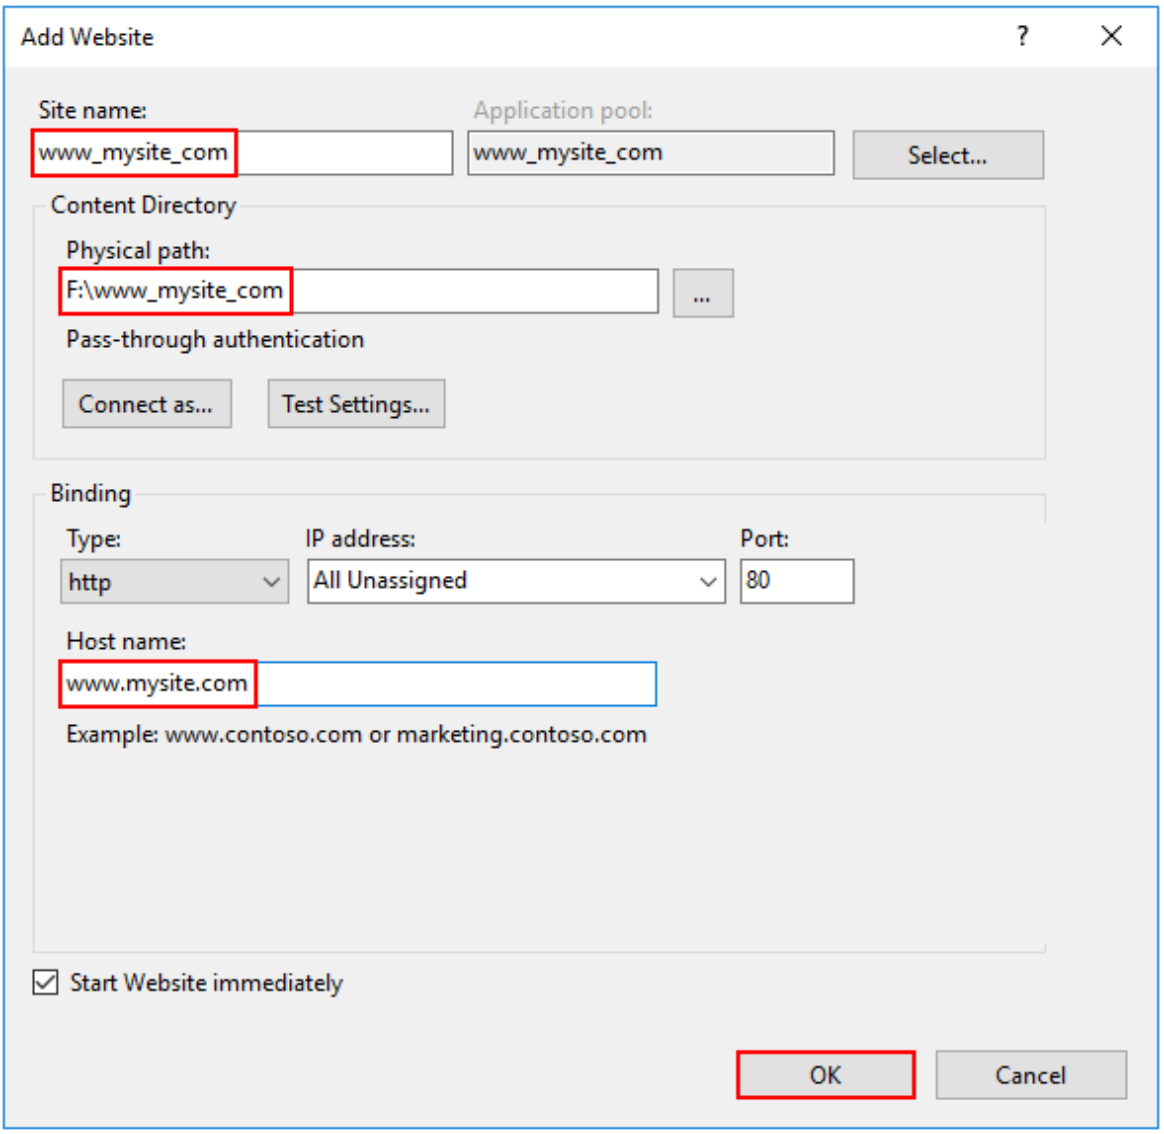
Configuration

IIS

- `%windir%\System32\inetsrv\config\applicationHost.config`

IIS Express

- Visual Studio: `{APPLICATION ROOT}\.vs\config\applicationHost.config`
- *iisexpress.exe* CLI: `%USERPROFILE%\Documents\IISExpress\config\applicationhost.config`



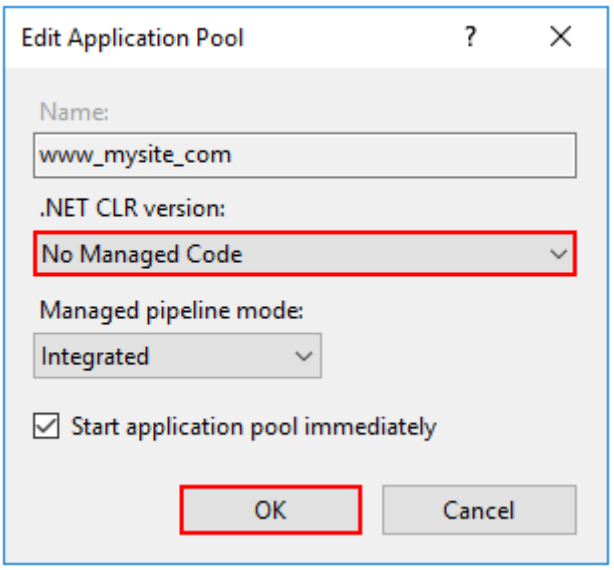
The files can be found by searching for `aspnetcore` in the `applicationHost.config` file.

Install Web Deploy when publishing with Visual Studio

When deploying apps to servers with Web Deploy, install the latest version of Web Deploy on the server. To install Web Deploy, see IIS Downloads: Web Deploy.

Create the IIS site

1. On the hosting system, create a folder to contain the app's published folders and files. In a following step, the folder's path is provided to IIS as the physical path to the app. For more information on an app's deployment folder and file layout, see ASP.NET Core directory structure.
2. In IIS Manager, open the server's node in the **Connections** panel. Right-click the **Sites** folder. Select **Add Website** from the contextual menu.
3. Provide a **Site name** and set the **Physical path** to the app's deployment folder. Provide the **Binding** configuration and create the website by selecting **OK**:



> ⚠ **Warning**
>
> Top-level wildcard bindings (`http://*:80/` and `http://+:80`) should **not** be used. Top-level wildcard bindings can open up your app to security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names rather than wildcards. Subdomain wildcard binding (for example, `*.mysub.com`) doesn't have this security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). See RFC 9110: HTTP Semantics (Section 7.2: Host and :authority) for more information.

4. Under the server's node, select **Application Pools**.

5. Right-click the site's app pool and select **Basic Settings** from the contextual menu.

6. In the **Edit Application Pool** window, set the **.NET CLR version** to **No Managed Code**:

ASP.NET Core runs in a separate process and manages the runtime. ASP.NET Core doesn't rely on loading the desktop CLR (.NET CLR). The Core Common Language Runtime (CoreCLR) for .NET Core is booted to host the app in the worker process. Setting the **.NET CLR version** to **No Managed Code** is optional but recommended.

- For a 32-bit (x86) self-contained deployment published with a 32-bit SDK that uses the in-process hosting model, enable the Application Pool for 32-bit. In IIS Manager, navigate to **Application Pools** in the **Connections** sidebar. Select the app's Application Pool. In the **Actions** sidebar, select **Advanced Settings**. Set **Enable 32-Bit Applications** to `True`.

- For a 64-bit (x64) self-contained deployment that uses the in-process hosting model, disable the app pool for 32-bit (x86) processes. In IIS Manager, navigate to **Application Pools** in the **Connections** sidebar. Select the app's Application Pool. In the **Actions** sidebar, select **Advanced Settings**. Set **Enable 32-Bit Applications** to `False`.

7. Confirm the process model identity has the proper permissions.

   If the default identity of the app pool (**Process Model** > **Identity**) is changed from **ApplicationPoolIdentity** to another identity, verify that the new identity has the required permissions to access the app's folder, database, and other required resources. For example, the app pool requires read and write access to folders where the app reads and writes files.

Windows Authentication configuration (Optional)
For more information, see Configure Windows authentication.

Shadow copy

Shadow copying app assemblies to the ASP.NET Core Module (ANCM) for IIS can provide a better end user experience than stopping the app by deploying an app offline file.

When an ASP.NET Core app is running on Windows, the binaries are locked so that they can't be modified or replaced. Shadow copying enables the app assemblies to be updated while the app is running by making a copy of the assemblies.

Shadow copy isn't intended to enable zero-downtime deployment, so its expected that IIS will still recycle the app, and some requests may get an 503 Service Unavailable response. We recommend using a pattern like blue-green deployments or Azure deployment slots for zero-downtime deployments. Shadow copy helps minimize downtime on deployments, but can't completely eliminate it.

Shadow copying is enabled by customizing the ANCM handler settings in `web.config`:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <system.webServer>
    <handlers>
      <remove name="aspNetCore"/>
      <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2"
resourceType="Unspecified"/>
    </handlers>
    <aspNetCore processPath="%LAUNCHER_PATH%" arguments="%LAUNCHER_ARGS%"
stdoutLogEnabled="false" stdoutLogFile=".logsstdout">
      <handlerSettings>
        <handlerSetting name="enableShadowCopy" value="true" />
        <!-- Ensure that the IIS ApplicationPool identity has permission to
this directory -->
        <handlerSetting name="shadowCopyDirectory"
value="../ShadowCopyDirectory/" />
      </handlerSettings>
    </aspNetCore>
  </system.webServer>
</configuration>
```

Transform web.config

Article • 07/31/2024

> **Important**

>
> For the current release, see the .NET 8 version of this article.

By Vijay Ramakrishnan

Transformations to the *web.config* file can be applied automatically when an app is published based on:

- Build configuration
- Profile
- Environment
- Custom

These transformations occur for either of the following *web.config* generation scenarios:

- Generated automatically by the `Microsoft.NET.Sdk.Web` SDK.
- Provided by the developer in the content root of the app.

Build configuration

Build configuration transforms are run first.

Include a *web.{CONFIGURATION}.config* file for each build configuration (Debug|Release) requiring a *web.config* transformation.

In the following example, a configuration-specific environment variable is set in *web.Release.config*:

XML

```
<?xml version="1.0"?>
<configuration xmlns:xdt="http://schemas.microsoft.com/XML-Document-
Transform">
  <location>
    <system.webServer>
```

```
      <aspNetCore>
        <environmentVariables xdt:Transform="InsertIfMissing">
          <environmentVariable name="Configuration_Specific"
                               value="Configuration_Specific_Value"
                               xdt:Locator="Match(name)"
                               xdt:Transform="InsertIfMissing" />
        </environmentVariables>
      </aspNetCore>
    </system.webServer>
  </location>
</configuration>
```

The transform is applied when the configuration is set to *Release*:

.NET CLI

```
dotnet publish --configuration Release
```

The MSBuild property for the configuration is `$(Configuration)`.

Profile

Profile transformations are run second, after Build configuration transforms.

Include a *web.{PROFILE}.config* file for each profile configuration requiring a *web.config* transformation.

In the following example, a profile-specific environment variable is set in *web.FolderProfile.config* for a folder publish profile:

XML

```
<?xml version="1.0"?>
<configuration xmlns:xdt="http://schemas.microsoft.com/XML-Document-
Transform">
  <location>
    <system.webServer>
      <aspNetCore>
        <environmentVariables xdt:Transform="InsertIfMissing">
          <environmentVariable name="Profile_Specific"
                               value="Profile_Specific_Value"
                               xdt:Locator="Match(name)"
                               xdt:Transform="InsertIfMissing" />
        </environmentVariables>
      </aspNetCore>
    </system.webServer>
  </location>
</configuration>
```

The transform is applied when the profile is *FolderProfile*:

.NET CLI

```
dotnet publish --configuration Release /p:PublishProfile=FolderProfile
```

The MSBuild property for the profile name is `$(PublishProfile)`.

If no profile is passed, the default profile name is **FileSystem** and *web.FileSystem.config* is applied if the file is present in the app's content root.

Environment

Environment transformations are run third, after Build configuration and Profile transforms.

Include a *web.{ENVIRONMENT}.config* file for each environment requiring a *web.config* transformation.

In the following example, an environment-specific environment variable is set in *web.Production.config* for the Production environment:

XML

```
<?xml version="1.0"?>
<configuration xmlns:xdt="http://schemas.microsoft.com/XML-Document-
Transform">
  <location>
    <system.webServer>
      <aspNetCore>
        <environmentVariables xdt:Transform="InsertIfMissing">
          <environmentVariable name="Environment_Specific"
                               value="Environment_Specific_Value"
                               xdt:Locator="Match(name)"
                               xdt:Transform="InsertIfMissing" />
        </environmentVariables>
      </aspNetCore>
    </system.webServer>
  </location>
</configuration>
```

The transform is applied when the environment is *Production*:

.NET CLI

```
dotnet publish --configuration Release /p:EnvironmentName=Production
```

The MSBuild property for the environment is `$(EnvironmentName)`.

When publishing from Visual Studio and using a publish profile, see Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment.

The `ASPNETCORE_ENVIRONMENT` environment variable is automatically added to the *web.config* file when the environment name is specified.

Custom

Custom transformations are run last, after Build configuration, Profile, and Environment transforms.

Include a *{CUSTOM_NAME}.transform* file for each custom configuration requiring a *web.config* transformation.

In the following example, a custom transform environment variable is set in *custom.transform*:

XML

```
<?xml version="1.0"?>
<configuration xmlns:xdt="http://schemas.microsoft.com/XML-Document-
Transform">
  <location>
    <system.webServer>
      <aspNetCore>
        <environmentVariables xdt:Transform="InsertIfMissing">
          <environmentVariable name="Custom_Specific"
                               value="Custom_Specific_Value"
                               xdt:Locator="Match(name)"
                               xdt:Transform="InsertIfMissing" />
        </environmentVariables>
      </aspNetCore>
    </system.webServer>
  </location>
</configuration>
```

The transform is applied when the `CustomTransformFileName` property is passed to the dotnet publish command:

.NET CLI

```
dotnet publish --configuration Release
/p:CustomTransformFileName=custom.transform
```

The MSBuild property for the profile name is `$(CustomTransformFileName)`.

Prevent web.config transformation

To prevent transformations of the *web.config* file, set the MSBuild property `$(IsWebConfigTransformDisabled)`:

.NET CLI

```
dotnet publish /p:IsWebConfigTransformDisabled=true
```

Use ASP.NET Core with HTTP/2 on IIS

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Justin Kotalik

HTTP/2 is supported with ASP.NET Core in the following IIS deployment scenarios:

- Windows Server 2016 or later / Windows 10 or later
- IIS 10 or later
- TLS 1.2 or later connection
- When hosting out-of-process: Public-facing edge server connections use HTTP/2, but the reverse proxy connection to the Kestrel server uses HTTP/1.1.

For an in-process deployment when an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`. For an out-of-process deployment when an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/1.1`.

For more information on the in-process and out-of-process hosting models, see ASP.NET Core Module (ANCM) for IIS.

HTTP/2 is enabled by default for HTTPS/TLS connections. Connections fall back to HTTP/1.1 if an HTTP/2 connection isn't established. For more information on HTTP/2 configuration with IIS deployments, see HTTP/2 on IIS.

Advanced HTTP/2 features to support gRPC

Additional HTTP/2 features in IIS support gRPC, including support for response trailers and sending reset frames.

Requirements to run gRPC on IIS:

- In-process hosting.
- Windows 11 Build 22000 or later, Windows Server 2022 Build 20348 or later.

- TLS 1.2 or later connection.

Trailers

HTTP Trailers are similar to HTTP Headers, except they are sent after the response body is sent. For IIS and HTTP.sys, only HTTP/2 response trailers are supported.

C#

```
if (httpContext.Response.SupportsTrailers())
{
    httpContext.Response.DeclareTrailer("trailername");

    // Write body
    httpContext.Response.WriteAsync("Hello world");

    httpContext.Response.AppendTrailer("trailername", "TrailerValue");
}
```

In the preceding example code:

- `SupportsTrailers` ensures that trailers are supported for the response.
- `DeclareTrailer` adds the given trailer name to the `Trailer` response header. Declaring a response's trailers is optional, but recommended. If `DeclareTrailer` is called, it must be before the response headers are sent.
- `AppendTrailer` appends the trailer.

Reset

Reset allows for the server to reset a HTTP/2 request with a specified error code. A reset request is considered aborted.

C#

```
var resetFeature = httpContext.Features.Get<IHttpResetFeature>();
resetFeature.Reset(errorCode: 2);
```

`Reset` in the preceding code example specifies the `INTERNAL_ERROR` error code. For more information about HTTP/2 error codes, visit the HTTP/2 specification error code section.

Use ASP.NET Core with HTTP/3 on IIS

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Chris Ross

HTTP/3 is fully supported with ASP.NET Core in the following IIS scenarios:

- In-process
- Out-of-Process. In Out-of-Process, IIS responds to the client using HTTP/3, but the reverse proxy connection to the Kestrel server uses HTTP/1.1.

For more information on the in-process and out-of-process hosting models, see ASP.NET Core Module (ANCM) for IIS.

The following requirements also need to be met:

- Windows Server 2022 / Windows 11 or later
- An `https` url binding is used.
- The EnableHttp3 registry key is set.

For an in-process deployment when an HTTP/3 connection is established, HttpRequest.Protocol reports `HTTP/3`. For an out-of-process deployment when an HTTP/3 connection is established, HttpRequest.Protocol reports `HTTP/1.1` because that is how IIS proxies the requests to Kestrel.

Alt-Svc

HTTP/3 is discovered as an upgrade from HTTP/1.1 or HTTP/2 via the alt-svc header. That means the first request will normally use HTTP/1.1 or HTTP/2 before switching to HTTP/3. IIS doesn't automatically add the `alt-svc` header, it must be added by the application. The following code is a middleware example that adds the `alt-svc` response header.

C#

```
app.Use((context, next) =>
{
    context.Response.Headers.AltSvc = "h3=\":443\"";
    return next(context);
});
```

Place the preceding code early in the request pipeline.

IIS also supports sending an AltSvc HTTP/2 protocol message rather than a response header to notify the client that HTTP/3 is available. See the EnableAltSvc registry key. Note this requires netsh sslcert bindings that use host names rather than IP addresses.

HTTP.sys web server implementation in ASP.NET Core

Article • 10/21/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Tom Dykstra and Chris Ross

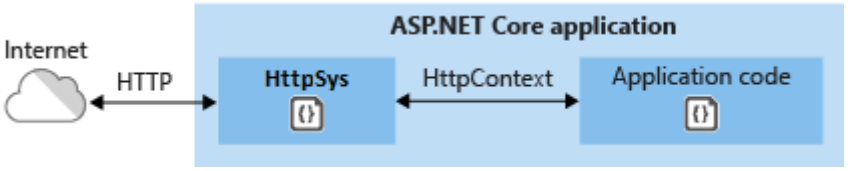
HTTP.sys is a web server for ASP.NET Core that only runs on Windows. HTTP.sys is an alternative to Kestrel server and offers some features that Kestrel doesn't provide.

> **Important**
>
> HTTP.sys isn't compatible with the ASP.NET Core Module and can't be used with IIS or IIS Express.

HTTP.sys supports the following features:

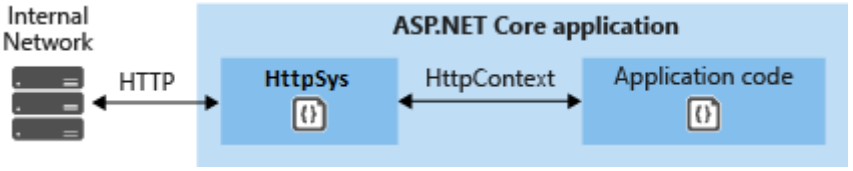
- Windows Authentication
- Port sharing
- HTTPS with SNI
- HTTP/2 over TLS (Windows 10 or later)
- Direct file transmission
- Response caching
- WebSockets (Windows 8 or later)

Supported Windows versions:



- Windows 7 or later
- Windows Server 2008 R2 or later

View or download sample code (how to download)



When to use HTTP.sys

HTTP.sys is useful for deployments where:

- There's a need to expose the server directly to the Internet without using IIS.

- An internal deployment requires a feature not available in Kestrel. For more information, see Kestrel vs. HTTP.sys

HTTP.sys is mature technology that protects against many types of attacks and provides the robustness, security, and scalability of a full-featured web server. IIS itself runs as an HTTP listener on top of HTTP.sys.

HTTP/2 support

HTTP/2 is enabled for ASP.NET Core apps when the following base requirements are met:

- Windows Server 2016/Windows 10 or later
- Application-Layer Protocol Negotiation (ALPN) connection
- TLS 1.2 or later connection

If an HTTP/2 connection is established, HttpRequest.Protocol reports `HTTP/2`.

HTTP/2 is enabled by default. If an HTTP/2 connection isn't established, the connection falls back to HTTP/1.1. In a future release of Windows, HTTP/2 configuration flags will be available, including the ability to disable HTTP/2 with HTTP.sys.

HTTP/3 support

HTTP/3 is enabled for ASP.NET Core apps when the following base requirements are met:

- Windows Server 2022/Windows 11 or later
- An `https` url binding is used.
- The EnableHttp3 registry key is set.

The preceding Windows 11 Build versions may require the use of a Windows Insider build.

HTTP/3 is discovered as an upgrade from HTTP/1.1 or HTTP/2 via the `alt-svc` header. That means the first request will normally use HTTP/1.1 or HTTP/2 before switching to HTTP/3. Http.Sys doesn't automatically add the `alt-svc` header, it must be added by the application. The following code is a middleware example that adds the `alt-svc` response header.

```
C#
```

```
app.Use((context, next) =>
{
    context.Response.Headers.AltSvc = "h3=\":443\"";
    return next(context);
});
```

Place the preceding code early in the request pipeline.

Http.Sys also supports sending an AltSvc HTTP/2 protocol message rather than a response header to notify the client that HTTP/3 is available. See the EnableAltSvc registry key. This requires netsh sslcert bindings that use host names rather than IP addresses.

Kernel mode authentication with Kerberos

HTTP.sys delegates to kernel mode authentication with the Kerberos authentication protocol. User mode authentication isn't supported with Kerberos and HTTP.sys. The machine account must be used to decrypt the Kerberos token/ticket that's obtained from Active Directory and forwarded by the client to the server to authenticate the user. Register the Service Principal Name (SPN) for the host, not the user of the app.

Support for kernel-mode response buffering

In some scenarios, high volumes of small writes with high latency can cause significant performance impact to `HTTP.sys`. This impact is due to the lack of a Pipe buffer in the `HTTP.sys` implementation. To improve performance in these scenarios, support for response buffering is included in `HTTP.sys`. Enable buffering by setting HttpSysOptions.EnableKernelResponseBuffering to `true`.

Response buffering should be enabled by an app that does synchronous I/O, or asynchronous I/O with no more than one outstanding write at a time. In these scenarios,

response buffering can significantly improve throughput over high-latency connections.

Apps that use asynchronous I/O and that may have more than one write outstanding at a time should ***not*** use this flag. Enabling this flag can result in higher CPU and memory usage by HTTP.Sys.

How to use HTTP.sys

Configure the ASP.NET Core app to use HTTP.sys

Call the UseHttpSys extension method when building the host, specifying any required HttpSysOptions. The following example sets options to their default values:

C#

```
using Microsoft.AspNetCore.Hosting.Server;
using Microsoft.AspNetCore.Hosting.Server.Features;
using Microsoft.AspNetCore.Http.Features;
using Microsoft.AspNetCore.Server.HttpSys;

var builder = WebApplication.CreateBuilder(args);

builder.WebHost.UseHttpSys(options =>
{
    options.AllowSynchronousIO = false;
    options.Authentication.Schemes = AuthenticationSchemes.None;
    options.Authentication.AllowAnonymous = true;
    options.MaxConnections = null;
    options.MaxRequestBodySize = 30_000_000;
    options.UrlPrefixes.Add("http://localhost:5005");
});

builder.Services.AddRazorPages();

var app = builder.Build();
```

Additional HTTP.sys configuration is handled through registry settings.

For more information about HTTP.sys options, see HttpSysOptions.

MaxRequestBodySize

The maximum allowed size of any request body in bytes. When set to `null`, the maximum request body size is unlimited. This limit has no effect on upgraded connections, which are always unlimited.

The recommended method to override the limit in an ASP.NET Core MVC app for a single `IActionResult` is to use the RequestSizeLimitAttribute attribute on an action method:

C#

```
[RequestSizeLimit(100000000)]
public IActionResult MyActionMethod()
```

An exception is thrown if the app attempts to configure the limit on a request after the app has started reading the request. An `IsReadOnly` property can be used to indicate if the `MaxRequestBodySize` property is in a read-only state, meaning it's too late to configure the limit.

If the app should override MaxRequestBodySize per-request, use the IHttpMaxRequestBodySizeFeature:

C#

```
app.Use((context, next) =>
{
    context.Features.GetRequiredFeature<IHttpMaxRequestBodySizeFeature>()
                                            .MaxRequestBodySize = 10 *
1024;

    var server = context.RequestServices
        .GetRequiredService<IServer>();
    var serverAddressesFeature = server.Features

.GetRequiredFeature<IServerAddressesFeature>();

    var addresses = string.Join(", ", serverAddressesFeature.Addresses);

    var loggerFactory = context.RequestServices
        .GetRequiredService<ILoggerFactory>();
    var logger = loggerFactory.CreateLogger("Sample");

    logger.LogInformation("Addresses: {addresses}", addresses);

    return next(context);
});
```

If using Visual Studio, make sure the app isn't configured to run IIS or IIS Express.

In Visual Studio, the default launch profile is for IIS Express. To run the project as a console app, manually change the selected profile, as shown in the following screenshot:

Configure Windows Server

1. Determine the ports to open for the app and use Windows Firewall or the New-NetFirewallRule PowerShell cmdlet to open firewall ports to allow traffic to reach HTTP.sys. In the following commands and app configuration, port 443 is used.

2. When deploying to an Azure VM, open the ports in the Network Security Group. In the following commands and app configuration, port 443 is used.

3. Obtain and install X.509 certificates, if required.

   On Windows, create self-signed certificates using the New-SelfSignedCertificate PowerShell cmdlet. For an unsupported example, see UpdateIISExpressSSLForChrome.ps1.

   Install either self-signed or CA-signed certificates in the server's **Local Machine** > **Personal** store.

4. If the app is a framework-dependent deployment, install .NET Core, .NET Framework, or both (if the app is a .NET Core app targeting the .NET Framework).

   - **.NET Core**: If the app requires .NET Core, obtain and run the **.NET Core Runtime** installer from .NET Core Downloads. Don't install the full SDK on the server.
   - **.NET Framework**: If the app requires .NET Framework, see the .NET Framework installation guide. Install the required .NET Framework. The installer for the latest .NET Framework is available from the .NET Core Downloads page.

   If the app is a self-contained deployment, the app includes the runtime in its deployment. No framework installation is required on the server.

5. Configure URLs and ports in the app.

   By default, ASP.NET Core binds to `http://localhost:5000`. To configure URL prefixes and ports, options include:

- UseUrls
- `urls` command-line argument
- `ASPNETCORE_URLS` environment variable
- UrlPrefixes

The following code example shows how to use UrlPrefixes with the server's local IP address `10.0.0.4` on port 443:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.WebHost.UseHttpSys(options =>
{
    options.UrlPrefixes.Add("https://10.0.0.4:443");
});

builder.Services.AddRazorPages();

var app = builder.Build();
```

An advantage of `UrlPrefixes` is that an error message is generated immediately for improperly formatted prefixes.

The settings in `UrlPrefixes` override `UseUrls`/`urls`/`ASPNETCORE_URLS` settings. Therefore, an advantage of `UseUrls`, `urls`, and the `ASPNETCORE_URLS` environment variable is that it's easier to switch between Kestrel and HTTP.sys.

HTTP.sys recognizes two types of wild cards in URL prefixes:

- `*` is a *weak binding*, also known as a *fallback binding*. If the URL prefix is `http://*:5000`, and something else is bound to port 5000, this binding won't be used.
- `+` is a *strong binding*. If the URL prefix is `http://+:5000`, this binding will be used before other port 5000 bindings.

For more information, see UrlPrefix Strings.

> ⚠ **Warning**
>
> Top-level wildcard bindings (`http://*:80/` and `http://+:80`) should **not** be used. Top-level wildcard bindings create app security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names or IP addresses rather than wildcards. Subdomain wildcard binding (for example,

`*.mysub.com`) isn't a security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). For more information, see RFC 9110: Section 7.2: Host and :authority.

Apps and containers are often given only a port to listen on, like port 80, without additional constraints like host or path. HTTP_PORTS and HTTPS_PORTS are config keys that specify the listening ports for the Kestrel and HTTP.sys servers. These keys may be specified as environment variables defined with the `DOTNET_` or `ASPNETCORE_` prefixes, or specified directly through any other config input, such as `appsettings.json`. Each is a semicolon-delimited list of port values, as shown in the following example:

```
ASPNETCORE_HTTP_PORTS=80;8080
ASPNETCORE_HTTPS_PORTS=443;8081
```

The preceding example is shorthand for the following configuration, which specifies the scheme (HTTP or HTTPS) and any host or IP.

```
ASPNETCORE_URLS=http://*:80/;http://*:8080/;https://*:443/;https://*:80
81/
```

The HTTP_PORTS and HTTPS_PORTS configuration keys are lower priority and are overridden by URLS or values provided directly in code. Certificates still need to be configured separately via server-specific mechanics for HTTPS.

These configuration keys are equivalent to top-level wildcard bindings. They're convenient for development and container scenarios, but avoid wildcards when running on a machine that may also host other services.

6. Preregister URL prefixes on the server.

   The built-in tool for configuring HTTP.sys is *netsh.exe*. *netsh.exe* is used to reserve URL prefixes and assign X.509 certificates. The tool requires administrator privileges.

   Use the *netsh.exe* tool to register URLs for the app:

   ```
   Console
   ```

```
netsh http add urlacl url=<URL> user=<USER>
```

- `<URL>`: The fully qualified Uniform Resource Locator (URL). Don't use a wildcard binding. Use a valid hostname or local IP address. *The URL must include a trailing slash.*
- `<USER>`: Specifies the user or user-group name.

In the following example, the local IP address of the server is `10.0.0.4`:

Console

```
netsh http add urlacl url=https://10.0.0.4:443/ user=Users
```

When a URL is registered, the tool responds with `URL reservation successfully added`.

To delete a registered URL, use the `delete urlacl` command:

Console

```
netsh http delete urlacl url=<URL>
```

7. Register X.509 certificates on the server.

   Use the *netsh.exe* tool to register certificates for the app:

   Console

   ```
   netsh http add sslcert ipport=<IP>:<PORT> certhash=<THUMBPRINT> appid="
   {<GUID>}"
   ```

   - `<IP>`: Specifies the local IP address for the binding. Don't use a wildcard binding. Use a valid IP address.
   - `<PORT>`: Specifies the port for the binding.
   - `<THUMBPRINT>`: The X.509 certificate thumbprint.
   - `<GUID>`: A developer-generated GUID to represent the app for informational purposes.

   For reference purposes, store the GUID in the app as a package tag:

   - In Visual Studio:

    - Open the app's project properties by right-clicking on the app in **Solution Explorer** and selecting **Properties**.
    - Select the **Package** tab.
    - Enter the GUID that you created in the **Tags** field.
- When not using Visual Studio:

    - Open the app's project file.

    - Add a `<PackageTags>` property to a new or existing `<PropertyGroup>` with the GUID that you created:

      XML

      ```
      <PropertyGroup>
        <PackageTags>00001111-aaaa-2222-bbbb-
      3333cccc4444</PackageTags>
      </PropertyGroup>
      ```

In the following example:

- The local IP address of the server is `10.0.0.4`.
- An online random GUID generator provides the `appid` value.

Console

```
netsh http add sslcert
    ipport=10.0.0.4:443
    certhash=b66ee04419d4ee37464ab8785ff02449980eae10
    appid="{00001111-aaaa-2222-bbbb-3333cccc4444}"
```

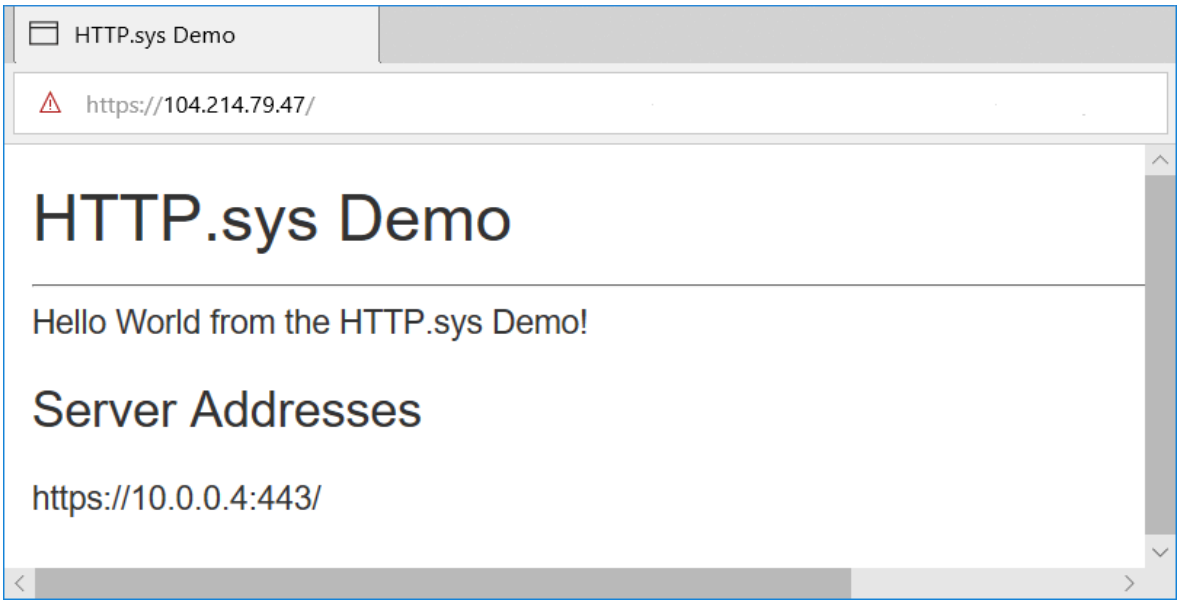
When a certificate is registered, the tool responds with `SSL Certificate successfully added`.

To delete a certificate registration, use the `delete sslcert` command:

Console

```
netsh http delete sslcert ipport=<IP>:<PORT>
```

Reference documentation for *netsh.exe*:



- Netsh Commands for Hypertext Transfer Protocol (HTTP)
- UrlPrefix Strings

8. Run the app.

Administrator privileges aren't required to run the app when binding to localhost using HTTP (not HTTPS) with a port number greater than 1024. For other configurations (for example, using a local IP address or binding to port 443), run the app with administrator privileges.

The app responds at the server's public IP address. In this example, the server is reached from the Internet at its public IP address of `104.214.79.47`.

A development certificate is used in this example. The page loads securely after bypassing the browser's untrusted certificate warning.

Proxy server and load balancer scenarios

For apps hosted by HTTP.sys that interact with requests from the Internet or a corporate network, additional configuration might be required when hosting behind proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Get detailed timing information with IHttpSysRequestTimingFeature

IHttpSysRequestTimingFeature provides detailed timing information for requests:

- Timestamps are obtained using QueryPerformanceCounter.
- The timestamp frequency can be obtained via QueryPerformanceFrequency.
- The index of the timing can be cast to HttpSysRequestTimingType to know what the timing represents.
- The value may be 0 if the timing isn't available for the current request.

- Requires Windows 10 version 2004, Windows Server 2022, or later.

C#

```
using Microsoft.AspNetCore.Http.Features;
using Microsoft.AspNetCore.Server.HttpSys;

var builder = WebApplication.CreateBuilder(args);

builder.WebHost.UseHttpSys();

var app = builder.Build();

app.Use((context, next) =>
{
    var feature =
context.Features.GetRequiredFeature<IHttpSysRequestTimingFeature>();

    var loggerFactory =
context.RequestServices.GetRequiredService<ILoggerFactory>();
    var logger = loggerFactory.CreateLogger("Sample");

    var timestamps = feature.Timestamps;

    for (var i = 0; i < timestamps.Length; i++)
    {
        var timestamp = timestamps[i];
        var timingType = (HttpSysRequestTimingType)i;

        logger.LogInformation("Timestamp {timingType}: {timestamp}",
                                            timingType, timestamp);
    }

    return next(context);
});

app.MapGet("/", () => Results.Ok());

app.Run();
```

IHttpSysRequestTimingFeature.TryGetTimestamp retrieves the timestamp for the provided timing type:

C#

```
using Microsoft.AspNetCore.Http.Features;
using Microsoft.AspNetCore.Server.HttpSys;
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.UseHttpSys();

var app = builder.Build();
```

```
app.Use((context, next) =>
{
    var feature =
context.Features.GetRequiredFeature<IHttpSysRequestTimingFeature>();

    var loggerFactory =
context.RequestServices.GetRequiredService<ILoggerFactory>();
    var logger = loggerFactory.CreateLogger("Sample");

    var timingType = HttpSysRequestTimingType.RequestRoutingEnd;

    if (feature.TryGetTimestamp(timingType, out var timestamp))
    {
        logger.LogInformation("Timestamp {timingType}: {timestamp}",
                                            timingType, timestamp);
    }
    else
    {
        logger.LogInformation("Timestamp {timingType}: not available for the
"
                                             + "current request",
timingType);
    }

    return next(context);
});

app.MapGet("/", () => Results.Ok());

app.Run();
```

IHttpSysRequestTimingFeature.TryGetElapsedTime gives the elapsed time between two specified timings:

C#

```
using Microsoft.AspNetCore.Http.Features;
using Microsoft.AspNetCore.Server.HttpSys;

var builder = WebApplication.CreateBuilder(args);

builder.WebHost.UseHttpSys();

var app = builder.Build();

app.Use((context, next) =>
{
    var feature =
context.Features.GetRequiredFeature<IHttpSysRequestTimingFeature>();

    var loggerFactory =
context.RequestServices.GetRequiredService<ILoggerFactory>();
```

```
    var logger = loggerFactory.CreateLogger("Sample");

    var startingTimingType = HttpSysRequestTimingType.RequestRoutingStart;
    var endingTimingType = HttpSysRequestTimingType.RequestRoutingEnd;

    if (feature.TryGetElapsedTime(startingTimingType, endingTimingType, out
var elapsed))
    {
        logger.LogInformation(
            "Elapsed time {startingTimingType} to {endingTimingType}:
{elapsed}",
            startingTimingType,
            endingTimingType,
            elapsed);
    }
    else
    {
        logger.LogInformation(
            "Elapsed time {startingTimingType} to {endingTimingType}:"
            + " not available for the current request.",
            startingTimingType,
            endingTimingType);
    }

    return next(context);
});

app.MapGet("/", () => Results.Ok());

app.Run();
```

Advanced HTTP/2 features to support gRPC

Additional HTTP/2 features in HTTP.sys support gRPC, including support for response trailers and sending reset frames.

Requirements to run gRPC with HTTP.sys:

- Windows 11 Build 22000 or later, Windows Server 2022 Build 20348 or later.
- TLS 1.2 or later connection.

Trailers

HTTP Trailers are similar to HTTP Headers, except they are sent after the response body is sent. For IIS and HTTP.sys, only HTTP/2 response trailers are supported.

```
C#
```

```
if (httpContext.Response.SupportsTrailers())
{
    httpContext.Response.DeclareTrailer("trailername");

    // Write body
    httpContext.Response.WriteAsync("Hello world");

    httpContext.Response.AppendTrailer("trailername", "TrailerValue");
}
```

In the preceding example code:

- `SupportsTrailers` ensures that trailers are supported for the response.
- `DeclareTrailer` adds the given trailer name to the `Trailer` response header. Declaring a response's trailers is optional, but recommended. If `DeclareTrailer` is called, it must be before the response headers are sent.
- `AppendTrailer` appends the trailer.

Reset

Reset allows for the server to reset a HTTP/2 request with a specified error code. A reset request is considered aborted.

C#

```
var resetFeature = httpContext.Features.Get<IHttpResetFeature>();
resetFeature.Reset(errorCode: 2);
```

`Reset` in the preceding code example specifies the `INTERNAL_ERROR` error code. For more information about HTTP/2 error codes, visit the HTTP/2 specification error code section.

Tracing

For information about how to get traces from HTTP.sys, see HTTP.sys Manageability Scenarios.

.NET Hot Reload support for ASP.NET Core

Article • 04/10/2024

.NET Hot Reload applies code changes, including changes to stylesheets, to a running app without restarting the app and without losing app state. Hot Reload is supported for all ASP.NET Core 6.0 and later projects.

Generally, updated code is rerun to take effect with the following conditions:

- Some startup logic is only run once:
  - Middleware, unless the code update is to an inline middleware delegate.
  - Configured services.
  - Route creation and configuration, unless the code update is to a route handler delegate (for example, `OnInitialized`).
- In Blazor apps, the framework triggers a Razor component render automatically.
- In MVC and Razor Pages apps, Hot Reload triggers a browser refresh automatically.
- Removing a Razor component parameter attribute doesn't cause the component to rerender. The app must be restarted.

For more information on supported scenarios, see Supported code changes (C# and Visual Basic).

Blazor WebAssembly

Blazor WebAssembly Hot Reload supports the following code changes:

- New types.
- Nested classes.
- Most changes to method bodies, such as adding, removing, and editing variables, expressions, and statements.
- Changes to the bodies of lambda expressions and local functions.
- Adding static and instance methods to existing types.
- Adding static and instance fields, events, and properties to existing types.
- Adding static lambdas to existing methods.
- Adding lambdas that capture `this` to existing methods that already captured `this` previously.

Note that when an attribute is removed that previously set the value of a component parameter, the component is disposed and re-initialized to set the removed parameter

back to its default value.

The following code changes aren't supported for Blazor WebAssembly apps:

- Adding a new await operator or yield keyword expression.
- Changing the names of method parameters.

.NET CLI

Hot Reload is activated using the dotnet watch command:

.NET CLI

```
dotnet watch
```

To force the app to rebuild and restart, use the keyboard combination `Ctrl`+`R` in the command shell.

When an unsupported code edit is made, called a *rude edit*, `dotnet watch` asks you if you want to restart the app:

- **Yes**: Restarts the app.
- **No**: Doesn't restart the app and leaves the app running without the changes applied.
- **Always**: Restarts the app as needed when rude edits occur.
- **Never**: Doesn't restart the app and avoids future prompts.

To disable support for Hot Reload, pass the `--no-hot-reload` option to the `dotnet watch` command:

.NET CLI

```
dotnet watch --no-hot-reload
```

Disable Hot Reload

The following setting in `Properties/launchSettings.json` disables Hot Reload:

JSON

```
"hotReloadEnabled" : false
```

How to use dev tunnels in Visual Studio 2022 with ASP.NET Core apps

Article • 11/06/2024

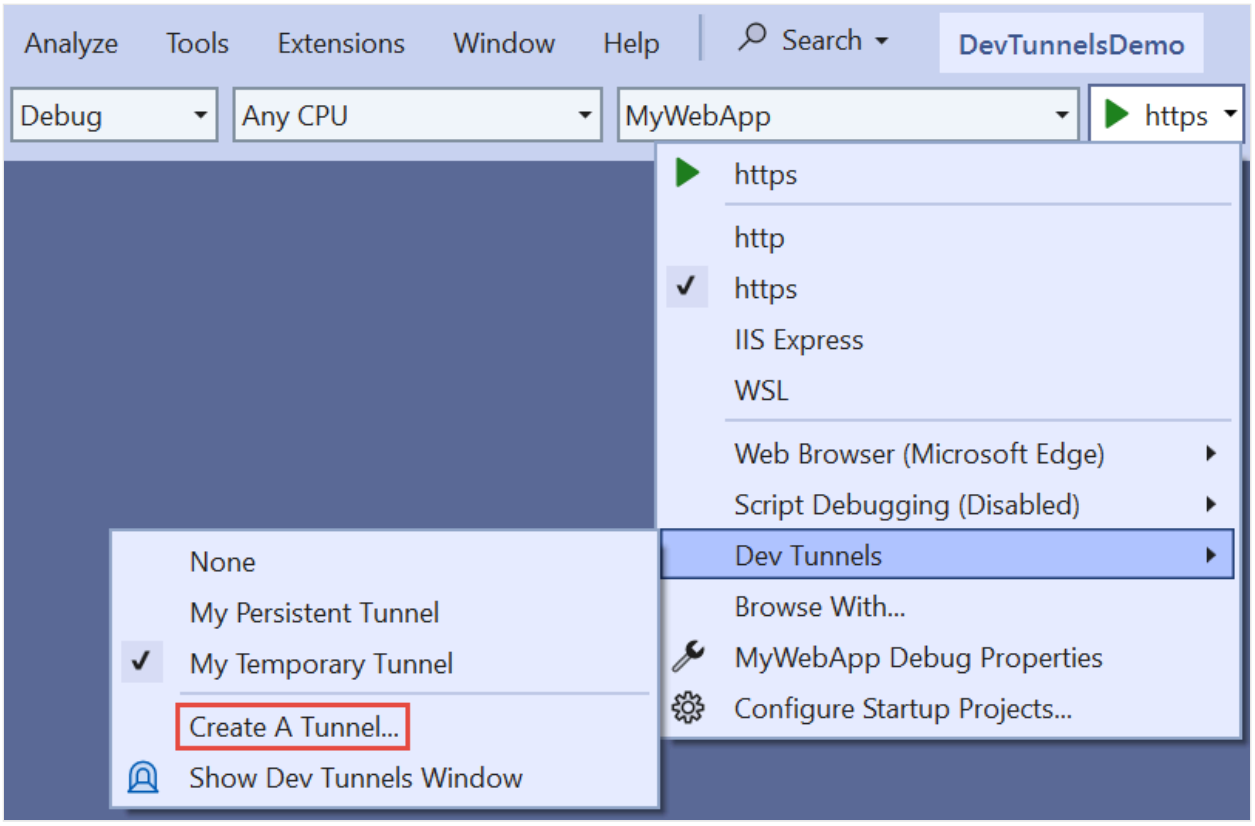
The *dev tunnels* feature of Visual Studio 2022 enables ad-hoc connections between machines that can't directly connect to each other. A URL is created that enables any device with an internet connection to connect to an ASP.NET Core project while it runs on localhost.

Use cases

Some of the scenarios that dev tunnels enable:

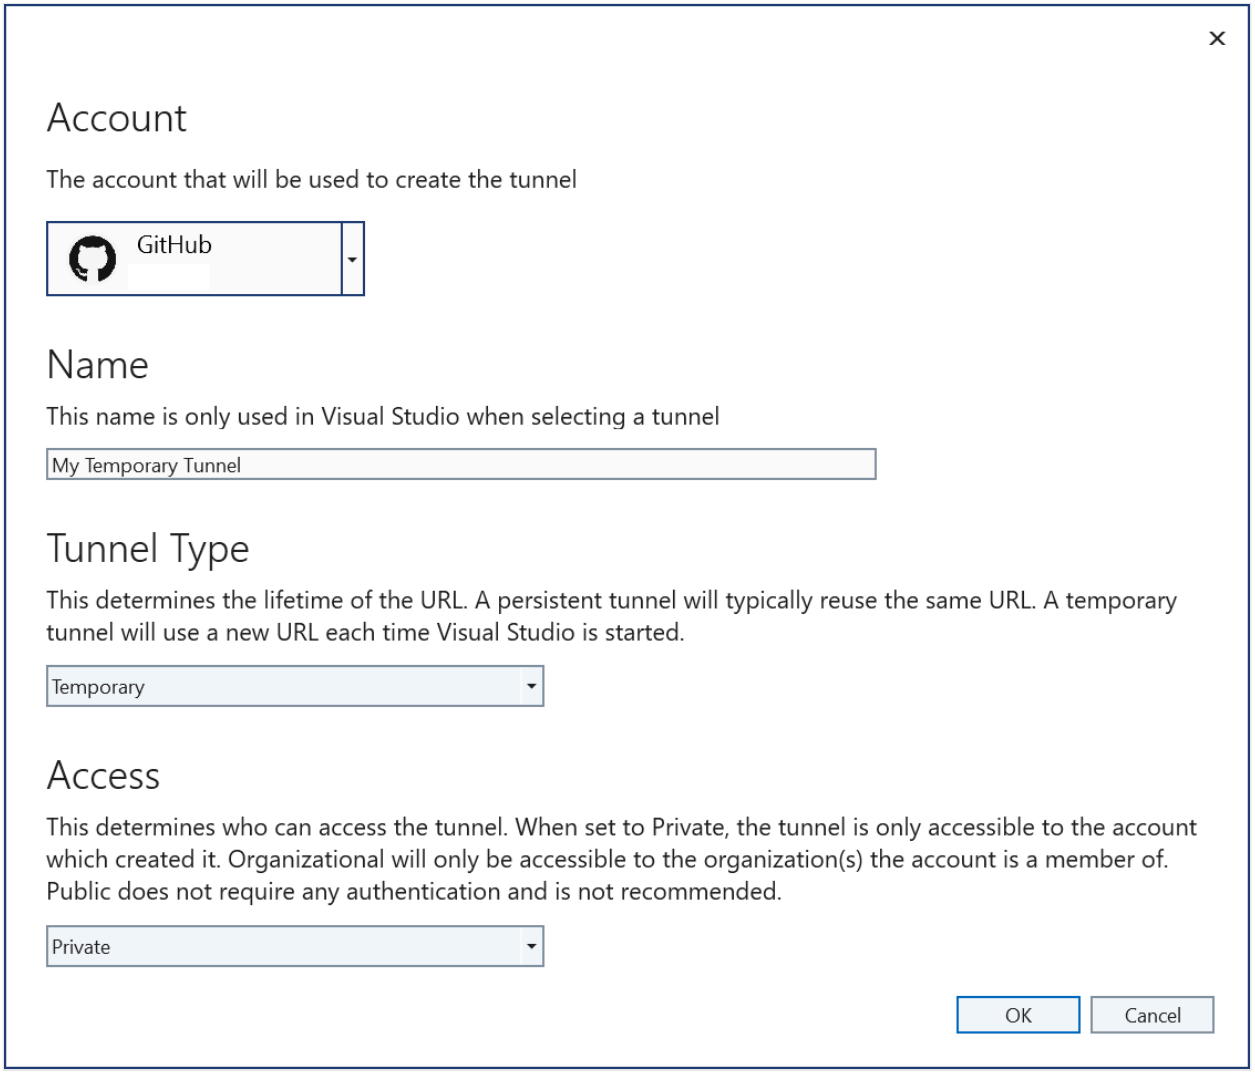
- Test a web app on other devices, like mobile phones and tablets.
- Test an app with external services. For instance, test and debug Power Platform connectors, Azure Communication Services APIs, or Twilio webhooks.
- Make an app temporarily available to others over the internet, for a presentation or to invite others to review your work on a web app or API.
- As an alternative to other port-forwarding solutions.

Prerequisites



- Visual Studio 2022 version 17.6 or later with the **ASP.NET and web development** workload installed. You need to be signed in to Visual Studio to create and use dev tunnels. The feature isn't available in Visual Studio for Mac.
- One or more ASP.NET Core projects. This article uses a solution with two sample projects to demonstrate the feature.

Create a tunnel

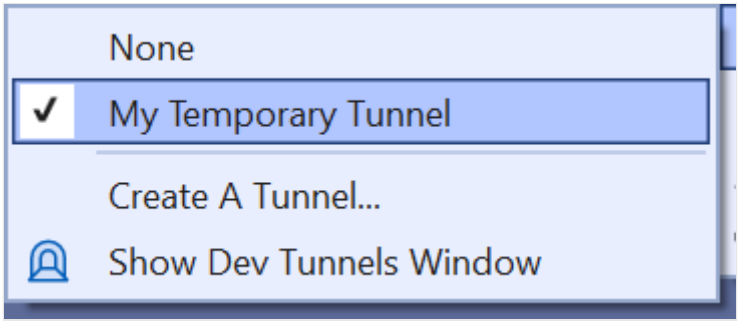


To create a tunnel:

In Visual Studio 2022, open an ASP.NET Core web project, or a solution with at least one web project set as a startup project.

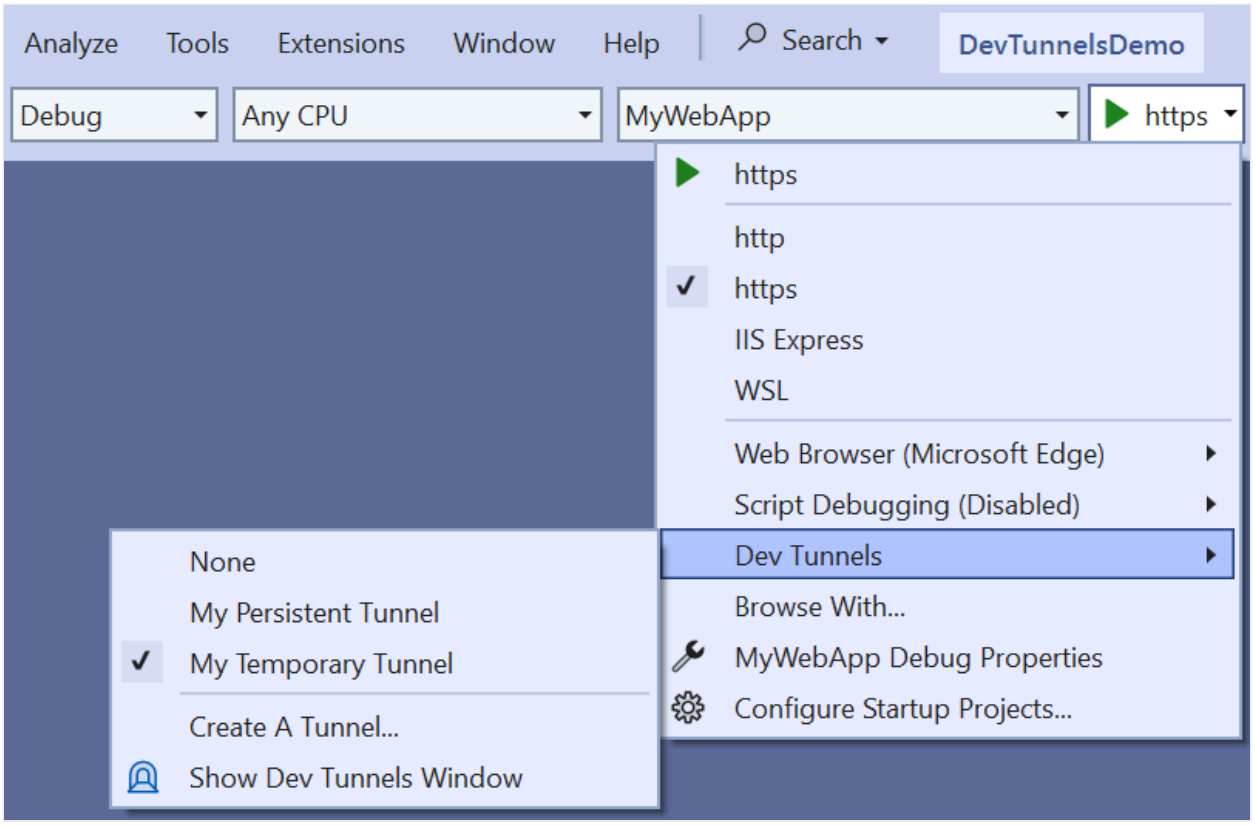
In the debug dropdown, select **Dev Tunnels** > **Create A Tunnel**.

The tunnel creation dialog opens.



- Select the account to use to create the tunnel. Account types that can be used to create tunnels include Azure, Microsoft Account (MSA), and GitHub.
- Enter a name for the tunnel. This name identifies the tunnel in the Visual Studio UI.
- Choose the tunnel type, Persistent or Temporary:
  - A temporary tunnel gets a new URL each time Visual Studio is started.
  - A persistent tunnel gets the same URL each time Visual Studio is started. For more information, see Persistent vs. temporary tunnels later in this article.
- Choose the authentication that is required for access to the tunnel. The following options are available:
  - Private: The tunnel is accessible only to the account that created it.
  - Organization: The tunnel is accessible to accounts in the same organization as the one that created it. If this option is selected for a personal Microsoft account (MSA), the effect is the same as selecting Private. Organization support for Github accounts isn't supported.
  - Public: No authentication required. Choose this option only if it's safe to make the web app or API accessible to anyone on the internet.
- Select **OK**.

Visual Studio displays confirmation of tunnel creation:

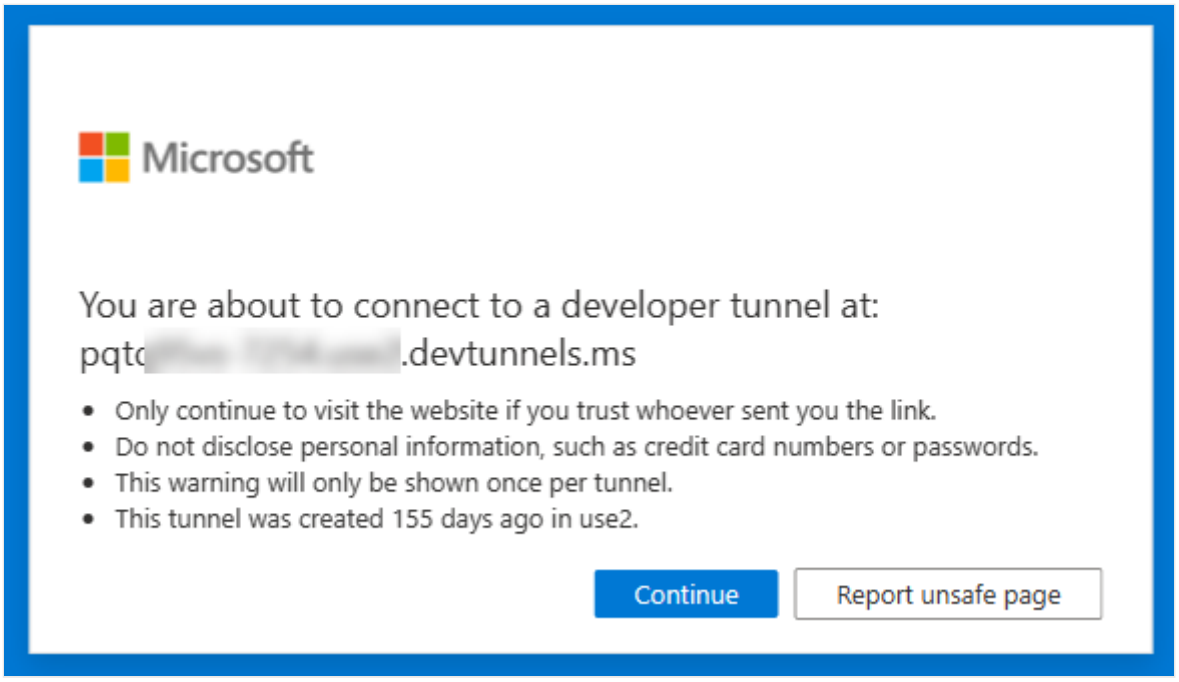


The tunnel appears in the debug dropdown **Dev Tunnels** flyout:

Specify the active tunnel

A project or solution can have multiple tunnels, but only one at a time is active. The **Dev Tunnels** flyout in the debug dropdown can specify the active tunnel. When there is an active tunnel, it's used for all ASP.NET Core projects that are started in Visual Studio. Once a tunnel is selected as active, it remains active until Visual Studio is closed. In the following illustration, **My Temporary Tunnel** is active:

Choose not to use a tunnel by selecting **None** in the flyout. When Visual Studio is restarted, it defaults back to **None**.



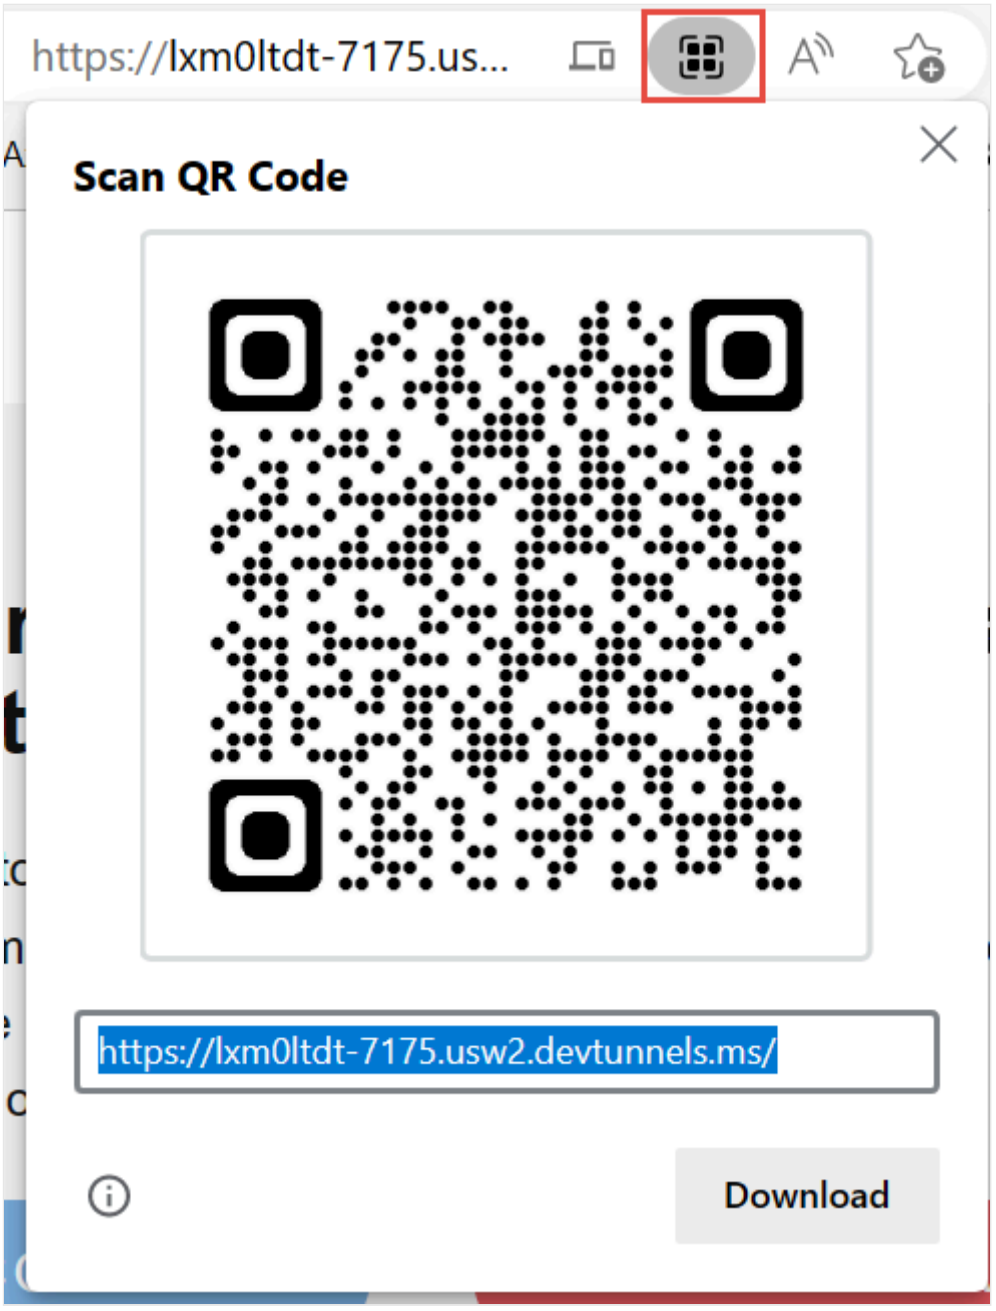
Use a tunnel

When a tunnel is active and Visual Studio runs a web app, the web browser opens to a tunnel URL instead of a localhost URL. The tunnel URL looks like the following example:

```
https://0pbvlk3m-7032.usw2.devtunnels.ms
```

Now any authenticated user can open the same URL on any other internet-connected device. As long as the project continues to run locally, any device with an internet connection can access the web application that is running on a development machine.

For web projects that have browser support, a warning page is shown on the first request sent to the tunnel URL from each device:

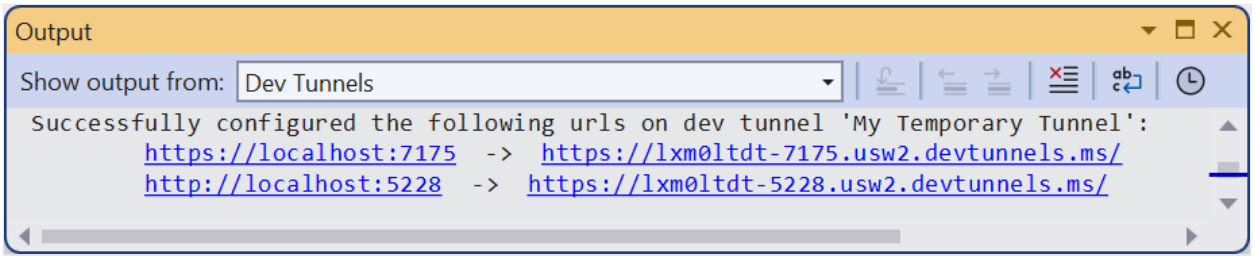


After **Continue** is selected, the request is routed to the local web app. This notification page isn't shown for API requests using dev tunnels.

Use a tunnel to test on a phone or tablet

To test a web app from an external device like a phone or tablet, navigate to the tunnel URL. To make it easier to reproduce the URL on the external device:

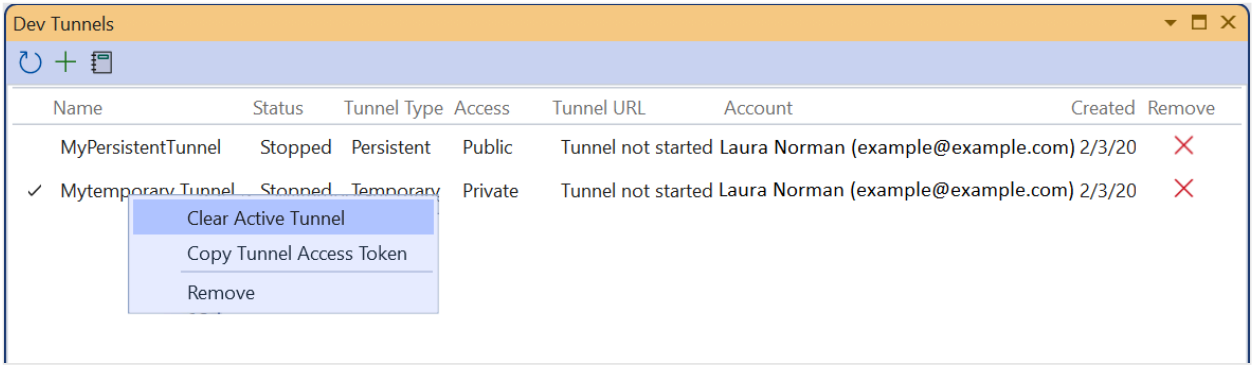
- Navigate to the tunnel URL in an Edge browser on the local machine.
- Generate a QR code to the URL in the Edge browser on the local machine:
  - Select the URL bar and the QR code button appears.



- Select the QR code button to generate and view the QR code.

- Scan this QR code with a phone or tablet to navigate to the URL.

Dev Tunnels output window



To show the URL of a tunnel of a running project, select **Dev Tunnels** in the **Show output from** dropdown.

This window is especially useful for projects that don't open a browser by default. For example, when working with an Azure Function, this may be the easiest way to discover the public URL that is being used by the dev tunnel.

Dev Tunnels tool window

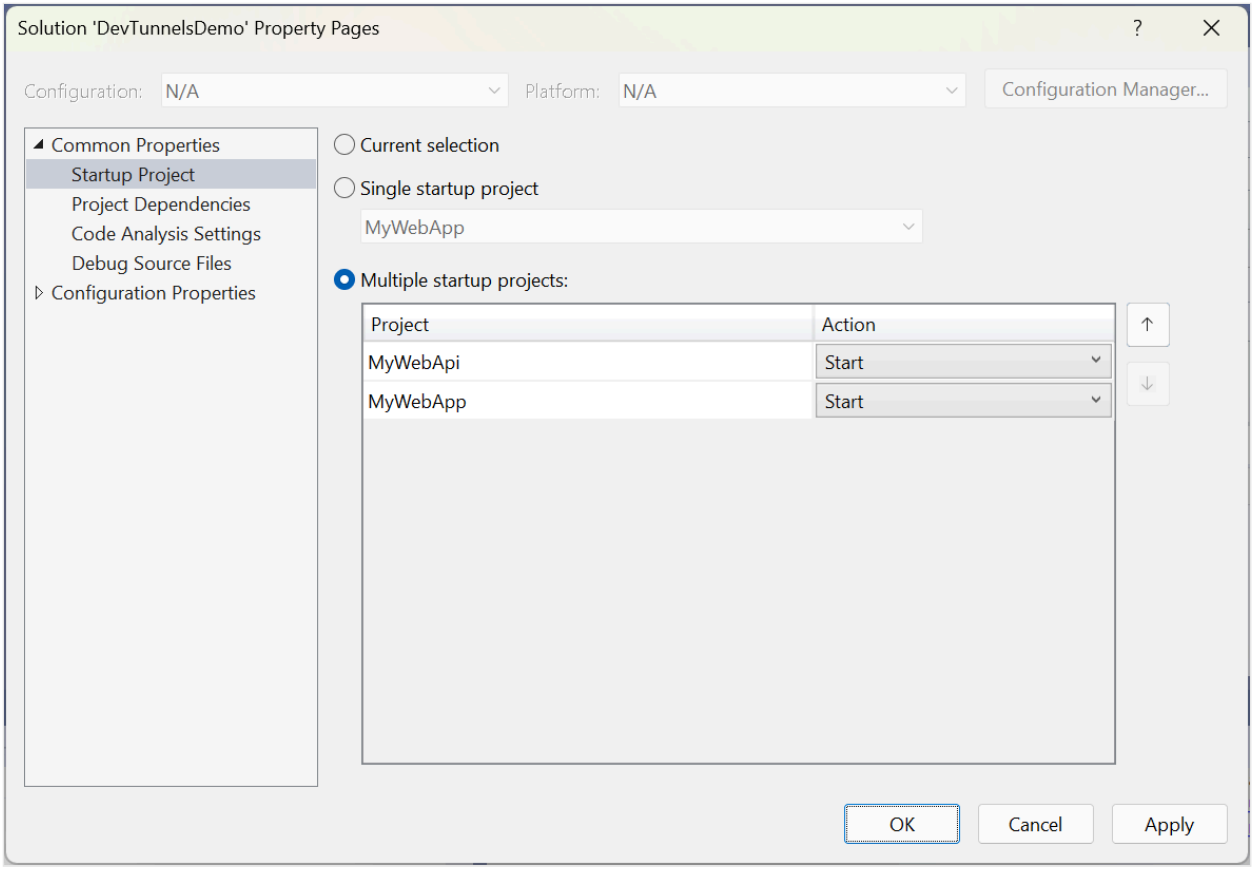
View and manage dev tunnels in the **Dev Tunnels** tool window:

To open the **Dev Tunnels** window, select the **Show Dev Tunnels Window** menu option in the debug dropdown. Alternatively, select **View** > **Other Windows** > **Dev Tunnels**.

From the **Dev Tunnels** window, create a new tunnel by selecting the green `+` button.

Delete a tunnel by using the red `x` button to the right of the tunnel.

The context menu for a tunnel provides the following options:



- **Clear Active Tunnel**: Shown when a tunnel is configured as active (indicated by the checkmark on the left hand side), this resets it so the solution is not using a tunnel.
- **Make Active Tunnel**: Shown for tunnels that are not configured as active.
- **Copy Tunnel Access Token**: Provided for scenarios where a tunnel is created with private or organizational access, and the app is a web API. To authenticate for the tunnel, copy and paste the tunnel access token as a header of the form `X-Tunnel-Authorization tunnel <TOKEN>` in the request. If this header is not specified, the request will be blocked because the authentication check failed.
- **Remove**

Tunnel URL environment variables

The dev tunnels feature provides a way to get the tunnel URL of a project programmatically at run time. When an app is launched that uses a tunnel, Visual Studio creates the environment variable `VS_TUNNEL_URL`. The `VS_TUNNEL_URL` value is the URL for the tunnel that is used for the current project. `VS_TUNNEL_URL` can be useful when

integrating the app with an external service, where the tunnel URL needs to be passed to the external service.

If multiple ASP.NET Core projects are configured to start in Visual Studio, the app that is starting up gets an environment variable for any project that started before it. The pattern for this variable name is `VS_TUNNEL_URL_{ProjectName}`, where `{ProjectName}` is the name of the other project. For example, consider this example showing two projects set to start:

Since MyWebApi is above MyWebApp, it's started before the MyWebApp project. When the MyWebApi project is started, it receives its tunnel URL in the `VS_TUNNEL_URL` environment variable. When the MyWebApp project is started, it receives its own tunnel URL in `VS_TUNNEL_URL` and the other project's tunnel URL is provided in the `VS_TUNNEL_URL_MyWebApi` environment variable.

To illustrate, the following highlighted lines of code have been added to the *Program.cs* file in MyWebApp:

C#

```
public class Program
{
    public static void Main(string[] args)
    {
```

```
Console.WriteLine($"Tunnel URL: {Environment.
    GetEnvironmentVariable("VS_TUNNEL_URL")}");
Console.WriteLine($"API project tunnel URL: {Environment.
    GetEnvironmentVariable("VS_TUNNEL_URL_MyWebApi")}");
```

When the web app is started the console output looks like the following example:

Console

```
Tunnel URL: https://lxm0ltdt-7175.usw2.devtunnels.ms/
API project tunnel URL: https://lxm0ltdt-7042.usw2.devtunnels.ms/
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: https://localhost:7175
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: http://localhost:5228
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path: C:\DevTunnelsDemo\MyWebApp
```

For information about how to set up multiple startup projects, see How to: Set multiple startup projects.

Persistent versus temporary tunnels

A persistent tunnel is one that uses the same URL after exiting and restarting Visual Studio. Having a URL that doesn't change can be useful when integrating a web app with an external service. For example, implementing a GitHub webhook, or developing an API to integrate with a Power Platform app. In such cases, you might need to specify the callback URL to the external service. With a persistent tunnel, the external service URL only needs to be configured once. Using a temporary tunnel, the tunnel URL must be configured each time Visual Studio restarts.

Persistent doesn't mean the tunnel works when Visual Studio isn't open. A tunnel URL connects to the local machine only if the ASP.NET Core project that the tunnel URL connects to is running in Visual Studio.

A temporary tunnel is fine when the dev tunnel URL needs to work for a short time. For example, sharing in-progress work on a web app with others, or testing an app on an external device. In some cases, it might be best to get a new URL each time Visual Studio starts.

The following resources use an early preview version of the dev tunnels feature, so parts of them are out of date:

- Use dev tunnels in Visual Studio to debug your web APIs
- ACS Call Automation and Azure OpenAI Service
- Use Visual Studio dev tunnels to handle Twilio Webhooks.

Use .http files in Visual Studio 2022

Article • 07/23/2024

The Visual Studio 2022 `.http` file editor provides a convenient way to test ASP.NET Core projects, especially API apps. The editor provides a UI that:

- Creates and updates `.http` files.
- Sends HTTP requests specified in `.http` files.
- Displays the responses.

This article contains documentation for:

- The .http file syntax.
- How to create an .http file.
- How to send a request from an .http file.
- Where to find .http file options that can be configured..
- How to create requests in .http files by using the Visual Studio 2022 **Endpoints Explorer**.

The `.http` file format and editor was inspired by the Visual Studio Code REST Client extension. The Visual Studio 2022 `.http` editor recognizes `.rest` as an alternative file extension for the same file format.

Prerequisites

- Visual Studio 2022 version 17.8 or later with the **ASP.NET and web development** workload installed.

`.http` file syntax

The following sections explain `.http` file syntax.

Requests

The format for an HTTP request is `HTTPMethod URL HTTPVersion`, all on one line, where:

- `HTTPMethod` is the HTTP method to use, for example:
  - OPTIONS
  - GET
  - HEAD

    - POST
    - PUT
    - PATCH
    - DELETE
    - TRACE
    - CONNECT
- `URL` is the URL to send the request to. The URL can include query string parameters. The URL doesn't have to point to a local web project. It can point to any URL that Visual Studio can access.
- `HTTPVersion` is optional and specifies the HTTP version that should be used, that is, `HTTP/1.1`, `HTTP/2`, or `HTTP/3`.

A file can contain multiple requests by using lines with `###` as delimiters. The following example showing three requests in a file illustrates this syntax:

```HTTP
GET https://localhost:7220/weatherforecast

###

GET https://localhost:7220/weatherforecast?date=2023-05-11&location=98006

###

GET https://localhost:7220/weatherforecast HTTP/3

###
```

Request headers

To add one or more headers, add each header on its own line immediately after the request line. Don't include any blank lines between the request line and the first header or between subsequent header lines. The format is `HeaderName: Value`, as shown in the following examples:

```HTTP
GET https://localhost:7220/weatherforecast
Date: Wed, 27 Apr 2023 07:28:00 GMT

###

GET https://localhost:7220/weatherforecast
Cache-Control: max-age=604800
```

```
Age: 100

###
```

> **Important**
>
> When calling an API that authenticates with headers, do not commit any secrets to a source code repository. See the supported methods for storing secrets later in this article, such as ASP.NET Core user secrets, Azure Key Vault and DPAPI encryption.

Request body

Add the request body after a blank line, as shown in the following example:

HTTP

```
POST https://localhost:7220/weatherforecast
Content-Type: application/json
Accept-Language: en-US,en;q=0.5

{
    "date": "2023-05-10",
    "temperatureC": 30,
    "summary": "Warm"
}

###
```

Comments

Lines that start with either `#` or `//` are comments. These lines are ignored when Visual Studio sends HTTP requests.

Variables

A line that starts with `@` defines a variable by using the syntax `@VariableName=Value`.

Variables can be referenced in requests that are defined later in the file. They're referenced by wrapping their names in double curly braces, `{{` and `}}`. The following example shows two variables defined and used in a request:

HTTP

```
@hostname=localhost
@port=44320
GET https://{{hostname}}:{{port}}/weatherforecast
```

Variables can be defined using values of other variables that were defined earlier in the file. The following example uses one variable in the request instead of the two shown in the preceding example:

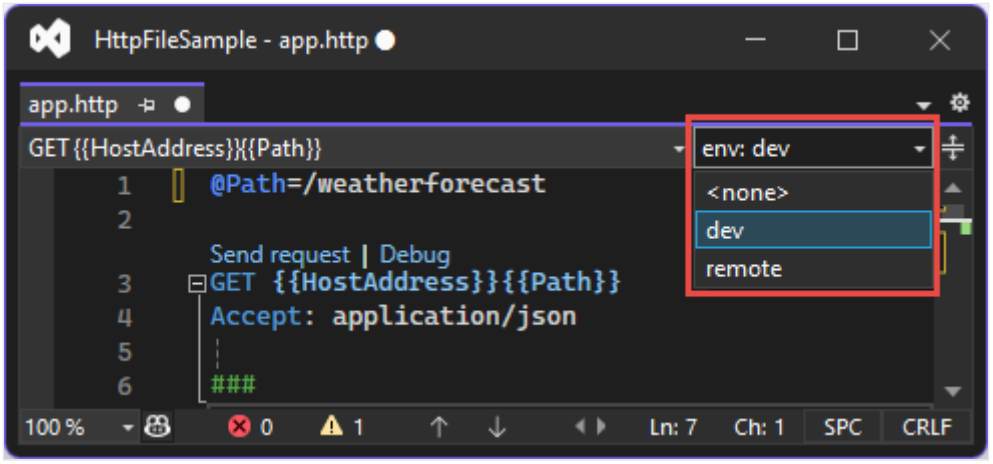
HTTP

```
@hostname=localhost
@port=44320
@host={{hostname}}:{{port}}
GET https://{{host}}/api/search/tool
```

Environment files

To give variables different values in different environments, create a file named `http-client.env.json`. Locate the file in the same directory as the `.http` file or in one of its parent directories. Here's an example of an environment file:

JSON



```
{
  "dev": {
    "HostAddress": "https://localhost:44320"
  },
  "remote": {
    "HostAddress": "https://contoso.com"
  }
}
```

The environment file is a JSON file that contains one or more named environments, such as "dev" and "remote" in the preceding example. Each named environment contains one or more variables, such as `HostAddress` in the preceding example. Variables from an environment file are referenced the same way as other variables, as shown in the following example:

HTTP

```
GET {{HostAddress}}/api/search/tool
```

The value that is used for the variable when sending a request is determined by an environment selector dropdown at the upper right corner of the `.http` file editor. The following screenshot shows the selector:

The environment file doesn't have to be in the project folder. Visual Studio looks for an environment file in the folder where the `.http` file exists. If it's not in that folder, Visual Studio looks through the parent directories to find it. When a file named `http-client.env.json` is found, the search ends. The file found nearest to the `.http` file is used.

After creating or editing an `.http` file, you might have to close and reopen the project to see the changes reflected in the environment selector. Press `F6` to select the environment selector.

Visual Studio displays warnings in the following situations:

- The `.http` file references a variable that isn't defined in the `.http` file or in the environment file.
- The environment file contains a variable that isn't referenced in the `.http` file.

A variable defined in an environment file can be the same as one defined in the `.http` file, or it can be different. If a variable is defined in both the `.http` file and the environment file, the value in the `.http` file overrides the value in the environment file.

User-specific environment files

A user-specific value is any value that an individual developer wants to test with but doesn't want to share with the team. Since the `http-client.env.json` file is checked in to source control by default, it wouldn't be appropriate to add user-specific values to this file. Instead, put them in a file named `http-client.env.json.user` located in the same folder as the `http-client.env.json` file. Files that end with `.user` should be

excluded from source control by default when using Visual Studio source control features.

When the `http-client.env.json` file is loaded, Visual Studio looks for a sibling `http-client.env.json.user` file. If a variable is defined in an environment in both the `http-client.env.json` file and the `http-client.env.json.user` file, the value in the `http-client.env.json.user` file wins.

Here's an example scenario that shows how a user-specific environment file works. Suppose the `.http` file has the following content:

HTTP

```
GET {{HostAddress}}/{{Path}}
Accept: application/json
```

And suppose the `http-client.env.json` file contains the following content:

JSON

```
{
  "dev": {
    "HostAddress": "https://localhost:7128",
    "Path": "/weatherforecast"
  },
  "remote": {
    "HostAddress": "https://contoso.com",
    "Path": "/weatherforecast"
  }
}
```

And suppose there's a user-specific environment file that contains the following content:

JSON

```
{
  "dev": {
    "Path": "/swagger/index.html"
  }
}
```

When the user selects the "dev" environment, the request is sent to `https://localhost:7128/swagger/index.html` because the `Path` value in the `http-client.env.json.user` file overrides the value from the `http-client.env.json` file.

With the same environment files, suppose the variables are defined in the `.http` file:

HTTP

```
@HostAddress=https://contoso.com
@Path=/weatherforecast

GET {{HostAddress}}/{{Path}}
Accept: application/json
```

In this scenario, the "dev" environment request is sent to `https://contoso.com/weatherforecast` because variable definitions in `.http` files override environment file definitions.

ASP.NET Core user secrets

To get a value from user secrets, use an environment file that is located in the same folder as the ASP.NET Core project. In the environment file, define a variable that has `provider` and `secretName` properties. Set the `provider` value to `AspnetUserSecrets` and set `secretName` to the name of the desired user secret. For example, the following environment file defines a variable named `ApiKeyDev` that gets its value from the `config:ApiKeyDev` user secret:

JSON

```
{
  "dev": {
    "ApiKeyDev": {
      "provider": "AspnetUserSecrets",
      "secretName": "config:ApiKeyDev"
    }
  }
}
```

To use this variable in the `.http` file, reference it like a standard variable. For example:

HTTP

```
GET {{HostAddress}}{{Path}}
X-API-KEY: {{ApiKeyDev}}
```

When the request is sent, the value of the `ApiKeyDev` secret is in the X-API-KEY header.

As you type in the `http` file, the editor shows a completion list for the variable name but doesn't show its value.

Azure Key Vault

Azure Key Vault is one of several key management solutions in Azure that can be used for secrets management. Of the three secrets stores currently supported for `.http` files, Key Vault is the best choice for sharing secrets across different users. The other two options—ASP.NET User Secrets and DPAPI encryption—aren't easily shared.

To use a value from Azure Key Vault, you must be signed into Visual Studio with an account that has access to the desired Key Vault. Define a variable in an environment file with the metadata to access the secret. The variable is named `AKVSecret` in the following example:

JSON

```
{
  "dev": {
    "AKVSecret": {
      "provider": "AzureKeyVault",
      "secretName": "SecretInKeyVault",
      "resourceId": "/subscriptions/3a914c59-8175a9e0e540/resourceGroups/my-key-vault-rg/providers/Microsoft.KeyVault/vaults/my-key-vault-01182024"
    }
  }
}
```

The variable `AKVSecret` pulls its value from Azure Key Vault. The following properties are defined on `AKVSecret`:

Expand table

Name	Description
provider	For Key Vault, always use `AzureKeyVault`.
secretName	Name of the secret to extract.
resourceId	Azure resource ID for the specific Key Vault to access.

The value for the `resourceId` property can be found in the Azure portal. Go to **Settings** > **Properties** to find it. For `secretName`, use the name of the secret that appears on the **Secrets** page in the Azure portal.

For example, the following `.http` file has a request that uses this secret value.

HTTP

```
GET {{HostAddress}}{{Path}}
X-AKV-SECRET: {{akvSecret}}
```

DPAPI encryption

On Windows, there is a Data Protection API (DPAPI) that can be used to encrypt sensitive data. When DPAPI is used to encrypt data, the encrypted values are always machine-specific, and they're also user-specific in `.http` files. These values can't be shared with other users.

To encrypt a value, use the following console application:

C#

```
using System.Security.Cryptography;
using System.Text;

string stringToEncrypt = "Hello, World!";
byte[] encBytes =
ProtectedData.Protect(Encoding.Unicode.GetBytes(stringToEncrypt),
optionalEntropy: null, scope: DataProtectionScope.CurrentUser);
string base64 = Convert.ToBase64String(encBytes);
Console.WriteLine(base64);
```

The preceding console application references the System.Security.Cryptography.ProtectedData NuGet package. To enable the encrypted value to work in the `.http` file, encrypt with the scope set to DataProtectionScope.CurrentUser. The encrypted value is a base64 encoded string that can be copied and pasted into the environment file.

In the environment file, create a variable that has `provider` and `value` properties. Set `provider` to `Encrypted`, and set `value` to the encrypted value. For example, the following environment file defines a variable named `dpapiValue` that gets its value from a string that was encrypted with DPAPI.

JSON

```
{
  "dev": {
    "dpapiValue": {
      "provider": "Encrypted",
      "value":
"AQAAANCMnd8BFdERjHoAwE/Cl+sBAAAA5qwfg4+Bhk2nsy6ujgg3GAAAAAACAAAAAAAQZgAAAAE
AACAAAAAqNXhXc098k1TtKmaI4cUAbJVALMVP1zOR7mhC1RBJegAAAAOgAAAAIAACAAAABKu4E
9WC/zX5LYZZhOS2pukxMTF9R4yS+XA9HoYF98GzAAAAAzFXatt461ZnVeUWgOV8M/DkqNviWUUje
```

```
xAXOF/JfpJMw/CdsizQyESus2QjsCtZlAAAAAL7ns3u9mEk6wSMIn+KNsW/vdAw51OaI+HPVrt5v
FvXRilTtvGbU/JnxsoIHj0Z7OOxlwOSg1Qdn60zEqmlFJBg=="
    }
  }
}
```

With the preceding environment file, `dpapiValue` can be used in the `.http` file like any other variable. For example:

HTTP

```
GET {{HostAddress}}{{Path}}
X-DPAPI-Secret: {{dpapiSecret}}
```

When this request is sent, X-DPAPI-Secret has the decrypted secret value.

Environment variables

To get the value of an environment variable, use `$processEnv`. The following example puts the value of the USERNAME environment variable in the X-UserName header.

HTTP

```
GET {{HostAddress}}{{Path}}
X-UserName: {{$processEnv USERNAME}}
```

If you try to use `$processEnv` to access an environment variable that doesn't exist, the `.http` file editor displays an error message.

`.env` files

To get the value of a variable that is defined in a .env file, use `$dotenv`. The `.env` file must be in the project folder. The format for `$dotenv` is the same as for `$processEnv`. For example, if the `.env` file has this content:

```
USERNAME=userFromDotenv
```

And the `.http` file has this content:

HTTP

```
GET {{HostAddress}}{{Path}}
X-UserName: {{$dotEnv USERNAME}}
```

The `X-UserName` header will have "userFromDotenv".

When `$dotenv` is entered in the editor, it shows completions for the variables defined in the `.env` file.

> ⓘ Note
>
> `.env` files might not be excluded from source control by default, so be careful to avoid checking in any secret values.

Random integers

To generate a random integer, use `$randomInt`. The syntax is `{{$randomInt [min max]}}` where the `min` and `max` values are optional.

Dates and times

- `$datetime` generates a `datetime` string in UTC. The syntax is `{{$datetime [format] [offset option]}}` where the format and offset options are optional.
- `$localDatetime` generates a `datetime` string in the local time zone. The syntax is `{{$localDatetime [format] [offset option]}}` where the format and offset options are optional.
- `$timeStamp` generates a `timestamp` in UTC. The `timestamp` is the number of seconds since the Unix Epoch in UTC time. The syntax is `{{$timestamp [offset option]}}` where the offset option is optional.

The `[format]` option is one of `rfc1123`, `iso8601`, or a custom format in quotation marks. For example:

HTTP

```
GET https://httpbin.org/headers
X-CUSTOM: {{$datetime "dd-MM-yyyy"}}
X-ISO8601: {{$datetime iso8601}}
X-ISO8601L: {{$localDatetime iso8601}}
X-RFC1123: {{$datetime rfc1123}}
X-RFC1123L: {{$localDatetime rfc1123}}
```

Here are some sample values that the preceding examples generate:

JSON

```
{
  "headers": {
    "X-Custom": "17-01-2024",
    "X-Iso8601": "2024-01-17T22:59:55.5345770+00:00",
    "X-Iso8601L": "2024-01-17T14:59:55.5345770-08:00",
    "X-Rfc1123": "Wed, 17 Jan 2024 22:59:55 GMT",
    "X-Rfc1123L": "Wed, 17 Jan 2024 14:59:55 -08"
  }
}
```

The `[offset option]` syntax is in the form `number` `unit` where `number` is an integer and `unit` is one of the following values:

Expand table

`unit`	**Explanation**
`ms`	Milliseconds
`s`	Seconds
`m`	Minutes
`h`	Hours
`d`	Days
`w`	Weeks
`M`	Months
`y`	Years

For example:

HTTP

```
GET https://httpbin.org/headers
X-Custom-Minus-1-Year: {{$datetime "dd-MM-yyyy" -1 y}}
X-RFC1123-Plus-1-Day: {{$datetime rfc1123 1 d}}
X-Timestamp-Plus-1-Year: {{$timestamp 1 y}}
```

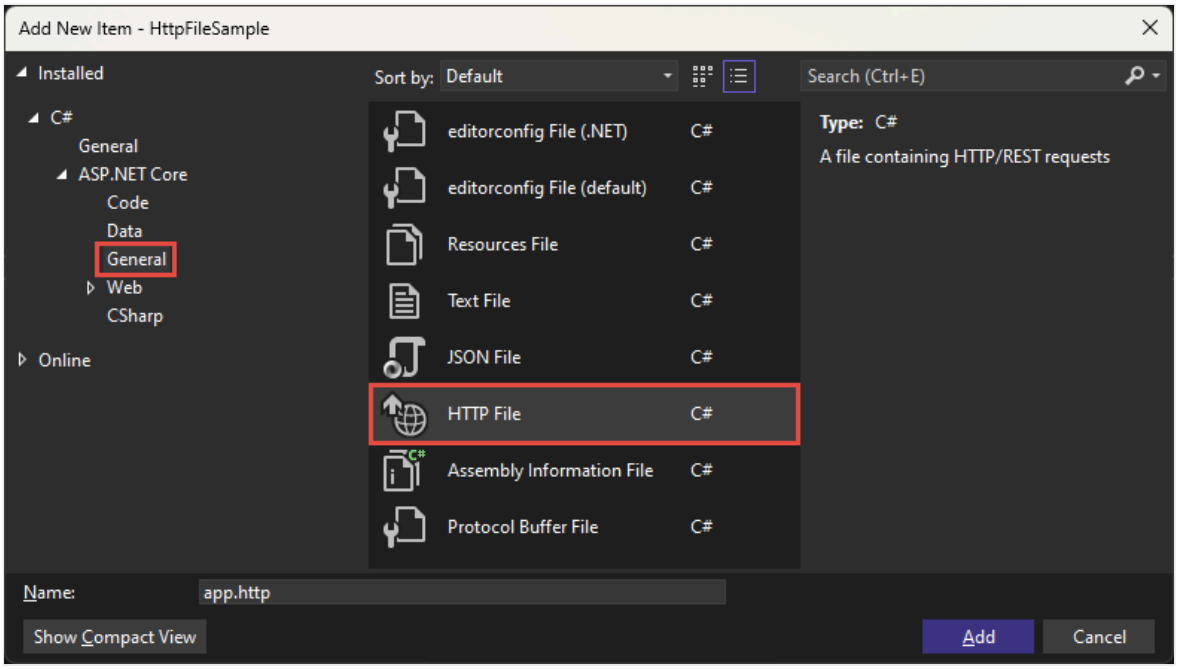
Here are some sample values that the preceding examples generate:

JSON

```
{
  "headers": {
    "X-Custom-Minus-1-Year": "17-01-2023",
    "X-Rfc1123-Plus-1-Day": "Thu, 18 Jan 2024 23:02:48 GMT",
    "X-Timestamp-Plus-1-Year": "1737154968"
  }
}
```

Some of the preceding examples use the free open-source website <httpbin.org>. This is a third-party website not affiliated with Microsoft. In these examples it returns a response body with the headers that were sent in the request. For information about other ways to use this resource for API testing, see the httpbin.org site's home page.

Unsupported syntax

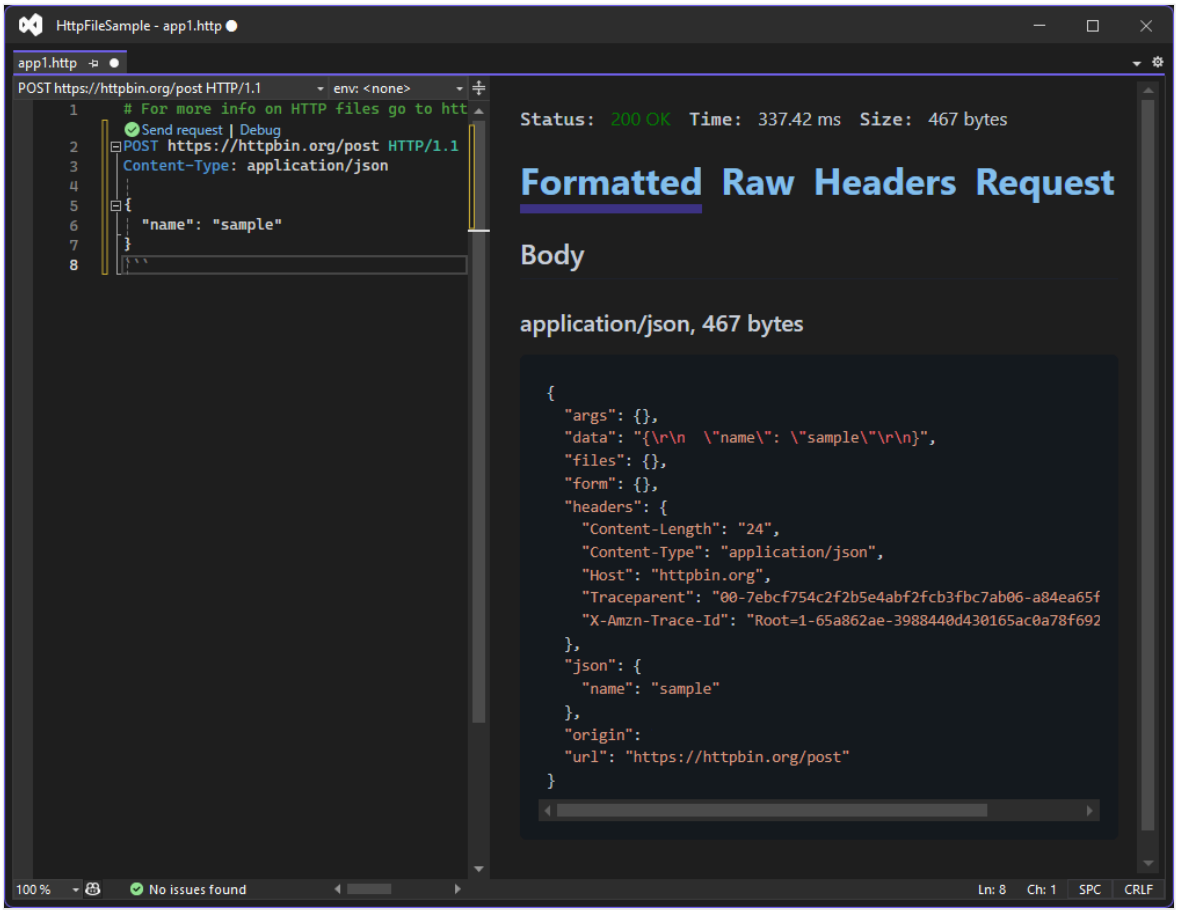


The Visual Studio 2022 `.http` file editor doesn't have all the features that the Visual Studio Code REST Client extension has. The following list includes some of the more significant features available only in the Visual Studio Code extension:

- Request line that spans more than one line
- Named requests
- Specify file path as body of the request
- Mixed format for body when using multipart/form-data
- GraphQL requests
- cURL request
- Copy/paste as cURL
- Request history
- Save response body to file
- Certificate based authentication
- Prompt variables
- Customize response preview
- Per-request settings

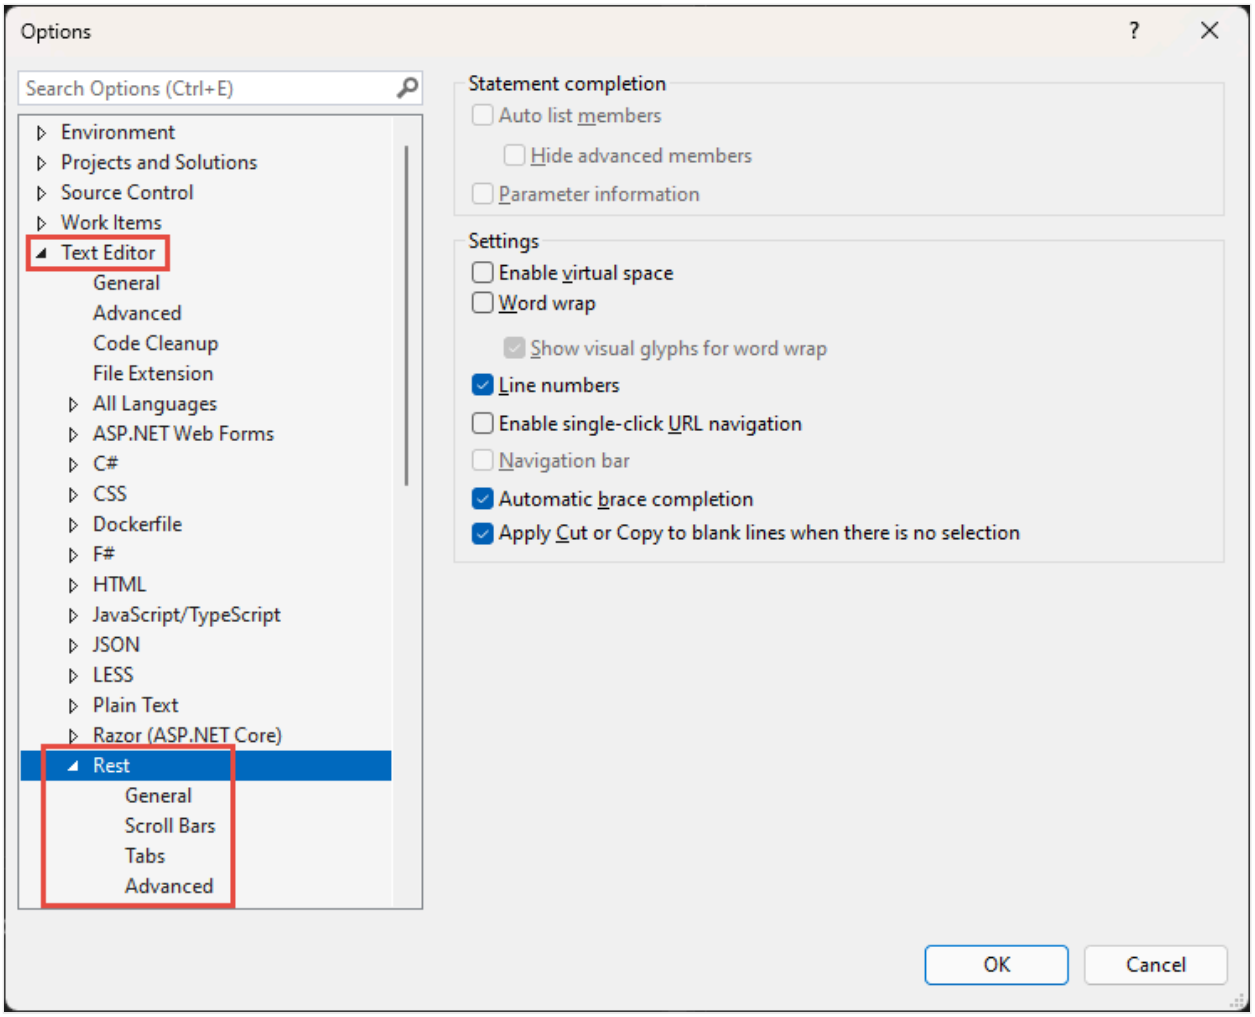
Create an `.http` file

- In **Solution Explorer**, right-click an ASP.NET Core project.
- In the context menu, select **Add** > **New Item**.
- In the **Add New Item** dialog, select **ASP.NET Core** > **General**.



- Select **HTTP File**, and select **Add**.

Send an HTTP request



- Add at least one request to an `.http` file and save the file.
- If the request URL points to localhost and the project's port, run the project before trying to send a request to it.
- Select the `Send Request` or `Debug` link that is directly above the request to be sent.

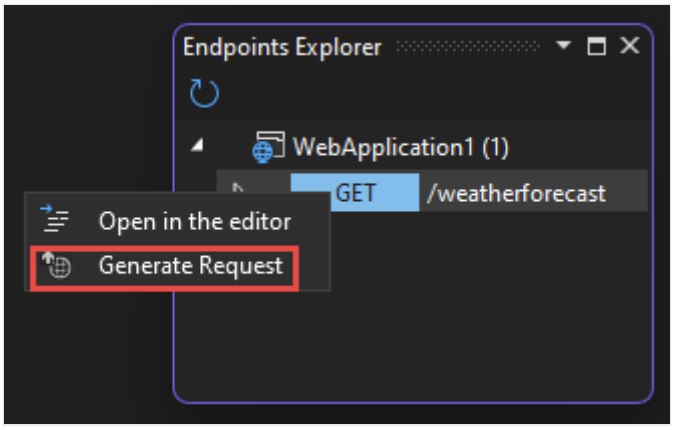
  The request is sent to the specified URL, and the response appears in a separate pane to the right of the editor window.

`.http` file options

Some aspects of `.http` file behavior can be configured. To see what's available, go to **Tools** > **Options** > **Text Editor** > **Rest**. For example, the timeout setting can be configured on the **Advanced** tab. Here's a screenshot of the **Options** dialog:

Use Endpoints Explorer

Endpoints Explorer is a tool window that shows all the endpoints that a web API defines. The tool enables you to send requests to the endpoints by using an `.http` file.



The initial set of endpoints that **Endpoints Explorer** displays are discovered statically. There are some endpoints that can't be discovered statically. For example, endpoints defined in a class library project can't be discovered until runtime. When you run or debug a web API, Visual Studio version 17.11 Preview discovers endpoints dynamically at run time also and adds those to **Endpoints Explorer**.

Open Endpoints Explorer

Select **View** > **Other Windows** > **Endpoints Explorer**.

Add a request to an `.http` file

Right-click a request in **Endpoints Explorer** and select **Generate Request**.

- If an `.http` file with the project name as the file name exists, the request is added to that file.
- Otherwise, an `.http` file is created with the project name as the file name, and the request is added to that file.

The preceding screenshot shows endpoints defined by the minimal API project template. The following example shows the request that is generated for the selected endpoint:

HTTP

```
GET {{WebApplication1_HostAddress}}/weatherforecast/
Accept: application/json

###
```

Send the request as described earlier in this article.

Test web APIs with the HttpRepl

Article • 07/28/2023

The HTTP Read-Eval-Print Loop (REPL) is:

- A lightweight, cross-platform command-line tool that's supported everywhere .NET Core is supported.
- Used for making HTTP requests to test ASP.NET Core web APIs (and non-ASP.NET Core web APIs) and view their results.
- Capable of testing web APIs hosted in any environment, including localhost and Azure App Service.

The following HTTP verbs are supported:

- DELETE
- GET
- HEAD
- OPTIONS
- PATCH
- POST
- PUT

To follow along, view or download the sample ASP.NET Core web API (how to download).

Prerequisites

- .NET Core 3.1 SDK

Installation

To install the HttpRepl, run the following command:

.NET CLI

```
dotnet tool install -g Microsoft.dotnet-httprepl
```

A .NET Core Global Tool is installed from the Microsoft.dotnet-httprepl NuGet package.

> **Note**
>
> By default the architecture of the .NET binaries to install represents the currently running OS architecture. To specify a different OS architecture, see **dotnet tool install, --arch option**. For more information, see GitHub issue **dotnet/AspNetCore.Docs #29262**.

On macOS, update the path:

```Bash
export PATH="$HOME/.dotnet/tools:$PATH"
```

Usage

After successful installation of the tool, run the following command to start the HttpRepl:

```Console
httprepl
```

To view the available HttpRepl commands, run one of the following commands:

```Console
httprepl -h
```

```Console
httprepl --help
```

The following output is displayed:

```Console
Usage:
  httprepl [<BASE_ADDRESS>] [options]

Arguments:
  <BASE_ADDRESS> - The initial base address for the REPL.

Options:
```

```
  -h|--help - Show help information.

Once the REPL starts, these commands are valid:

Setup Commands:
Use these commands to configure the tool for your API server

connect        Configures the directory structure and base address of the
api server
set header     Sets or clears a header for all requests. e.g. `set header
content-type application/json`

HTTP Commands:
Use these commands to execute requests against your application.

GET            get - Issues a GET request
POST           post - Issues a POST request
PUT            put - Issues a PUT request
DELETE         delete - Issues a DELETE request
PATCH          patch - Issues a PATCH request
HEAD           head - Issues a HEAD request
OPTIONS        options - Issues a OPTIONS request

Navigation Commands:
The REPL allows you to navigate your URL space and focus on specific APIs
that you are working on.

ls             Show all endpoints for the current path
cd             Append the given directory to the currently selected path, or
move up a path when using `cd ..`

Shell Commands:
Use these commands to interact with the REPL shell.

clear          Removes all text from the shell
echo [on/off]  Turns request echoing on or off, show the request that was
made when using request commands
exit           Exit the shell

REPL Customization Commands:
Use these commands to customize the REPL behavior.

pref [get/set] Allows viewing or changing preferences, e.g. 'pref set
editor.command.default 'C:\\Program Files\\Microsoft VS Code\\Code.exe'`
run            Runs the script at the given path. A script is a set of
commands that can be typed with one command per line
ui             Displays the Swagger UI page, if available, in the default
browser

Use `help <COMMAND>` for more detail on an individual command. e.g. `help
get`.
For detailed tool info, see https://aka.ms/http-repl-doc.
```

The HttpRepl offers command completion. Pressing the `Tab` key iterates through the list of commands that complete the characters or API endpoint that you typed. The following sections outline the available CLI commands.

Connect to the web API

Connect to a web API by running the following command:

```
Console

httprepl <ROOT URI>
```

`<ROOT URI>` is the base URI for the web API. For example:

```
Console

httprepl https://localhost:5001
```

Alternatively, run the following command at any time while the HttpRepl is running:

```
Console

connect <ROOT URI>
```

For example:

```
Console

(Disconnected)> connect https://localhost:5001
```

Manually point to the OpenAPI description for the web API

The connect command above will attempt to find the OpenAPI description automatically. If for some reason it's unable to do so, you can specify the URI of the OpenAPI description for the web API by using the `--openapi` option:

```
Console

connect <ROOT URI> --openapi <OPENAPI DESCRIPTION ADDRESS>
```

For example:

```
Console

(Disconnected)> connect https://localhost:5001 --openapi
/swagger/v1/swagger.json
```

Enable verbose output for details on OpenAPI description searching, parsing, and validation

Specifying the `--verbose` option with the `connect` command will produce more details when the tool searches for the OpenAPI description, parses, and validates it.

```
Console

connect <ROOT URI> --verbose
```

For example:

```
Console

(Disconnected)> connect https://localhost:5001 --verbose
Checking https://localhost:5001/swagger.json... 404 NotFound
Checking https://localhost:5001/swagger/v1/swagger.json... 404 NotFound
Checking https://localhost:5001/openapi.json... Found
Parsing... Successful (with warnings)
The field 'info' in 'document' object is REQUIRED [#/info]
The field 'paths' in 'document' object is REQUIRED [#/paths]
```

Navigate the web API

View available endpoints

To list the different endpoints (controllers) at the current path of the web API address, run the `ls` or `dir` command:

```
Console

https://localhost:5001/> ls
```

The following output format is displayed:

Console

```
.        []
Fruits   [get|post]
People   [get|post]

https://localhost:5001/>
```

The preceding output indicates that there are two controllers available: `Fruits` and `People`. Both controllers support parameterless HTTP GET and POST operations.

Navigating into a specific controller reveals more detail. For example, the following command's output shows the `Fruits` controller also supports HTTP GET, PUT, and DELETE operations. Each of these operations expects an `id` parameter in the route:

Console

```
https://localhost:5001/fruits> ls
.      [get|post]
..     []
{id}   [get|put|delete]

https://localhost:5001/fruits>
```

Alternatively, run the `ui` command to open the web API's Swagger UI page in a browser. For example:

Console

```
https://localhost:5001/> ui
```

Navigate to an endpoint

To navigate to a different endpoint on the web API, run the `cd` command:

Console

```
https://localhost:5001/> cd people
```

The path following the `cd` command is case insensitive. The following output format is displayed:

Console

```
/people    [get|post]

https://localhost:5001/people>
```

Customize the HttpRepl

The HttpRepl's default colors can be customized. Additionally, a default text editor can be defined. The HttpRepl preferences are persisted across the current session and are honored in future sessions. Once modified, the preferences are stored in the following file:

Windows

%USERPROFILE%\.httpreplprefs

The *.httpreplprefs* file is loaded on startup and not monitored for changes at runtime. Manual modifications to the file take effect only after restarting the tool.

View the settings

To view the available settings, run the `pref get` command. For example:

Console

```
https://localhost:5001/> pref get
```

The preceding command displays the available key-value pairs:

Console

```
colors.json=Green
colors.json.arrayBrace=BoldCyan
colors.json.comma=BoldYellow
colors.json.name=BoldMagenta
colors.json.nameSeparator=BoldWhite
colors.json.objectBrace=Cyan
colors.protocol=BoldGreen
colors.status=BoldYellow
```

Set color preferences

Response colorization is currently supported for JSON only. To customize the default HttpRepl tool coloring, locate the key corresponding to the color to be changed. For instructions on how to find the keys, see the View the settings section. For example, change the `colors.json` key value from `Green` to `White` as follows:

Console

```
https://localhost:5001/people> pref set colors.json White
```

Only the allowed colors may be used. Subsequent HTTP requests display output with the new coloring.

When specific color keys aren't set, more generic keys are considered. To demonstrate this fallback behavior, consider the following example:

- If `colors.json.name` doesn't have a value, `colors.json.string` is used.
- If `colors.json.string` doesn't have a value, `colors.json.literal` is used.
- If `colors.json.literal` doesn't have a value, `colors.json` is used.
- If `colors.json` doesn't have a value, the command shell's default text color (`AllowedColors.None`) is used.

Set indentation size

Response indentation size customization is currently supported for JSON only. The default size is two spaces. For example:

JSON

```
[
  {
    "id": 1,
    "name": "Apple"
  },
  {
    "id": 2,
    "name": "Orange"
  },
  {
    "id": 3,
    "name": "Strawberry"
  }
]
```

To change the default size, set the `formatting.json.indentSize` key. For example, to always use four spaces:

Console

```
pref set formatting.json.indentSize 4
```

Subsequent responses honor the setting of four spaces:

JSON

```
[
    {
        "id": 1,
        "name": "Apple"
    },
    {
        "id": 2,
        "name": "Orange"
    },
    {
        "id": 3,
        "name": "Strawberry"
    }
]
```

Set the default text editor

By default, the HttpRepl has no text editor configured for use. To test web API methods requiring an HTTP request body, a default text editor must be set. The HttpRepl tool launches the configured text editor for the sole purpose of composing the request body. Run the following command to set your preferred text editor as the default:

Console

```
pref set editor.command.default "<EXECUTABLE>"
```

In the preceding command, `<EXECUTABLE>` is the full path to the text editor's executable file. For example, run the following command to set Visual Studio Code as the default text editor:

Windows

Console

```
pref set editor.command.default "C:\Program Files\Microsoft VS
Code\Code.exe"
```

To launch the default text editor with specific CLI arguments, set the `editor.command.default.arguments` key. For example, assume Visual Studio Code is the default text editor and that you always want the HttpRepl to open Visual Studio Code in a new session with extensions disabled. Run the following command:

Console

```
pref set editor.command.default.arguments "--disable-extensions --new-
window"
```

> **Tip**
>
> If your default editor is Visual Studio Code, you'll usually want to pass the `-w` or `--wait` argument to force Visual Studio Code to wait for you to close the file before returning.

Set the OpenAPI Description search paths

By default, the HttpRepl has a set of relative paths that it uses to find the OpenAPI description when executing the `connect` command without the `--openapi` option. These relative paths are combined with the root and base paths specified in the `connect` command. The default relative paths are:

- `swagger.json`
- `swagger/v1/swagger.json`
- `/swagger.json`
- `/swagger/v1/swagger.json`
- `openapi.json`
- `/openapi.json`

To use a different set of search paths in your environment, set the `swagger.searchPaths` preference. The value must be a pipe-delimited list of relative paths. For example:

Console

```
pref set swagger.searchPaths
"swagger/v2/swagger.json|swagger/v3/swagger.json"
```

Instead of replacing the default list altogether, the list can also be modified by adding or removing paths.

To add one or more search paths to the default list, set the `swagger.addToSearchPaths` preference. The value must be a pipe-delimited list of relative paths. For example:

```
Console

pref set swagger.addToSearchPaths
"openapi/v2/openapi.json|openapi/v3/openapi.json"
```

To remove one or more search paths from the default list, set the `swagger.addToSearchPaths` preference. The value must be a pipe-delimited list of relative paths. For example:

```
Console

pref set swagger.removeFromSearchPaths "swagger.json|/swagger.json"
```

Test HTTP GET requests

Synopsis

```
Console

get <PARAMETER> [-F|--no-formatting] [-h|--header] [--response:body] [--
response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

The following options are available for the `get` command:

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Example

To issue an HTTP GET request:

1. Run the `get` command on an endpoint that supports it:

   Console

   ```
   https://localhost:5001/people> get
   ```

   The preceding command displays the following output format:

   Console

   ```
   HTTP/1.1 200 OK
   Content-Type: application/json; charset=utf-8
   Date: Fri, 21 Jun 2019 03:38:45 GMT
   Server: Kestrel
   Transfer-Encoding: chunked

   [
     {
       "id": 1,
       "name": "Scott Hunter"
     },
     {
       "id": 2,
       "name": "Scott Hanselman"
   ```

```
  },
  {
    "id": 3,
    "name": "Scott Guthrie"
  }
]

https://localhost:5001/people>
```

2. Retrieve a specific record by passing a parameter to the `get` command:

```
Console

https://localhost:5001/people> get 2
```

The preceding command displays the following output format:

```
Console

HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Fri, 21 Jun 2019 06:17:57 GMT
Server: Kestrel
Transfer-Encoding: chunked

[
  {
    "id": 2,
    "name": "Scott Hanselman"
  }
]

https://localhost:5001/people>
```

Test HTTP POST requests

Synopsis

```
Console

post <PARAMETER> [-c|--content] [-f|--file] [-h|--header] [--no-body] [-F|--
no-formatting] [--response] [--response:body] [--response:headers] [-s|--
streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

- `-c|--content`

  Provides an inline HTTP request body. For example, `-c "{\"id\":2,\"name\":\"Cherry\"}"`.

- `-f|--file`

  Provides a path to a file containing the HTTP request body. For example, `-f "C:\request.json"`.

- `--no-body`

Indicates that no HTTP request body is needed.

Example

To issue an HTTP POST request:

1. Run the `post` command on an endpoint that supports it:

   Console

   ```
   https://localhost:5001/people> post -h Content-Type=application/json
   ```

   In the preceding command, the `Content-Type` HTTP request header is set to indicate a request body media type of JSON. The default text editor opens a *.tmp* file with a JSON template representing the HTTP request body. For example:

   JSON

   ```
   {
     "id": 0,
     "name": ""
   }
   ```

   > **Tip**
   >
   > To set the default text editor, see the **Set the default text editor** section.

2. Modify the JSON template to satisfy model validation requirements:

   JSON

   ```
   {
     "id": 0,
     "name": "Scott Addie"
   }
   ```

3. Save the *.tmp* file, and close the text editor. The following output appears in the command shell:

   Console

   ```
   HTTP/1.1 201 Created
   Content-Type: application/json; charset=utf-8
   Date: Thu, 27 Jun 2019 21:24:18 GMT
   ```

```
Location: https://localhost:5001/people/4
Server: Kestrel
Transfer-Encoding: chunked

{
  "id": 4,
  "name": "Scott Addie"
}

https://localhost:5001/people>
```

Test HTTP PUT requests

Synopsis

Console

```
put <PARAMETER> [-c|--content] [-f|--file] [-h|--header] [--no-body] [-F|--no-formatting] [--response] [--response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

- `-c|--content`

  Provides an inline HTTP request body. For example, `-c "{\"id\":2,\"name\":\"Cherry\"}"`.

- `-f|--file`

  Provides a path to a file containing the HTTP request body. For example, `-f "C:\request.json"`.

- `--no-body`

  Indicates that no HTTP request body is needed.

Example

To issue an HTTP PUT request:

1. *Optional*: Run the `get` command to view the data before modifying it:

   Console

   ```
   https://localhost:5001/fruits> get
   HTTP/1.1 200 OK
   Content-Type: application/json; charset=utf-8
   Date: Sat, 22 Jun 2019 00:07:32 GMT
   Server: Kestrel
   Transfer-Encoding: chunked

   [
     {
       "id": 1,
       "data": "Apple"
     },
   ```

```
  {
    "id": 2,
    "data": "Orange"
  },
  {
    "id": 3,
    "data": "Strawberry"
  }
]
```

2. Run the `put` command on an endpoint that supports it:

```
Console

https://localhost:5001/fruits> put 2 -h Content-Type=application/json
```

In the preceding command, the `Content-Type` HTTP request header is set to indicate a request body media type of JSON. The default text editor opens a *.tmp* file with a JSON template representing the HTTP request body. For example:

```
JSON

{
  "id": 0,
  "name": ""
}
```

> **Tip**
>
> To set the default text editor, see the **Set the default text editor** section.

3. Modify the JSON template to satisfy model validation requirements:

```
JSON

{
  "id": 2,
  "name": "Cherry"
}
```

4. Save the *.tmp* file, and close the text editor. The following output appears in the command shell:

```
Console
```

```
[main 2019-06-28T17:27:01.805Z] update#setState idle
HTTP/1.1 204 No Content
Date: Fri, 28 Jun 2019 17:28:21 GMT
Server: Kestrel
```

5. *Optional*: Issue a `get` command to see the modifications. For example, if you typed "Cherry" in the text editor, a `get` returns the following output:

Console

```
https://localhost:5001/fruits> get
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Sat, 22 Jun 2019 00:08:20 GMT
Server: Kestrel
Transfer-Encoding: chunked

[
  {
    "id": 1,
    "data": "Apple"
  },
  {
    "id": 2,
    "data": "Cherry"
  },
  {
    "id": 3,
    "data": "Strawberry"
  }
]

https://localhost:5001/fruits>
```

Test HTTP DELETE requests

Synopsis

Console

```
delete <PARAMETER> [-F|--no-formatting] [-h|--header] [--response] [--
response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Example

To issue an HTTP DELETE request:

1. *Optional*: Run the `get` command to view the data before modifying it:

   Console

   ```
   https://localhost:5001/fruits> get
   HTTP/1.1 200 OK
   Content-Type: application/json; charset=utf-8
   Date: Sat, 22 Jun 2019 00:07:32 GMT
   Server: Kestrel
   Transfer-Encoding: chunked
   ```

```
[
  {
    "id": 1,
    "data": "Apple"
  },
  {
    "id": 2,
    "data": "Orange"
  },
  {
    "id": 3,
    "data": "Strawberry"
  }
]
```

2. Run the `delete` command on an endpoint that supports it:

   Console

   ```
   https://localhost:5001/fruits> delete 2
   ```

   The preceding command displays the following output format:

   Console

   ```
   HTTP/1.1 204 No Content
   Date: Fri, 28 Jun 2019 17:36:42 GMT
   Server: Kestrel
   ```

3. *Optional*: Issue a `get` command to see the modifications. In this example, a `get` returns the following output:

   Console

   ```
   https://localhost:5001/fruits> get
   HTTP/1.1 200 OK
   Content-Type: application/json; charset=utf-8
   Date: Sat, 22 Jun 2019 00:16:30 GMT
   Server: Kestrel
   Transfer-Encoding: chunked

   [
     {
       "id": 1,
       "data": "Apple"
     },
     {
       "id": 3,
       "data": "Strawberry"
     }
   ```

```
]

https://localhost:5001/fruits>
```

Test HTTP PATCH requests

Synopsis

Console

```
patch <PARAMETER> [-c|--content] [-f|--file] [-h|--header] [--no-body] [-F|--no-formatting] [--response] [--response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't

exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

- `-c|--content`

  Provides an inline HTTP request body. For example, `-c "{\"id\":2,\"name\":\"Cherry\"}"`.

- `-f|--file`

  Provides a path to a file containing the HTTP request body. For example, `-f "C:\request.json"`.

- `--no-body`

  Indicates that no HTTP request body is needed.

Test HTTP HEAD requests

Synopsis

Console

```
head <PARAMETER> [-F|--no-formatting] [-h|--header] [--response] [--
response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Test HTTP OPTIONS requests

Synopsis

Console

```
options <PARAMETER> [-F|--no-formatting] [-h|--header] [--response] [--
response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Set HTTP request headers

To set an HTTP request header, use one of the following approaches:

- Set inline with the HTTP request. For example:

  Console

  ```
  https://localhost:5001/people> post -h Content-Type=application/json
  ```

  With the preceding approach, each distinct HTTP request header requires its own `-h` option.

- Set before sending the HTTP request. For example:

  Console

  ```
  https://localhost:5001/people> set header Content-Type application/json
  ```

  When setting the header before sending a request, the header remains set for the duration of the command shell session. To clear the header, provide an empty value. For example:

  Console

```
https://localhost:5001/people> set header Content-Type
```

Test secured endpoints

The HttpRepl supports the testing of secured endpoints in the following ways:

- Via the default credentials of the logged in user.
- Through the use of HTTP request headers.

Default credentials

Consider a web API you're testing that's hosted in IIS and secured with Windows authentication. You want the credentials of the user running the tool to flow across to the HTTP endpoints being tested. To pass the default credentials of the logged in user:

1. Set the `httpClient.useDefaultCredentials` preference to `true`:

   Console

   ```
   pref set httpClient.useDefaultCredentials true
   ```

2. Exit and restart the tool before sending another request to the web API.

Default proxy credentials

Consider a scenario in which the web API you're testing is behind a proxy secured with Windows authentication. You want the credentials of the user running the tool to flow to the proxy. To pass the default credentials of the logged in user:

1. Set the `httpClient.proxy.useDefaultCredentials` preference to `true`:

   Console

   ```
   pref set httpClient.proxy.useDefaultCredentials true
   ```

2. Exit and restart the tool before sending another request to the web API.

HTTP request headers

Examples of supported authentication and authorization schemes include:

- basic authentication
- JWT bearer tokens
- digest authentication

For example, you can send a bearer token to an endpoint with the following command:

Console

```
set header Authorization "bearer <TOKEN VALUE>"
```

To access an Azure-hosted endpoint or to use the Azure REST API, you need a bearer token. Use the following steps to obtain a bearer token for your Azure subscription via the Azure CLI. The HttpRepl sets the bearer token in an HTTP request header. A list of Azure App Service Web Apps is retrieved.

1. Sign in to Azure:

   Azure CLI

   ```
   az login
   ```

2. Get your subscription ID with the following command:

   Azure CLI

   ```
   az account show --query id
   ```

3. Copy your subscription ID and run the following command:

   Azure CLI

   ```
   az account set --subscription "<SUBSCRIPTION ID>"
   ```

4. Get your bearer token with the following command:

   Azure CLI

   ```
   az account get-access-token --query accessToken
   ```

5. Connect to the Azure REST API via the HttpRepl:

   Console

```
httprepl https://management.azure.com
```

6. Set the `Authorization` HTTP request header:

```
Console

https://management.azure.com/> set header Authorization "bearer <ACCESS
TOKEN>"
```

7. Navigate to the subscription:

```
Console

https://management.azure.com/> cd subscriptions/<SUBSCRIPTION ID>
```

8. Get a list of your subscription's Azure App Service Web Apps:

```
Console

https://management.azure.com/subscriptions/{SUBSCRIPTION ID}> get
providers/Microsoft.Web/sites?api-version=2016-08-01
```

The following response is displayed:

```
Console

HTTP/1.1 200 OK
Cache-Control: no-cache
Content-Length: 35948
Content-Type: application/json; charset=utf-8
Date: Thu, 19 Sep 2019 23:04:03 GMT
Expires: -1
Pragma: no-cache
Strict-Transport-Security: max-age=31536000; includeSubDomains
X-Content-Type-Options: nosniff
x-ms-correlation-request-id: <em>xxxxxxxx-xxxx-xxxx-xxxx-
xxxxxxxxxxxx</em>
x-ms-original-request-ids: <em>xxxxxxxx-xxxx-xxxx-xxxx-
xxxxxxxxxxxx;xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxxxx</em>
x-ms-ratelimit-remaining-subscription-reads: 11999
x-ms-request-id: xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxxxx
x-ms-routing-request-id: WESTUS:xxxxxxxxxxxxxxxx:xxxxxxxx-xxxx-xxxx-
xxxx-xxxxxxxxxx
{
  "value": [
    <AZURE RESOURCES LIST>
```

```
  ]
}
```

Toggle HTTP request display

By default, display of the HTTP request being sent is suppressed. It's possible to change the corresponding setting for the duration of the command shell session.

Enable request display

View the HTTP request being sent by running the `echo on` command. For example:

Console

```
https://localhost:5001/people> echo on
Request echoing is on
```

Subsequent HTTP requests in the current session display the request headers. For example:

Console

```
https://localhost:5001/people> post

[main 2019-06-28T18:50:11.930Z] update#setState idle
Request to https://localhost:5001...

POST /people HTTP/1.1
Content-Length: 41
Content-Type: application/json
User-Agent: HTTP-REPL

{
  "id": 0,
  "name": "Scott Addie"
}

Response from https://localhost:5001...

HTTP/1.1 201 Created
Content-Type: application/json; charset=utf-8
Date: Fri, 28 Jun 2019 18:50:21 GMT
Location: https://localhost:5001/people/4
Server: Kestrel
Transfer-Encoding: chunked

{
  "id": 4,
```

```
  "name": "Scott Addie"
}

https://localhost:5001/people>
```

Disable request display

Suppress display of the HTTP request being sent by running the `echo off` command. For example:

Console

```
https://localhost:5001/people> echo off
Request echoing is off
```

Run a script

If you frequently execute the same set of HttpRepl commands, consider storing them in a text file. Commands in the file take the same form as commands executed manually on the command line. The commands can be executed in a batched fashion using the `run` command. For example:

1. Create a text file containing a set of newline-delimited commands. To illustrate, consider a *people-script.txt* file containing the following commands:

   text

   ```
   set base https://localhost:5001
   ls
   cd People
   ls
   get 1
   ```

2. Execute the `run` command, passing in the text file's path. For example:

   Console

   ```
   https://localhost:5001/> run C:\http-repl-scripts\people-script.txt
   ```

   The following output appears:

   Console

```
https://localhost:5001/> set base https://localhost:5001
Using OpenAPI description at
https://localhost:5001/swagger/v1/swagger.json

https://localhost:5001/> ls
.        []
Fruits   [get|post]
People   [get|post]

https://localhost:5001/> cd People
/People    [get|post]

https://localhost:5001/People> ls
.      [get|post]
..     []
{id}   [get|put|delete]

https://localhost:5001/People> get 1
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Fri, 12 Jul 2019 19:20:10 GMT
Server: Kestrel
Transfer-Encoding: chunked

{
  "id": 1,
  "name": "Scott Hunter"
}

https://localhost:5001/People>
```

Clear the output

To remove all output written to the command shell by the HttpRepl tool, run the `clear` or `cls` command. To illustrate, imagine the command shell contains the following output:

Console

```
httprepl https://localhost:5001
(Disconnected)> set base "https://localhost:5001"
Using OpenAPI description at https://localhost:5001/swagger/v1/swagger.json

https://localhost:5001/> ls
.        []
Fruits   [get|post]
People   [get|post]
```

```
https://localhost:5001/>
```

Run the following command to clear the output:

Console

```
https://localhost:5001/> clear
```

After running the preceding command, the command shell contains only the following output:

Console

```
https://localhost:5001/>
```

HttpRepl telemetry

Article • 06/17/2024

The HttpRepl includes a telemetry feature that collects usage data. It's important that the HttpRepl team understands how the tool is used so it can be improved.

How to opt out

The HttpRepl telemetry feature is enabled by default. To opt out of the telemetry feature, set the `DOTNET_HTTPREPL_TELEMETRY_OPTOUT` environment variable to `1` or `true`.

Disclosure

The HttpRepl displays text similar to the following when you first run the tool. Text may vary slightly depending on the version of the tool you're running. This "first run" experience is how Microsoft notifies you about data collection.

Console

```
Telemetry
---------
The .NET tools collect usage data in order to help us improve your
experience. It is collected by Microsoft and shared with the community. You
can opt-out of telemetry by setting the DOTNET_HTTPREPL_TELEMETRY_OPTOUT
environment variable to '1' or 'true' using your favorite shell.
```

To suppress the "first run" experience text, set the `DOTNET_HTTPREPL_SKIP_FIRST_TIME_EXPERIENCE` environment variable to `1` or `true`.

Data points

The telemetry feature doesn't:

- Collect personal data, such as usernames, email addresses, or URLs.
- Scan your HTTP requests or responses.

The data is sent securely to Microsoft servers and held under restricted access.

Protecting your privacy is important to us. If you suspect the telemetry feature is collecting sensitive data or the data is being insecurely or inappropriately handled, take one of the following actions:

- File an issue in the dotnet/httprepl repository.
- Send an email to dotnet@microsoft.com for investigation.

The telemetry feature collects the following data.

Expand table

.NET SDK versions	Data
>=5.0	Timestamp of invocation.
>=5.0	Three-octet IP address used to determine the geographical location.
>=5.0	Operating system and version.
>=5.0	Runtime ID (RID) the tool is running on.
>=5.0	Whether the tool is running in a container.
>=5.0	Hashed Media Access Control (MAC) address: a cryptographically (SHA256) hashed and unique ID for a machine.
>=5.0	Kernel version.
>=5.0	HttpRepl version.
>=5.0	Whether the tool was started with `help`, `run`, or `connect` arguments. Actual argument values aren't collected.
>=5.0	Command invoked (for example, `get`) and whether it succeeded.
>=5.0	For the `connect` command, whether the `root`, `base`, or `openapi` arguments were supplied. Actual argument values aren't collected.
>=5.0	For the `pref` command, whether a `get` or `set` was issued and which preference was accessed. If not a well-known preference, the name is hashed. The value isn't collected.
>=5.0	For the `set header` command, the header name being set. If not a well-known header, the name is hashed. The value isn't collected.
>=5.0	For the `connect` command, whether a special case for `dotnet new webapi` was used and, whether it was bypassed via preference.
>=5.0	For all HTTP commands (for example, GET, POST, PUT), whether each of the options was specified. The values of the options aren't collected.

Unit and integration tests in Minimal API apps

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Fiyaz Bin Hasan, and Rick Anderson

Introduction to integration tests

Integration tests evaluate an app's components on a broader level than unit tests. Unit tests are used to test isolated software components, such as individual class methods. Integration tests confirm that two or more app components work together to produce an expected result, possibly including every component required to fully process a request.

These broader tests are used to test the app's infrastructure and whole framework, often including the following components:

- Database
- File system
- Network appliances
- Request-response pipeline

Unit tests use fabricated components, known as *fakes* or *mock objects*, in place of infrastructure components.

In contrast to unit tests, integration tests:

- Use the actual components that the app uses in production.
- Require more code and data processing.
- Take longer to run.

Therefore, limit the use of integration tests to the most important infrastructure scenarios. If a behavior can be tested using either a unit test or an integration test,

choose the unit test.

In discussions of integration tests, the tested project is frequently called the ***System Under Test***, or "**SUT**" for short. "SUT" is used throughout this article to refer to the ASP.NET Core app being tested.

Don't write integration tests for every permutation of data and file access with databases and file systems. Regardless of how many places across an app interact with databases and file systems, a focused set of read, write, update, and delete integration tests are usually capable of adequately testing database and file system components. Use unit tests for routine tests of method logic that interact with these components. In unit tests, the use of infrastructure fakes or mocks result in faster test execution.

ASP.NET Core integration tests

Integration tests in ASP.NET Core require the following:

- A test project is used to contain and execute the tests. The test project has a reference to the SUT.
- The test project creates a test web host for the SUT and uses a test server client to handle requests and responses with the SUT.
- A test runner is used to execute the tests and report the test results.

Integration tests follow a sequence of events that include the usual *Arrange*, *Act*, and *Assert* test steps:

1. The SUT's web host is configured.
2. A test server client is created to submit requests to the app.
3. The *Arrange* test step is executed: The test app prepares a request.
4. The *Act* test step is executed: The client submits the request and receives the response.
5. The *Assert* test step is executed: The *actual* response is validated as a *pass* or *fail* based on an *expected* response.
6. The process continues until all of the tests are executed.
7. The test results are reported.

Usually, the test web host is configured differently than the app's normal web host for the test runs. For example, a different database or different app settings might be used for the tests.

Infrastructure components, such as the test web host and in-memory test server (TestServer), are provided or managed by the Microsoft.AspNetCore.Mvc.Testing package. Use of this package streamlines test creation and execution.

The `Microsoft.AspNetCore.Mvc.Testing` package handles the following tasks:

- Copies the dependencies file (`.deps`) from the SUT into the test project's `bin` directory.
- Sets the content root to the SUT's project root so that static files and pages/views are found when the tests are executed.
- Provides the WebApplicationFactory class to streamline bootstrapping the SUT with `TestServer`.

The unit tests documentation describes how to set up a test project and test runner, along with detailed instructions on how to run tests and recommendations for how to name tests and test classes.

Separate unit tests from integration tests into different projects. Separating the tests:

- Helps ensure that infrastructure testing components aren't accidentally included in the unit tests.
- Allows control over which set of tests are run.

The sample code on GitHub provides an example of unit and integration tests on a Minimal API app.

IResult implementation types

Public IResult implementation types in the Microsoft.AspNetCore.Http.HttpResults namespace can be used to unit test minimal route handlers when using named methods instead of lambdas.

The following code uses the NotFound<TValue> class:

C#

```
[Fact]
public async Task GetTodoReturnsNotFoundIfNotExists()
{
    // Arrange
    await using var context = new MockDb().CreateDbContext();

    // Act
    var result = await TodoEndpointsV1.GetTodo(1, context);

    //Assert
    Assert.IsType<Results<Ok<Todo>, NotFound>>(result);

    var notFoundResult = (NotFound) result.Result;
```

```
    Assert.NotNull(notFoundResult);
}
```

The following code uses the Ok<TValue> class:

C#

```
[Fact]
public async Task GetTodoReturnsTodoFromDatabase()
{
    // Arrange
    await using var context = new MockDb().CreateDbContext();

    context.Todos.Add(new Todo
    {
        Id = 1,
        Title = "Test title",
        Description = "Test description",
        IsDone = false
    });

    await context.SaveChangesAsync();

    // Act
    var result = await TodoEndpointsV1.GetTodo(1, context);

    //Assert
    Assert.IsType<Results<Ok<Todo>, NotFound>>(result);

    var okResult = (Ok<Todo>)result.Result;

    Assert.NotNull(okResult.Value);
    Assert.Equal(1, okResult.Value.Id);
}
```

Test Razor components in ASP.NET Core Blazor

Article • 03/08/2024

> For the current release, see the .NET 8 version of this article.

By Egil Hansen

Testing Razor components is an important aspect of releasing stable and maintainable Blazor apps.

To test a Razor component, the *component under test* (CUT) is:

- Rendered with relevant input for the test.
- Depending on the type of test performed, possibly subject to interaction or modification. For example, event handlers can be triggered, such as an `onclick` event for a button.
- Inspected for expected values. A test passes when one or more inspected values matches the expected values for the test.

Test approaches

Two common approaches for testing Razor components are end-to-end (E2E) testing and unit testing:

- **Unit testing**: Unit tests are written with a unit testing library that provides:
  - Component rendering.
  - Inspection of component output and state.
  - Triggering of event handlers and life cycle methods.
  - Assertions that component behavior is correct.

  bUnit is an example of a library that enables Razor component unit testing.

- **E2E testing**: A test runner runs a Blazor app containing the CUT and automates a browser instance. The testing tool inspects and interacts with the CUT through the browser. Playwright for .NET is an example of an E2E testing framework that can be used with Blazor apps.

In unit testing, only the Razor component (Razor/C#) is involved. External dependencies, such as services and JS interop, must be mocked. In E2E testing, the Razor component and all of its auxiliary infrastructure are part of the test, including CSS, JS, and the DOM and browser APIs.

Test scope describes how extensive the tests are. Test scope typically has an influence on the speed of the tests. Unit tests run on a subset of the app's subsystems and usually execute in milliseconds. E2E tests, which test a broad group of the app's subsystems, can take several seconds to complete.

Unit testing also provides access to the instance of the CUT, allowing for inspection and verification of the component's internal state. This normally isn't possible in E2E testing.

With regard to the component's environment, E2E tests must make sure that the expected environmental state has been reached before verification starts. Otherwise, the result is unpredictable. In unit testing, the rendering of the CUT and the life cycle of the test are more integrated, which improves test stability.

E2E testing involves launching multiple processes, network and disk I/O, and other subsystem activity that often lead to poor test reliability. Unit tests are typically insulated from these sorts of issues.

The following table summarizes the difference between the two testing approaches.

Expand table

Capability	Unit testing	E2E testing
Test scope	Razor component (Razor/C#) only	Razor component (Razor/C#) with CSS/JS
Test execution time	Milliseconds	Seconds
Access to the component instance	Yes	No
Sensitive to the environment	No	Yes
Reliability	More reliable	Less reliable

Choose the most appropriate test approach

Consider the scenario when choosing the type of testing to perform. Some considerations are described in the following table.

Expand table

Scenario	Suggested approach	Remarks
Component without JS interop logic	Unit testing	When there's no dependency on JS interop in a Razor component, the component can be tested without access to JS or the DOM API. In this scenario, there are no disadvantages to choosing unit testing.
Component with simple JS interop logic	Unit testing	It's common for components to query the DOM or trigger animations through JS interop. Unit testing is usually preferred in this scenario, since it's straightforward to mock the JS interaction through the IJSRuntime interface.
Component that depends on complex JS code	Unit testing and separate JS testing	If a component uses JS interop to call a large or complex JS library but the interaction between the Razor component and JS library is simple, then the best approach is likely to treat the component and JS library or code as two separate parts and test each individually. Test the Razor component with a unit testing library, and test the JS with a JS testing library.
Component with logic that depends on JS manipulation of the browser DOM	E2E testing	When a component's functionality is dependent on JS and its manipulation of the DOM, verify both the JS and Blazor code together in an E2E test. This is the approach that the Blazor framework developers have taken with Blazor's browser rendering logic, which has tightly-coupled C# and JS code. The C# and JS code must work together to correctly render Razor components in a browser.
Component that depends on 3rd party class library with hard-to-mock dependencies	E2E testing	When a component's functionality is dependent on a 3rd party class library that has hard-to-mock dependencies, such as JS interop, E2E testing might be the only option to test the component.

Test components with bUnit

There's no official Microsoft testing framework for Blazor, but the community-driven project bUnit provides a convenient way to unit test Razor components.

> **Note**
>
> bUnit is a third-party testing library and isn't supported or maintained by Microsoft.

bUnit works with general-purpose testing frameworks, such as MSTest, NUnit, and xUnit. These testing frameworks make bUnit tests look and feel like regular unit tests. bUnit tests integrated with a general-purpose testing framework are ordinarily executed with:

- Visual Studio's Test Explorer.
- dotnet test CLI command in a command shell.
- An automated DevOps testing pipeline.

> **Note**
>
> Test concepts and test implementations across different test frameworks are similar but not identical. Refer to the test framework's documentation for guidance.

The following demonstrates the structure of a bUnit test on the `Counter` component in an app based on a Blazor project template. The `Counter` component displays and increments a counter based on the user selecting a button in the page:

razor

```razor
@page "/counter"

<h1>Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        currentCount++;
    }
}
```

The following bUnit test verifies that the CUT's counter is incremented correctly when the button is selected:

razor

```
@code {
    [Fact]
    public void CounterShouldIncrementWhenClicked()
    {
        // Arrange
        using var ctx = new TestContext();
        var cut = ctx.Render(@<Counter />);
        var paraElm = cut.Find("p");

        // Act
        cut.Find("button").Click();

        // Assert
        var paraElmText = paraElm.TextContent;
        paraElm.MarkupMatches("Current count: 1");
    }
}
```

Tests can also be written in a C# class file:

C#

```
public class CounterTests
{
    [Fact]
    public void CounterShouldIncrementWhenClicked()
    {
        // Arrange
        using var ctx = new TestContext();
        var cut = ctx.RenderComponent<Counter>();
        var paraElm = cut.Find("p");

        // Act
        cut.Find("button").Click();

        // Assert
        var paraElmText = paraElm.TextContent;
        paraElmText.MarkupMatches("Current count: 1");
    }
}
```

The following actions take place at each step of the test:

- *Arrange*: The `Counter` component is rendered using bUnit's `TestContext`. The CUT's paragraph element (`<p>`) is found and assigned to `paraElm`. In Razor syntax,

a component can be passed as a RenderFragment to bUnit.

- *Act*: The button's element (`<button>`) is located and selected by calling `Click`, which should increment the counter and update the content of the paragraph tag (`<p>`). The paragraph element text content is obtained by calling `TextContent`.
- *Assert*: `MarkupMatches` is called on the text content to verify that it matches the expected string, which is `Current count: 1`.

> **Note**
>
> The `MarkupMatches` assert method differs from a regular string comparison assertion (for example, `Assert.Equal("Current count: 1", paraElmText);`). `MarkupMatches` performs a semantic comparison of the input and expected HTML markup. A semantic comparison is aware of HTML semantics, meaning things like insignificant whitespace is ignored. This results in more stable tests. For more information, see Customizing the Semantic HTML Comparison.

Razor Pages unit tests in ASP.NET Core

Article • 09/17/2023

ASP.NET Core supports unit tests of Razor Pages apps. Tests of the data access layer (DAL) and page models help ensure:

- Parts of a Razor Pages app work independently and together as a unit during app construction.
- Classes and methods have limited scopes of responsibility.
- Additional documentation exists on how the app should behave.
- Regressions, which are errors brought about by updates to the code, are found during automated building and deployment.

This topic assumes that you have a basic understanding of Razor Pages apps and unit tests. If you're unfamiliar with Razor Pages apps or test concepts, see the following topics:

- Introduction to Razor Pages in ASP.NET Core
- Tutorial: Get started with Razor Pages in ASP.NET Core
- Unit testing C# in .NET Core using dotnet test and xUnit

View or download sample code (how to download)

The sample project is composed of two apps:

Expand table

App	Project folder	Description
Message app	*src/RazorPagesTestSample*	Allows a user to add a message, delete one message, delete all messages, and analyze messages (find the average number of words per message).
Test app	*tests/RazorPagesTestSample.Tests*	Used to unit test the DAL and Index page model of the message app.

The tests can be run using the built-in test features of an IDE, such as Visual Studio. If using Visual Studio Code or the command line, execute the following command at a command prompt in the *tests/RazorPagesTestSample.Tests* folder:

.NET CLI

```
dotnet test
```

Message app organization

The message app is a Razor Pages message system with the following characteristics:

- The Index page of the app (`Pages/Index.cshtml` and `Pages/Index.cshtml.cs`) provides a UI and page model methods to control the addition, deletion, and analysis of messages (find the average number of words per message).
- A message is described by the `Message` class (`Data/Message.cs`) with two properties: `Id` (key) and `Text` (message). The `Text` property is required and limited to 200 characters.
- Messages are stored using Entity Framework's in-memory database†.
- The app contains a DAL in its database context class, `AppDbContext` (`Data/AppDbContext.cs`). The DAL methods are marked `virtual`, which allows mocking the methods for use in the tests.
- If the database is empty on app startup, the message store is initialized with three messages. These *seeded messages* are also used in tests.

†The EF topic, Test with InMemory, explains how to use an in-memory database for tests with MSTest. This topic uses the xUnit test framework. Test concepts and test implementations across different test frameworks are similar but not identical.

Although the sample app doesn't use the repository pattern and isn't an effective example of the Unit of Work (UoW) pattern, Razor Pages supports these patterns of development. For more information, see Designing the infrastructure persistence layer and Test controller logic in ASP.NET Core (the sample implements the repository pattern).

Test app organization

The test app is a console app inside the *tests/RazorPagesTestSample.Tests* folder.

Expand table

Test app folder	Description
UnitTests	• `DataAccessLayerTest.cs` contains the unit tests for the DAL. • `IndexPageTests.cs` contains the unit tests for the Index page model.
Utilities	Contains the `TestDbContextOptions` method used to create new database context options for each DAL unit test so that the database is reset to its baseline condition for each test.

The test framework is xUnit. The object mocking framework is Moq.

Unit tests of the data access layer (DAL)

The message app has a DAL with four methods contained in the `AppDbContext` class (`src/RazorPagesTestSample/Data/AppDbContext.cs`). Each method has one or two unit tests in the test app.

Expand table

DAL method	Function
`GetMessagesAsync`	Obtains a `List<Message>` from the database sorted by the `Text` property.
`AddMessageAsync`	Adds a `Message` to the database.
`DeleteAllMessagesAsync`	Deletes all `Message` entries from the database.
`DeleteMessageAsync`	Deletes a single `Message` from the database by `Id`.

Unit tests of the DAL require DbContextOptions when creating a new `AppDbContext` for each test. One approach to creating the `DbContextOptions` for each test is to use a DbContextOptionsBuilder:

C#

```
var optionsBuilder = new DbContextOptionsBuilder<AppDbContext>()
    .UseInMemoryDatabase("InMemoryDb");

using (var db = new AppDbContext(optionsBuilder.Options))
{
    // Use the db here in the unit test.
}
```

The problem with this approach is that each test receives the database in whatever state the previous test left it. This can be problematic when trying to write atomic unit tests that don't interfere with each other. To force the `AppDbContext` to use a new database context for each test, supply a `DbContextOptions` instance that's based on a new service provider. The test app shows how to do this using its `Utilities` class method `TestDbContextOptions` (`tests/RazorPagesTestSample.Tests/Utilities/Utilities.cs`):

C#

```
public static DbContextOptions<AppDbContext> TestDbContextOptions()
{
    // Create a new service provider to create a new in-memory database.
    var serviceProvider = new ServiceCollection()
        .AddEntityFrameworkInMemoryDatabase()
        .BuildServiceProvider();

    // Create a new options instance using an in-memory database and
    // IServiceProvider that the context should resolve all of its
    // services from.
    var builder = new DbContextOptionsBuilder<AppDbContext>()
        .UseInMemoryDatabase("InMemoryDb")
        .UseInternalServiceProvider(serviceProvider);

    return builder.Options;
}
```

Using the `DbContextOptions` in the DAL unit tests allows each test to run atomically with a fresh database instance:

C#

```
using (var db = new AppDbContext(Utilities.TestDbContextOptions()))
{
    // Use the db here in the unit test.
}
```

Each test method in the `DataAccessLayerTest` class (`UnitTests/DataAccessLayerTest.cs`) follows a similar Arrange-Act-Assert pattern:

1. Arrange: The database is configured for the test and/or the expected outcome is defined.
2. Act: The test is executed.
3. Assert: Assertions are made to determine if the test result is a success.

For example, the `DeleteMessageAsync` method is responsible for removing a single message identified by its `Id` (`src/RazorPagesTestSample/Data/AppDbContext.cs`):

C#

```
public async virtual Task DeleteMessageAsync(int id)
{
    var message = await Messages.FindAsync(id);

    if (message != null)
    {
        Messages.Remove(message);
        await SaveChangesAsync();
```

```
    }
}
```

There are two tests for this method. One test checks that the method deletes a message when the message is present in the database. The other method tests that the database doesn't change if the message `Id` for deletion doesn't exist. The `DeleteMessageAsync_MessageIsDeleted_WhenMessageIsFound` method is shown below:

C#

```
[Fact]
public async Task DeleteMessageAsync_MessageIsDeleted_WhenMessageIsFound()
{
    using (var db = new AppDbContext(Utilities.TestDbContextOptions()))
    {
        // Arrange
        var seedMessages = AppDbContext.GetSeedingMessages();
        await db.AddRangeAsync(seedMessages);
        await db.SaveChangesAsync();
        var recId = 1;
        var expectedMessages =
            seedMessages.Where(message => message.Id != recId).ToList();

        // Act
        await db.DeleteMessageAsync(recId);

        // Assert
        var actualMessages = await db.Messages.AsNoTracking().ToListAsync();
        Assert.Equal(
            expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
            actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
    }
}
```

First, the method performs the Arrange step, where preparation for the Act step takes place. The seeding messages are obtained and held in `seedMessages`. The seeding messages are saved into the database. The message with an `Id` of `1` is set for deletion. When the `DeleteMessageAsync` method is executed, the expected messages should have all of the messages except for the one with an `Id` of `1`. The `expectedMessages` variable represents this expected outcome.

C#

```
// Arrange
var seedMessages = AppDbContext.GetSeedingMessages();
await db.AddRangeAsync(seedMessages);
await db.SaveChangesAsync();
var recId = 1;
```

```
var expectedMessages =
    seedMessages.Where(message => message.Id != recId).ToList();
```

The method acts: The `DeleteMessageAsync` method is executed passing in the `recId` of `1`:

C#

```
// Act
await db.DeleteMessageAsync(recId);
```

Finally, the method obtains the `Messages` from the context and compares it to the `expectedMessages` asserting that the two are equal:

C#

```
// Assert
var actualMessages = await db.Messages.AsNoTracking().ToListAsync();
Assert.Equal(
    expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
    actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
```

In order to compare that the two `List<Message>` are the same:

- The messages are ordered by `Id`.
- Message pairs are compared on the `Text` property.

A similar test method, `DeleteMessageAsync_NoMessageIsDeleted_WhenMessageIsNotFound` checks the result of attempting to delete a message that doesn't exist. In this case, the expected messages in the database should be equal to the actual messages after the `DeleteMessageAsync` method is executed. There should be no change to the database's content:

C#

```
[Fact]
public async Task
DeleteMessageAsync_NoMessageIsDeleted_WhenMessageIsNotFound()
{
    using (var db = new AppDbContext(Utilities.TestDbContextOptions()))
    {
        // Arrange
        var expectedMessages = AppDbContext.GetSeedingMessages();
        await db.AddRangeAsync(expectedMessages);
        await db.SaveChangesAsync();
        var recId = 4;
```

```
        // Act
        try
        {
            await db.DeleteMessageAsync(recId);
        }
        catch
        {
            // recId doesn't exist
        }

        // Assert
        var actualMessages = await db.Messages.AsNoTracking().ToListAsync();
        Assert.Equal(
            expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
            actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
    }
}
```

Unit tests of the page model methods

Another set of unit tests is responsible for tests of page model methods. In the message app, the Index page models are found in the `IndexModel` class in `src/RazorPagesTestSample/Pages/Index.cshtml.cs`.

Expand table

Page model method	Function
`OnGetAsync`	Obtains the messages from the DAL for the UI using the `GetMessagesAsync` method.
`OnPostAddMessageAsync`	If the ModelState is valid, calls `AddMessageAsync` to add a message to the database.
`OnPostDeleteAllMessagesAsync`	Calls `DeleteAllMessagesAsync` to delete all of the messages in the database.
`OnPostDeleteMessageAsync`	Executes `DeleteMessageAsync` to delete a message with the `Id` specified.
`OnPostAnalyzeMessagesAsync`	If one or more messages are in the database, calculates the average number of words per message.

The page model methods are tested using seven tests in the `IndexPageTests` class (`tests/RazorPagesTestSample.Tests/UnitTests/IndexPageTests.cs`). The tests use the familiar Arrange-Assert-Act pattern. These tests focus on:

- Determining if the methods follow the correct behavior when the ModelState is invalid.
- Confirming the methods produce the correct IActionResult.
- Checking that property value assignments are made correctly.

This group of tests often mock the methods of the DAL to produce expected data for the Act step where a page model method is executed. For example, the `GetMessagesAsync` method of the `AppDbContext` is mocked to produce output. When a page model method executes this method, the mock returns the result. The data doesn't come from the database. This creates predictable, reliable test conditions for using the DAL in the page model tests.

The `OnGetAsync_PopulatesThePageModel_WithAListOfMessages` test shows how the `GetMessagesAsync` method is mocked for the page model:

```
C#

var mockAppDbContext = new Mock<AppDbContext>(optionsBuilder.Options);
var expectedMessages = AppDbContext.GetSeedingMessages();
mockAppDbContext.Setup(
    db => db.GetMessagesAsync()).Returns(Task.FromResult(expectedMessages));
var pageModel = new IndexModel(mockAppDbContext.Object);
```

When the `OnGetAsync` method is executed in the Act step, it calls the page model's `GetMessagesAsync` method.

Unit test Act step (`tests/RazorPagesTestSample.Tests/UnitTests/IndexPageTests.cs`):

```
C#

// Act
await pageModel.OnGetAsync();
```

`IndexPage` page model's `OnGetAsync` method (`src/RazorPagesTestSample/Pages/Index.cshtml.cs`):

```
C#

public async Task OnGetAsync()
{
    Messages = await _db.GetMessagesAsync();
}
```

The `GetMessagesAsync` method in the DAL doesn't return the result for this method call. The mocked version of the method returns the result.

In the `Assert` step, the actual messages (`actualMessages`) are assigned from the `Messages` property of the page model. A type check is also performed when the messages are assigned. The expected and actual messages are compared by their `Text` properties. The test asserts that the two `List<Message>` instances contain the same messages.

C#

```
// Assert
var actualMessages = Assert.IsAssignableFrom<List<Message>>
(pageModel.Messages);
Assert.Equal(
    expectedMessages.OrderBy(m => m.Id).Select(m => m.Text),
    actualMessages.OrderBy(m => m.Id).Select(m => m.Text));
```

Other tests in this group create page model objects that include the DefaultHttpContext, the ModelStateDictionary, an ActionContext to establish the `PageContext`, a `ViewDataDictionary`, and a `PageContext`. These are useful in conducting tests. For example, the message app establishes a `ModelState` error with AddModelError to check that a valid PageResult is returned when `OnPostAddMessageAsync` is executed:

C#

```
[Fact]
public async Task
OnPostAddMessageAsync_ReturnsAPageResult_WhenModelStateIsInvalid()
{
    // Arrange
    var optionsBuilder = new DbContextOptionsBuilder<AppDbContext>()
        .UseInMemoryDatabase("InMemoryDb");
    var mockAppDbContext = new Mock<AppDbContext>(optionsBuilder.Options);
    var expectedMessages = AppDbContext.GetSeedingMessages();
    mockAppDbContext.Setup(db =>
db.GetMessagesAsync()).Returns(Task.FromResult(expectedMessages));
    var httpContext = new DefaultHttpContext();
    var modelState = new ModelStateDictionary();
    var actionContext = new ActionContext(httpContext, new RouteData(), new
PageActionDescriptor(), modelState);
    var modelMetadataProvider = new EmptyModelMetadataProvider();
    var viewData = new ViewDataDictionary(modelMetadataProvider,
modelState);
    var tempData = new TempDataDictionary(httpContext,
Mock.Of<ITempDataProvider>());
    var pageContext = new PageContext(actionContext)
    {
```

```
            ViewData = viewData
        };
        var pageModel = new IndexModel(mockAppDbContext.Object)
        {
            PageContext = pageContext,
            TempData = tempData,
            Url = new UrlHelper(actionContext)
        };
        pageModel.ModelState.AddModelError("Message.Text", "The Text field is
required.");

        // Act
        var result = await pageModel.OnPostAddMessageAsync();

        // Assert
        Assert.IsType<PageResult>(result);
    }
```

Unit test controller logic in ASP.NET Core

Article • 06/17/2024

By Steve Smith

Unit tests involve testing a part of an app in isolation from its infrastructure and dependencies. When unit testing controller logic, only the contents of a single action are tested, not the behavior of its dependencies or of the framework itself.

Unit testing controllers

Set up unit tests of controller actions to focus on the controller's behavior. A controller unit test avoids scenarios such as filters, routing, and model binding. Tests that cover the interactions among components that collectively respond to a request are handled by *integration tests*. For more information on integration tests, see Integration tests in ASP.NET Core.

If you're writing custom filters and routes, unit test them in isolation, not as part of tests on a particular controller action.

To demonstrate controller unit tests, review the following controller in the sample app.

View or download sample code (how to download)

The Home controller displays a list of brainstorming sessions and allows the creation of new brainstorming sessions with a POST request:

C#

```
public class HomeController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public HomeController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }

    public async Task<IActionResult> Index()
    {
        var sessionList = await _sessionRepository.ListAsync();

        var model = sessionList.Select(session => new
StormSessionViewModel()
```

```
            {
                Id = session.Id,
                DateCreated = session.DateCreated,
                Name = session.Name,
                IdeaCount = session.Ideas.Count
            });

            return View(model);
        }

        public class NewSessionModel
        {
            [Required]
            public string SessionName { get; set; }
        }

        [HttpPost]
        public async Task<IActionResult> Index(NewSessionModel model)
        {
            if (!ModelState.IsValid)
            {
                return BadRequest(ModelState);
            }
            else
            {
                await _sessionRepository.AddAsync(new BrainstormSession()
                {
                    DateCreated = DateTimeOffset.Now,
                    Name = model.SessionName
                });
            }

            return RedirectToAction(actionName: nameof(Index));
        }
    }
```

The preceding controller:

- Follows the Explicit Dependencies Principle.
- Expects dependency injection (DI) to provide an instance of `IBrainstormSessionRepository`.
- Can be tested with a mocked `IBrainstormSessionRepository` service using a mock object framework, such as Moq. A *mocked object* is a fabricated object with a predetermined set of property and method behaviors used for testing. For more information, see Introduction to integration tests.

The `HTTP GET Index` method has no looping or branching and only calls one method. The unit test for this action:

- Mocks the `IBrainstormSessionRepository` service using the `GetTestSessions` method. `GetTestSessions` creates two mock brainstorm sessions with dates and session names.
- Executes the `Index` method.
- Makes assertions on the result returned by the method:
  - A ViewResult is returned.
  - The ViewDataDictionary.Model is a `StormSessionViewModel`.
  - There are two brainstorming sessions stored in the `ViewDataDictionary.Model`.

C#

```
[Fact]
public async Task Index_ReturnsAViewResult_WithAListOfBrainstormSessions()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);

    // Act
    var result = await controller.Index();

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsAssignableFrom<IEnumerable<StormSessionViewModel>>(
        viewResult.ViewData.Model);
    Assert.Equal(2, model.Count());
}
```

C#

```
private List<BrainstormSession> GetTestSessions()
{
    var sessions = new List<BrainstormSession>();
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 2),
        Id = 1,
        Name = "Test One"
    });
    sessions.Add(new BrainstormSession()
    {
        DateCreated = new DateTime(2016, 7, 1),
        Id = 2,
        Name = "Test Two"
    });
    return sessions;
}
```

The Home controller's `HTTP POST Index` method tests verifies that:

- When ModelState.IsValid is `false`, the action method returns a *400 Bad Request* ViewResult with the appropriate data.
- When `ModelState.IsValid` is `true`:
  - The `Add` method on the repository is called.
  - A RedirectToActionResult is returned with the correct arguments.

An invalid model state is tested by adding errors using AddModelError as shown in the first test below:

C#

```
[Fact]
public async Task
IndexPost_ReturnsBadRequestResult_WhenModelStateIsInvalid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.ListAsync())
        .ReturnsAsync(GetTestSessions());
    var controller = new HomeController(mockRepo.Object);
    controller.ModelState.AddModelError("SessionName", "Required");
    var newSession = new HomeController.NewSessionModel();

    // Act
    var result = await controller.Index(newSession);

    // Assert
    var badRequestResult = Assert.IsType<BadRequestObjectResult>(result);
    Assert.IsType<SerializableError>(badRequestResult.Value);
}

[Fact]
public async Task
IndexPost_ReturnsARedirectAndAddsSession_WhenModelStateIsValid()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.AddAsync(It.IsAny<BrainstormSession>()))
        .Returns(Task.CompletedTask)
        .Verifiable();
    var controller = new HomeController(mockRepo.Object);
    var newSession = new HomeController.NewSessionModel()
    {
        SessionName = "Test Name"
    };

    // Act
    var result = await controller.Index(newSession);
```

```
    // Assert
    var redirectToActionResult = Assert.IsType<RedirectToActionResult>
(result);
    Assert.Null(redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
    mockRepo.Verify();
}
```

When ModelState isn't valid, the same `ViewResult` is returned as for a GET request. The test doesn't attempt to pass in an invalid model. Passing an invalid model isn't a valid approach, since model binding isn't running (although an integration test does use model binding). In this case, model binding isn't tested. These unit tests are only testing the code in the action method.

The second test verifies that when the `ModelState` is valid:

- A new `BrainstormSession` is added (via the repository).
- The method returns a `RedirectToActionResult` with the expected properties.

Mocked calls that aren't called are normally ignored, but calling `Verifiable` at the end of the setup call allows mock validation in the test. This is performed with the call to `mockRepo.Verify`, which fails the test if the expected method wasn't called.

> **Note**
>
> The Moq library used in this sample makes it possible to mix verifiable, or "strict", mocks with non-verifiable mocks (also called "loose" mocks or stubs). Learn more about customizing Mock behavior with Moq.

SessionController in the sample app displays information related to a particular brainstorming session. The controller includes logic to deal with invalid `id` values (there are two `return` scenarios in the following example to cover these scenarios). The final `return` statement returns a new `StormSessionViewModel` to the view (`Controllers/SessionController.cs`):

C#

```
public class SessionController : Controller
{
    private readonly IBrainstormSessionRepository _sessionRepository;

    public SessionController(IBrainstormSessionRepository sessionRepository)
    {
        _sessionRepository = sessionRepository;
    }
```

```
    public async Task<IActionResult> Index(int? id)
    {
        if (!id.HasValue)
        {
            return RedirectToAction(actionName: nameof(Index),
                controllerName: "Home");
        }

        var session = await _sessionRepository.GetByIdAsync(id.Value);
        if (session == null)
        {
            return Content("Session not found.");
        }

        var viewModel = new StormSessionViewModel()
        {
            DateCreated = session.DateCreated,
            Name = session.Name,
            Id = session.Id
        };

        return View(viewModel);
    }
}
```

The unit tests include one test for each `return` scenario in the Session controller `Index` action:

C#

```
[Fact]
public async Task IndexReturnsARedirectToIndexHomeWhenIdIsNull()
{
    // Arrange
    var controller = new SessionController(sessionRepository: null);

    // Act
    var result = await controller.Index(id: null);

    // Assert
    var redirectToActionResult =
        Assert.IsType<RedirectToActionResult>(result);
    Assert.Equal("Home", redirectToActionResult.ControllerName);
    Assert.Equal("Index", redirectToActionResult.ActionName);
}

[Fact]
public async Task
IndexReturnsContentWithSessionNotFoundWhenSessionNotFound()
{
    // Arrange
    int testSessionId = 1;
```

```
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var contentResult = Assert.IsType<ContentResult>(result);
    Assert.Equal("Session not found.", contentResult.Content);
}

[Fact]
public async Task IndexReturnsViewResultWithStormSessionViewModel()
{
    // Arrange
    int testSessionId = 1;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSessions().FirstOrDefault(
            s => s.Id == testSessionId));
    var controller = new SessionController(mockRepo.Object);

    // Act
    var result = await controller.Index(testSessionId);

    // Assert
    var viewResult = Assert.IsType<ViewResult>(result);
    var model = Assert.IsType<StormSessionViewModel>(
        viewResult.ViewData.Model);
    Assert.Equal("Test One", model.Name);
    Assert.Equal(2, model.DateCreated.Day);
    Assert.Equal(testSessionId, model.Id);
}
```

Moving to the Ideas controller, the app exposes functionality as a web API on the `api/ideas` route:

- A list of ideas (`IdeaDTO`) associated with a brainstorming session is returned by the `ForSession` method.
- The `Create` method adds new ideas to a session.

C#

```
[HttpGet("forsession/{sessionId}")]
public async Task<IActionResult> ForSession(int sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);
    if (session == null)
    {
        return NotFound(sessionId);
```

```
        }

        var result = session.Ideas.Select(idea => new IdeaDTO()
        {
            Id = idea.Id,
            Name = idea.Name,
            Description = idea.Description,
            DateCreated = idea.DateCreated
        }).ToList();

        return Ok(result);
    }

    [HttpPost("create")]
    public async Task<IActionResult> Create([FromBody]NewIdeaModel model)
    {
        if (!ModelState.IsValid)
        {
            return BadRequest(ModelState);
        }

        var session = await _sessionRepository.GetByIdAsync(model.SessionId);
        if (session == null)
        {
            return NotFound(model.SessionId);
        }

        var idea = new Idea()
        {
            DateCreated = DateTimeOffset.Now,
            Description = model.Description,
            Name = model.Name
        };
        session.AddIdea(idea);

        await _sessionRepository.UpdateAsync(session);

        return Ok(session);
    }
```

Avoid returning business domain entities directly via API calls. Domain entities:

- Often include more data than the client requires.
- Unnecessarily couple the app's internal domain model with the publicly exposed API.

Mapping between domain entities and the types returned to the client can be performed:

- Manually with a LINQ `Select`, as the sample app uses. For more information, see LINQ (Language Integrated Query).

- Automatically with a library, such as AutoMapper.

Next, the sample app demonstrates unit tests for the `Create` and `ForSession` API methods of the Ideas controller.

The sample app contains two `ForSession` tests. The first test determines if `ForSession` returns a NotFoundObjectResult (HTTP Not Found) for an invalid session:

C#

```
[Fact]
public async Task ForSession_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
    var notFoundObjectResult = Assert.IsType<NotFoundObjectResult>(result);
    Assert.Equal(testSessionId, notFoundObjectResult.Value);
}
```

The second `ForSession` test determines if `ForSession` returns a list of session ideas (`<List<IdeaDTO>>`) for a valid session. The checks also examine the first idea to confirm its `Name` property is correct:

C#

```
[Fact]
public async Task ForSession_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSession(testSessionId);

    // Assert
```

```
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(okResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

To test the behavior of the `Create` method when the `ModelState` is invalid, the sample app adds a model error to the controller as part of the test. Don't try to test model validation or model binding in unit tests—just test the action method's behavior when confronted with an invalid `ModelState`:

C#

```
[Fact]
public async Task Create_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.Create(model: null);

    // Assert
    Assert.IsType<BadRequestObjectResult>(result);
}
```

The second test of `Create` depends on the repository returning `null`, so the mock repository is configured to return `null`. There's no need to create a test database (in memory or otherwise) and construct a query that returns this result. The test can be accomplished in a single statement, as the sample code illustrates:

C#

```
[Fact]
public async Task Create_ReturnsHttpNotFound_ForInvalidSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync((BrainstormSession)null);
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.Create(new NewIdeaModel());

    // Assert
```

```
    Assert.IsType<NotFoundObjectResult>(result);
}
```

The third `Create` test, `Create_ReturnsNewlyCreatedIdeaForSession`, verifies that the repository's `UpdateAsync` method is called. The mock is called with `Verifiable`, and the mocked repository's `Verify` method is called to confirm the verifiable method is executed. It's not the unit test's responsibility to ensure that the `UpdateAsync` method saved the data—that can be performed with an integration test.

C#

```
[Fact]
public async Task Create_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.Create(newIdea);

    // Assert
    var okResult = Assert.IsType<OkObjectResult>(result);
    var returnSession = Assert.IsType<BrainstormSession>(okResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnSession.Ideas.Count());
    Assert.Equal(testName, returnSession.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription,
returnSession.Ideas.LastOrDefault().Description);
}
```

Test ActionResult<T>

ActionResult<T> (ActionResult<TValue>) can return a type deriving from `ActionResult` or return a specific type.

The sample app includes a method that returns a `List<IdeaDTO>` for a given session `id`. If the session `id` doesn't exist, the controller returns NotFound:

C#

```
[HttpGet("forsessionactionresult/{sessionId}")]
[ProducesResponseType(200)]
[ProducesResponseType(404)]
public async Task<ActionResult<List<IdeaDTO>>> ForSessionActionResult(int
sessionId)
{
    var session = await _sessionRepository.GetByIdAsync(sessionId);

    if (session == null)
    {
        return NotFound(sessionId);
    }

    var result = session.Ideas.Select(idea => new IdeaDTO()
    {
        Id = idea.Id,
        Name = idea.Name,
        Description = idea.Description,
        DateCreated = idea.DateCreated
    }).ToList();

    return result;
}
```

Two tests of the `ForSessionActionResult` controller are included in the `ApiIdeasControllerTests`.

The first test confirms that the controller returns an `ActionResult` but not a nonexistent list of ideas for a nonexistent session `id`:

- The `ActionResult` type is `ActionResult<List<IdeaDTO>>`.
- The Result is a NotFoundObjectResult.

C#

```
[Fact]
public async Task
ForSessionActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var mockRepo = new Mock<IBrainstormSessionRepository>();
```

```
    var controller = new IdeasController(mockRepo.Object);
    var nonExistentSessionId = 999;

    // Act
    var result = await
controller.ForSessionActionResult(nonExistentSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the second test confirms that the method returns:

- An `ActionResult` with a `List<IdeaDTO>` type.
- The ActionResult<T>.Value is a `List<IdeaDTO>` type.
- The first item in the list is a valid idea matching the idea stored in the mock session (obtained by calling `GetTestSession`).

C#

```
[Fact]
public async Task ForSessionActionResult_ReturnsIdeasForSession()
{
    // Arrange
    int testSessionId = 123;
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(GetTestSession());
    var controller = new IdeasController(mockRepo.Object);

    // Act
    var result = await controller.ForSessionActionResult(testSessionId);

    // Assert
    var actionResult = Assert.IsType<ActionResult<List<IdeaDTO>>>(result);
    var returnValue = Assert.IsType<List<IdeaDTO>>(actionResult.Value);
    var idea = returnValue.FirstOrDefault();
    Assert.Equal("One", idea.Name);
}
```

The sample app also includes a method to create a new `Idea` for a given session. The controller returns:

- BadRequest for an invalid model.
- NotFound if the session doesn't exist.
- CreatedAtAction when the session is updated with the new idea.

C#

```
[HttpPost("createactionresult")]
[ProducesResponseType(201)]
[ProducesResponseType(400)]
[ProducesResponseType(404)]
public async Task<ActionResult<BrainstormSession>>
CreateActionResult([FromBody]NewIdeaModel model)
{
    if (!ModelState.IsValid)
    {
        return BadRequest(ModelState);
    }

    var session = await _sessionRepository.GetByIdAsync(model.SessionId);

    if (session == null)
    {
        return NotFound(model.SessionId);
    }

    var idea = new Idea()
    {
        DateCreated = DateTimeOffset.Now,
        Description = model.Description,
        Name = model.Name
    };
    session.AddIdea(idea);

    await _sessionRepository.UpdateAsync(session);

    return CreatedAtAction(nameof(CreateActionResult), new { id = session.Id
}, session);
}
```

Three tests of `CreateActionResult` are included in the `ApiIdeasControllerTests`.

The first text confirms that a BadRequest is returned for an invalid model.

C#

```
[Fact]
public async Task CreateActionResult_ReturnsBadRequest_GivenInvalidModel()
{
    // Arrange & Act
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);
    controller.ModelState.AddModelError("error", "some error");

    // Act
    var result = await controller.CreateActionResult(model: null);

    // Assert
```

```
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>
(result);
    Assert.IsType<BadRequestObjectResult>(actionResult.Result);
}
```

The second test checks that a NotFound is returned if the session doesn't exist.

C#

```
[Fact]
public async Task
CreateActionResult_ReturnsNotFoundObjectResultForNonexistentSession()
{
    // Arrange
    var nonExistentSessionId = 999;
    string testName = "test name";
    string testDescription = "test description";
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = nonExistentSessionId
    };

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>
(result);
    Assert.IsType<NotFoundObjectResult>(actionResult.Result);
}
```

For a valid session `id`, the final test confirms that:

- The method returns an `ActionResult` with a `BrainstormSession` type.
- The ActionResult<T>.Result is a CreatedAtActionResult. `CreatedAtActionResult` is analogous to a *201 Created* response with a `Location` header.
- The ActionResult<T>.Value is a `BrainstormSession` type.
- The mock call to update the session, `UpdateAsync(testSession)`, was invoked. The `Verifiable` method call is checked by executing `mockRepo.Verify()` in the assertions.
- Two `Idea` objects are returned for the session.
- The last item (the `Idea` added by the mock call to `UpdateAsync`) matches the `newIdea` added to the session in the test.

C#

```
[Fact]
public async Task CreateActionResult_ReturnsNewlyCreatedIdeaForSession()
{
    // Arrange
    int testSessionId = 123;
    string testName = "test name";
    string testDescription = "test description";
    var testSession = GetTestSession();
    var mockRepo = new Mock<IBrainstormSessionRepository>();
    mockRepo.Setup(repo => repo.GetByIdAsync(testSessionId))
        .ReturnsAsync(testSession);
    var controller = new IdeasController(mockRepo.Object);

    var newIdea = new NewIdeaModel()
    {
        Description = testDescription,
        Name = testName,
        SessionId = testSessionId
    };
    mockRepo.Setup(repo => repo.UpdateAsync(testSession))
        .Returns(Task.CompletedTask)
        .Verifiable();

    // Act
    var result = await controller.CreateActionResult(newIdea);

    // Assert
    var actionResult = Assert.IsType<ActionResult<BrainstormSession>>
(result);
    var createdAtActionResult = Assert.IsType<CreatedAtActionResult>
(actionResult.Result);
    var returnValue = Assert.IsType<BrainstormSession>
(createdAtActionResult.Value);
    mockRepo.Verify();
    Assert.Equal(2, returnValue.Ideas.Count());
    Assert.Equal(testName, returnValue.Ideas.LastOrDefault().Name);
    Assert.Equal(testDescription,
returnValue.Ideas.LastOrDefault().Description);
}
```

Integration tests in ASP.NET Core

Article • 06/17/2024

By Jos van der Til, Martin Costello, and Javier Calvarro Nelson.

Integration tests ensure that an app's components function correctly at a level that includes the app's supporting infrastructure, such as the database, file system, and network. ASP.NET Core supports integration tests using a unit test framework with a test web host and an in-memory test server.

This article assumes a basic understanding of unit tests. If unfamiliar with test concepts, see the Unit Testing in .NET Core and .NET Standard article and its linked content.

View or download sample code (how to download)

The sample app is a Razor Pages app and assumes a basic understanding of Razor Pages. If you're unfamiliar with Razor Pages, see the following articles:

- Introduction to Razor Pages
- Get started with Razor Pages
- Razor Pages unit tests

For testing SPAs, we recommend a tool such as Playwright for .NET, which can automate a browser.

Introduction to integration tests

Integration tests evaluate an app's components on a broader level than unit tests. Unit tests are used to test isolated software components, such as individual class methods. Integration tests confirm that two or more app components work together to produce an expected result, possibly including every component required to fully process a request.

These broader tests are used to test the app's infrastructure and whole framework, often including the following components:

- Database
- File system
- Network appliances
- Request-response pipeline

Unit tests use fabricated components, known as *fakes* or *mock objects*, in place of infrastructure components.

In contrast to unit tests, integration tests:

- Use the actual components that the app uses in production.
- Require more code and data processing.
- Take longer to run.

Therefore, limit the use of integration tests to the most important infrastructure scenarios. If a behavior can be tested using either a unit test or an integration test, choose the unit test.

In discussions of integration tests, the tested project is frequently called the ***System Under Test***, or "**SUT**" for short. "SUT" is used throughout this article to refer to the ASP.NET Core app being tested.

Don't write integration tests for every permutation of data and file access with databases and file systems. Regardless of how many places across an app interact with databases and file systems, a focused set of read, write, update, and delete integration tests are usually capable of adequately testing database and file system components. Use unit tests for routine tests of method logic that interact with these components. In unit tests, the use of infrastructure fakes or mocks result in faster test execution.

ASP.NET Core integration tests

Integration tests in ASP.NET Core require the following:

- A test project is used to contain and execute the tests. The test project has a reference to the SUT.
- The test project creates a test web host for the SUT and uses a test server client to handle requests and responses with the SUT.
- A test runner is used to execute the tests and report the test results.

Integration tests follow a sequence of events that include the usual *Arrange*, *Act*, and *Assert* test steps:

1. The SUT's web host is configured.
2. A test server client is created to submit requests to the app.
3. The *Arrange* test step is executed: The test app prepares a request.
4. The *Act* test step is executed: The client submits the request and receives the response.
5. The *Assert* test step is executed: The *actual* response is validated as a *pass* or *fail* based on an *expected* response.
6. The process continues until all of the tests are executed.
7. The test results are reported.

Usually, the test web host is configured differently than the app's normal web host for the test runs. For example, a different database or different app settings might be used for the tests.

Infrastructure components, such as the test web host and in-memory test server (TestServer), are provided or managed by the Microsoft.AspNetCore.Mvc.Testing package. Use of this package streamlines test creation and execution.

The `Microsoft.AspNetCore.Mvc.Testing` package handles the following tasks:

- Copies the dependencies file (`.deps`) from the SUT into the test project's `bin` directory.
- Sets the content root to the SUT's project root so that static files and pages/views are found when the tests are executed.
- Provides the WebApplicationFactory class to streamline bootstrapping the SUT with `TestServer`.

The unit tests documentation describes how to set up a test project and test runner, along with detailed instructions on how to run tests and recommendations for how to name tests and test classes.

Separate unit tests from integration tests into different projects. Separating the tests:

- Helps ensure that infrastructure testing components aren't accidentally included in the unit tests.
- Allows control over which set of tests are run.

There's virtually no difference between the configuration for tests of Razor Pages apps and MVC apps. The only difference is in how the tests are named. In a Razor Pages app, tests of page endpoints are usually named after the page model class (for example, `IndexPageTests` to test component integration for the Index page). In an MVC app, tests are usually organized by controller classes and named after the controllers they test (for example, `HomeControllerTests` to test component integration for the Home controller).

Test app prerequisites

The test project must:

- Reference the Microsoft.AspNetCore.Mvc.Testing package.
- Specify the Web SDK in the project file (`<Project Sdk="Microsoft.NET.Sdk.Web">`).

These prerequisites can be seen in the sample app. Inspect the `tests/RazorPagesProject.Tests/RazorPagesProject.Tests.csproj` file. The sample app

uses the xUnit test framework and the AngleSharp parser library, so the sample app also references:

- AngleSharp
- xunit
- xunit.runner.visualstudio

In apps that use xunit.runner.visualstudio version 2.4.2 or later, the test project must reference the Microsoft.NET.Test.Sdk package.

Entity Framework Core is also used in the tests. See the project file in GitHub.

SUT environment

If the SUT's environment isn't set, the environment defaults to Development.

Basic tests with the default WebApplicationFactory

Expose the implicitly defined `Program` class to the test project by doing one of the following:

- Expose internal types from the web app to the test project. This can be done in the SUT project's file (`.csproj`):

  XML

  ```
  <ItemGroup>
       <InternalsVisibleTo Include="MyTestProject" />
  </ItemGroup>
  ```

- Make the Program class public using a partial class declaration:

  diff

  ```
  var builder = WebApplication.CreateBuilder(args);
  // ... Configure services, routes, etc.
  app.Run();
  + public partial class Program { }
  ```

  The sample app uses the `Program` partial class approach.

WebApplicationFactory<TEntryPoint> is used to create a TestServer for the integration tests. `TEntryPoint` is the entry point class of the SUT, usually `Program.cs`.

Test classes implement a *class fixture* interface (IClassFixture) to indicate the class contains tests and provide shared object instances across the tests in the class.

The following test class, `BasicTests`, uses the `WebApplicationFactory` to bootstrap the SUT and provide an HttpClient to a test method, `Get_EndpointsReturnSuccessAndCorrectContentType`. The method verifies the response status code is successful (200-299) and the `Content-Type` header is `text/html; charset=utf-8` for several app pages.

CreateClient() creates an instance of `HttpClient` that automatically follows redirects and handles cookies.

C#

```
public class BasicTests
    : IClassFixture<WebApplicationFactory<Program>>
{
    private readonly WebApplicationFactory<Program> _factory;

    public BasicTests(WebApplicationFactory<Program> factory)
    {
        _factory = factory;
    }

    [Theory]
    [InlineData("/")]
    [InlineData("/Index")]
    [InlineData("/About")]
    [InlineData("/Privacy")]
    [InlineData("/Contact")]
    public async Task Get_EndpointsReturnSuccessAndCorrectContentType(string
url)
    {
        // Arrange
        var client = _factory.CreateClient();

        // Act
        var response = await client.GetAsync(url);

        // Assert
        response.EnsureSuccessStatusCode(); // Status Code 200-299
        Assert.Equal("text/html; charset=utf-8",
            response.Content.Headers.ContentType.ToString());
    }
}
```

By default, non-essential cookies aren't preserved across requests when the General Data Protection Regulation consent policy is enabled. To preserve non-essential cookies, such as those used by the TempData provider, mark them as essential in your tests. For instructions on marking a cookie as essential, see Essential cookies.

AngleSharp vs `Application Parts` for antiforgery checks

This article uses the AngleSharp parser to handle the antiforgery checks by loading pages and parsing the HTML. For testing the endpoints of controller and Razor Pages views at a lower-level, without caring about how they render in the browser, consider using `Application Parts`. The Application Parts approach injects a controller or Razor Page into the app that can be used to make JSON requests to get the required values. For more information, see the blog Integration Testing ASP.NET Core Resources Protected with Antiforgery Using Application Parts and associated GitHub repo by Martin Costello.

Customize WebApplicationFactory

Web host configuration can be created independently of the test classes by inheriting from WebApplicationFactory<TEntryPoint> to create one or more custom factories:

1. Inherit from `WebApplicationFactory` and override ConfigureWebHost. The IWebHostBuilder allows the configuration of the service collection with IWebHostBuilder.ConfigureServices

```
C#

public class CustomWebApplicationFactory<TProgram>
    : WebApplicationFactory<TProgram> where TProgram : class
{
    protected override void ConfigureWebHost(IWebHostBuilder builder)
    {
        builder.ConfigureServices(services =>
        {
            var dbContextDescriptor = services.SingleOrDefault(
                d => d.ServiceType ==
                    typeof(DbContextOptions<ApplicationDbContext>));

            services.Remove(dbContextDescriptor);

            var dbConnectionDescriptor = services.SingleOrDefault(
                d => d.ServiceType ==
                    typeof(DbConnection));
```

```
            services.Remove(dbConnectionDescriptor);

            // Create open SqliteConnection so EF won't automatically
close it.
            services.AddSingleton<DbConnection>(container =>
            {
                var connection = new
SqliteConnection("DataSource=:memory:");
                connection.Open();

                return connection;
            });

            services.AddDbContext<ApplicationDbContext>((container,
options) =>
            {
                var connection =
container.GetRequiredService<DbConnection>();
                options.UseSqlite(connection);
            });
        });

        builder.UseEnvironment("Development");
    }
}
```

Database seeding in the sample app is performed by the `InitializeDbForTests` method. The method is described in the Integration tests sample: Test app organization section.

The SUT's database context is registered in `Program.cs`. The test app's `builder.ConfigureServices` callback is executed *after* the app's `Program.cs` code is executed. To use a different database for the tests than the app's database, the app's database context must be replaced in `builder.ConfigureServices`.

The sample app finds the service descriptor for the database context and uses the descriptor to remove the service registration. The factory then adds a new `ApplicationDbContext` that uses an in-memory database for the tests..

To connect to a different database, change the `DbConnection`. To use a SQL Server test database:

- Reference the Microsoft.EntityFrameworkCore.SqlServer NuGet package in the project file.
- Call `UseInMemoryDatabase`.

2. Use the custom `CustomWebApplicationFactory` in test classes. The following example uses the factory in the `IndexPageTests` class:

```
C#

public class IndexPageTests :
    IClassFixture<CustomWebApplicationFactory<Program>>
{
    private readonly HttpClient _client;
    private readonly CustomWebApplicationFactory<Program>
        _factory;

    public IndexPageTests(
        CustomWebApplicationFactory<Program> factory)
    {
        _factory = factory;
        _client = factory.CreateClient(new
WebApplicationFactoryClientOptions
        {
            AllowAutoRedirect = false
        });
    }
```

The sample app's client is configured to prevent the `HttpClient` from following redirects. As explained later in the Mock authentication section, this permits tests to check the result of the app's first response. The first response is a redirect in many of these tests with a `Location` header.

3. A typical test uses the `HttpClient` and helper methods to process the request and the response:

```
C#

[Fact]
public async Task Post_DeleteAllMessagesHandler_ReturnsRedirectToRoot()
{
    // Arrange
    var defaultPage = await _client.GetAsync("/");
    var content = await HtmlHelpers.GetDocumentAsync(defaultPage);

    //Act
    var response = await _client.SendAsync(
        (IHtmlFormElement)content.QuerySelector("form[id='messages']"),

(IHtmlButtonElement)content.QuerySelector("button[id='deleteAllBtn']"))
;

    // Assert
    Assert.Equal(HttpStatusCode.OK, defaultPage.StatusCode);
    Assert.Equal(HttpStatusCode.Redirect, response.StatusCode);
```

```
        Assert.Equal("/", response.Headers.Location.OriginalString);
    }
```

Any POST request to the SUT must satisfy the antiforgery check that's automatically made by the app's data protection antiforgery system. In order to arrange for a test's POST request, the test app must:

1. Make a request for the page.
2. Parse the antiforgery cookie and request validation token from the response.
3. Make the POST request with the antiforgery cookie and request validation token in place.

The `SendAsync` helper extension methods (`Helpers/HttpClientExtensions.cs`) and the `GetDocumentAsync` helper method (`Helpers/HtmlHelpers.cs`) in the sample app use the AngleSharp parser to handle the antiforgery check with the following methods:

- `GetDocumentAsync`: Receives the HttpResponseMessage and returns an `IHtmlDocument`. `GetDocumentAsync` uses a factory that prepares a *virtual response* based on the original `HttpResponseMessage`. For more information, see the AngleSharp documentation.
- `SendAsync` extension methods for the `HttpClient` compose an HttpRequestMessage and call SendAsync(HttpRequestMessage) to submit requests to the SUT. Overloads for `SendAsync` accept the HTML form (`IHtmlFormElement`) and the following:
  - Submit button of the form (`IHtmlElement`)
  - Form values collection (`IEnumerable<KeyValuePair<string, string>>`)
  - Submit button (`IHtmlElement`) and form values (`IEnumerable<KeyValuePair<string, string>>`)

AngleSharp is a **third-party parsing library used for demonstration purposes** in this article and the sample app. AngleSharp isn't supported or required for integration testing of ASP.NET Core apps. Other parsers can be used, such as the Html Agility Pack (HAP). Another approach is to write code to handle the antiforgery system's request verification token and antiforgery cookie directly. See AngleSharp vs Application Parts for antiforgery checks in this article for more information.

The EF-Core in-memory database provider can be used for limited and basic testing, however the ***SQLite provider* is the recommended choice for in-memory testing**.

See Extend Startup with startup filters which shows how to configure middleware using IStartupFilter, which is useful when a test requires a custom service or middleware.

Customize the client with WithWebHostBuilder

When additional configuration is required within a test method, WithWebHostBuilder creates a new `WebApplicationFactory` with an IWebHostBuilder that is further customized by configuration.

The sample code calls `WithWebHostBuilder` to replace configured services with test stubs. For more information and example usage, see Inject mock services in this article.

The `Post_DeleteMessageHandler_ReturnsRedirectToRoot` test method of the sample app demonstrates the use of `WithWebHostBuilder`. This test performs a record delete in the database by triggering a form submission in the SUT.

Because another test in the `IndexPageTests` class performs an operation that deletes all of the records in the database and may run before the `Post_DeleteMessageHandler_ReturnsRedirectToRoot` method, the database is reseeded in this test method to ensure that a record is present for the SUT to delete. Selecting the first delete button of the `messages` form in the SUT is simulated in the request to the SUT:

C#

```
[Fact]
public async Task Post_DeleteMessageHandler_ReturnsRedirectToRoot()
{
    // Arrange
    using (var scope = _factory.Services.CreateScope())
    {
        var scopedServices = scope.ServiceProvider;
        var db = scopedServices.GetRequiredService<ApplicationDbContext>();

        Utilities.ReinitializeDbForTests(db);
    }

    var defaultPage = await _client.GetAsync("/");
    var content = await HtmlHelpers.GetDocumentAsync(defaultPage);

    //Act
    var response = await _client.SendAsync(
        (IHtmlFormElement)content.QuerySelector("form[id='messages']"),
        (IHtmlButtonElement)content.QuerySelector("form[id='messages']")
            .QuerySelector("div[class='panel-body']")
            .QuerySelector("button"));

    // Assert
    Assert.Equal(HttpStatusCode.OK, defaultPage.StatusCode);
    Assert.Equal(HttpStatusCode.Redirect, response.StatusCode);
```

```
    Assert.Equal("/", response.Headers.Location.OriginalString);
}
```

Client options

See the WebApplicationFactoryClientOptions page for defaults and available options when creating `HttpClient` instances.

Create the `WebApplicationFactoryClientOptions` class and pass it to the CreateClient() method:

C#

```
public class IndexPageTests :
    IClassFixture<CustomWebApplicationFactory<Program>>
{
    private readonly HttpClient _client;
    private readonly CustomWebApplicationFactory<Program>
        _factory;

    public IndexPageTests(
        CustomWebApplicationFactory<Program> factory)
    {
        _factory = factory;
        _client = factory.CreateClient(new
WebApplicationFactoryClientOptions
        {
            AllowAutoRedirect = false
        });
    }
```

NOTE: To avoid HTTPS redirection warnings in logs when using HTTPS Redirection Middleware, set `BaseAddress = new Uri("https://localhost")`

Inject mock services

Services can be overridden in a test with a call to ConfigureTestServices on the host builder. To scope the overridden services to the test itself, the WithWebHostBuilder method is used to retrieve a host builder. This can be seen in the following tests:

- Get_QuoteService_ProvidesQuoteInPage
- Get_GithubProfilePageCanGetAGithubUser
- Get_SecurePageIsReturnedForAnAuthenticatedUser

The sample SUT includes a scoped service that returns a quote. The quote is embedded in a hidden field on the Index page when the Index page is requested.

`Services/IQuoteService.cs`:

C#

```
public interface IQuoteService
{
    Task<string> GenerateQuote();
}
```

`Services/QuoteService.cs`:

C#

```
// Quote ©1975 BBC: The Doctor (Tom Baker); Dr. Who: Planet of Evil
// https://www.bbc.co.uk/programmes/p00pyrx6
public class QuoteService : IQuoteService
{
    public Task<string> GenerateQuote()
    {
        return Task.FromResult<string>(
            "Come on, Sarah. We've an appointment in London, " +
            "and we're already 30,000 years late.");
    }
}
```

`Program.cs`:

C#

```
services.AddScoped<IQuoteService, QuoteService>();
```

`Pages/Index.cshtml.cs`:

C#

```
public class IndexModel : PageModel
{
    private readonly ApplicationDbContext _db;
    private readonly IQuoteService _quoteService;

    public IndexModel(ApplicationDbContext db, IQuoteService quoteService)
    {
        _db = db;
        _quoteService = quoteService;
    }
```

```
    [BindProperty]
    public Message Message { get; set; }

    public IList<Message> Messages { get; private set; }

    [TempData]
    public string MessageAnalysisResult { get; set; }

    public string Quote { get; private set; }

    public async Task OnGetAsync()
    {
        Messages = await _db.GetMessagesAsync();

        Quote = await _quoteService.GenerateQuote();
    }
```

`Pages/Index.cs`:

CSHTML

```
<input id="quote" type="hidden" value="@Model.Quote">
```

The following markup is generated when the SUT app is run:

HTML

```
<input id="quote" type="hidden" value="Come on, Sarah. We&#x27;ve an
appointment in
    London, and we&#x27;re already 30,000 years late.">
```

To test the service and quote injection in an integration test, a mock service is injected into the SUT by the test. The mock service replaces the app's `QuoteService` with a service provided by the test app, called `TestQuoteService`:

`IntegrationTests.IndexPageTests.cs`:

C#

```
// Quote ©1975 BBC: The Doctor (Tom Baker); Pyramids of Mars
// https://www.bbc.co.uk/programmes/p00pys55
public class TestQuoteService : IQuoteService
{
    public Task<string> GenerateQuote()
    {
        return Task.FromResult(
            "Something's interfering with time, Mr. Scarman, " +
            "and time is my business.");
```

```
    }
}
```

`ConfigureTestServices` is called, and the scoped service is registered:

C#

```
[Fact]
public async Task Get_QuoteService_ProvidesQuoteInPage()
{
    // Arrange
    var client = _factory.WithWebHostBuilder(builder =>
        {
            builder.ConfigureTestServices(services =>
            {
                services.AddScoped<IQuoteService, TestQuoteService>();
            });
        })
        .CreateClient();

    //Act
    var defaultPage = await client.GetAsync("/");
    var content = await HtmlHelpers.GetDocumentAsync(defaultPage);
    var quoteElement = content.QuerySelector("#quote");

    // Assert
    Assert.Equal("Something's interfering with time, Mr. Scarman, " +
        "and time is my business.", quoteElement.Attributes["value"].Value);
}
```

The markup produced during the test's execution reflects the quote text supplied by `TestQuoteService`, thus the assertion passes:

HTML

```
<input id="quote" type="hidden" value="Something&#x27;s interfering with
time,
    Mr. Scarman, and time is my business.">
```

Mock authentication

Tests in the `AuthTests` class check that a secure endpoint:

- Redirects an unauthenticated user to the app's sign in page.
- Returns content for an authenticated user.

In the SUT, the `/SecurePage` page uses an AuthorizePage convention to apply an AuthorizeFilter to the page. For more information, see Razor Pages authorization conventions.

C#

```
services.AddRazorPages(options =>
{
    options.Conventions.AuthorizePage("/SecurePage");
});
```

In the `Get_SecurePageRedirectsAnUnauthenticatedUser` test, a WebApplicationFactoryClientOptions is set to disallow redirects by setting AllowAutoRedirect to `false`:

C#

```
[Fact]
public async Task Get_SecurePageRedirectsAnUnauthenticatedUser()
{
    // Arrange
    var client = _factory.CreateClient(
        new WebApplicationFactoryClientOptions
        {
            AllowAutoRedirect = false
        });

    // Act
    var response = await client.GetAsync("/SecurePage");

    // Assert
    Assert.Equal(HttpStatusCode.Redirect, response.StatusCode);
    Assert.StartsWith("http://localhost/Identity/Account/Login",
        response.Headers.Location.OriginalString);
}
```

By disallowing the client to follow the redirect, the following checks can be made:

- The status code returned by the SUT can be checked against the expected HttpStatusCode.Redirect result, not the final status code after the redirect to the sign in page, which would be HttpStatusCode.OK.
- The `Location` header value in the response headers is checked to confirm that it starts with `http://localhost/Identity/Account/Login`, not the final sign in page response, where the `Location` header wouldn't be present.

The test app can mock an AuthenticationHandler<TOptions> in ConfigureTestServices in order to test aspects of authentication and authorization. A minimal scenario returns an

AuthenticateResult.Success:

```
C#

public class TestAuthHandler :
AuthenticationHandler<AuthenticationSchemeOptions>
{
    public TestAuthHandler(IOptionsMonitor<AuthenticationSchemeOptions>
options,
        ILoggerFactory logger, UrlEncoder encoder)
        : base(options, logger, encoder)
    {
    }

    protected override Task<AuthenticateResult> HandleAuthenticateAsync()
    {
        var claims = new[] { new Claim(ClaimTypes.Name, "Test user") };
        var identity = new ClaimsIdentity(claims, "Test");
        var principal = new ClaimsPrincipal(identity);
        var ticket = new AuthenticationTicket(principal, "TestScheme");

        var result = AuthenticateResult.Success(ticket);

        return Task.FromResult(result);
    }
}
```

The `TestAuthHandler` is called to authenticate a user when the authentication scheme is set to `TestScheme` where `AddAuthentication` is registered for `ConfigureTestServices`. It's important for the `TestScheme` scheme to match the scheme your app expects. Otherwise, authentication won't work.

```
C#

[Fact]
public async Task Get_SecurePageIsReturnedForAnAuthenticatedUser()
{
    // Arrange
    var client = _factory.WithWebHostBuilder(builder =>
        {
            builder.ConfigureTestServices(services =>
            {
                services.AddAuthentication(defaultScheme: "TestScheme")
                    .AddScheme<AuthenticationSchemeOptions, TestAuthHandler>
(
                        "TestScheme", options => { });
            });
        })
        .CreateClient(new WebApplicationFactoryClientOptions
        {
            AllowAutoRedirect = false,
```

```
        });

    client.DefaultRequestHeaders.Authorization =
        new AuthenticationHeaderValue(scheme: "TestScheme");

    //Act
    var response = await client.GetAsync("/SecurePage");

    // Assert
    Assert.Equal(HttpStatusCode.OK, response.StatusCode);
}
```

For more information on `WebApplicationFactoryClientOptions`, see the Client options section.

Basic tests for authentication middleware

See this GitHub repository for basic tests of authentication middleware. It contains a test server that's specific to the test scenario.

Set the environment

Set the environment in the custom application factory:

C#

```
public class CustomWebApplicationFactory<TProgram>
    : WebApplicationFactory<TProgram> where TProgram : class
{
    protected override void ConfigureWebHost(IWebHostBuilder builder)
    {
        builder.ConfigureServices(services =>
        {
            var dbContextDescriptor = services.SingleOrDefault(
                d => d.ServiceType ==
                    typeof(DbContextOptions<ApplicationDbContext>));

            services.Remove(dbContextDescriptor);

            var dbConnectionDescriptor = services.SingleOrDefault(
                d => d.ServiceType ==
                    typeof(DbConnection));

            services.Remove(dbConnectionDescriptor);

            // Create open SqliteConnection so EF won't automatically close
it.
            services.AddSingleton<DbConnection>(container =>
            {
```

```
                var connection = new
SqliteConnection("DataSource=:memory:");
                connection.Open();

                return connection;
            });

            services.AddDbContext<ApplicationDbContext>((container, options)
=>
            {
                var connection = container.GetRequiredService<DbConnection>
();
                options.UseSqlite(connection);
            });
        });

        builder.UseEnvironment("Development");
    }
}
```

How the test infrastructure infers the app content root path

The `WebApplicationFactory` constructor infers the app content root path by searching for a WebApplicationFactoryContentRootAttribute on the assembly containing the integration tests with a key equal to the `TEntryPoint` assembly `System.Reflection.Assembly.FullName`. In case an attribute with the correct key isn't found, `WebApplicationFactory` falls back to searching for a solution file (*.sln*) and appends the `TEntryPoint` assembly name to the solution directory. The app root directory (the content root path) is used to discover views and content files.

Disable shadow copying

Shadow copying causes the tests to execute in a different directory than the output directory. If your tests rely on loading files relative to `Assembly.Location` and you encounter issues, you might have to disable shadow copying.

To disable shadow copying when using xUnit, create a `xunit.runner.json` file in your test project directory, with the correct configuration setting :

JSON

```
{
  "shadowCopy": false
```

```
}
```

Disposal of objects

After the tests of the `IClassFixture` implementation are executed, TestServer and HttpClient are disposed when xUnit disposes of the WebApplicationFactory. If objects instantiated by the developer require disposal, dispose of them in the `IClassFixture` implementation. For more information, see Implementing a Dispose method.

Integration tests sample

The sample app is composed of two apps:

Expand table

App	Project directory	Description
Message app (the SUT)	`src/RazorPagesProject`	Allows a user to add, delete one, delete all, and analyze messages.
Test app	`tests/RazorPagesProject.Tests`	Used to integration test the SUT.

The tests can be run using the built-in test features of an IDE, such as Visual Studio. If using Visual Studio Code or the command line, execute the following command at a command prompt in the `tests/RazorPagesProject.Tests` directory:

Console

```
dotnet test
```

Message app (SUT) organization

The SUT is a Razor Pages message system with the following characteristics:

- The Index page of the app (`Pages/Index.cshtml` and `Pages/Index.cshtml.cs`) provides a UI and page model methods to control the addition, deletion, and analysis of messages (average words per message).
- A message is described by the `Message` class (`Data/Message.cs`) with two properties: `Id` (key) and `Text` (message). The `Text` property is required and limited to 200 characters.
- Messages are stored using Entity Framework's in-memory database†.

- The app contains a data access layer (DAL) in its database context class, `AppDbContext` (`Data/AppDbContext.cs`).
- If the database is empty on app startup, the message store is initialized with three messages.
- The app includes a `/SecurePage` that can only be accessed by an authenticated user.

†The EF article, Test with InMemory, explains how to use an in-memory database for tests with MSTest. This topic uses the xUnit test framework. Test concepts and test implementations across different test frameworks are similar but not identical.

Although the app doesn't use the repository pattern and isn't an effective example of the Unit of Work (UoW) pattern, Razor Pages supports these patterns of development. For more information, see Designing the infrastructure persistence layer and Test controller logic (the sample implements the repository pattern).

Test app organization

The test app is a console app inside the `tests/RazorPagesProject.Tests` directory.

Expand table

Test app directory	Description
`AuthTests`	Contains test methods for: • Accessing a secure page by an unauthenticated user. • Accessing a secure page by an authenticated user with a mock AuthenticationHandler<TOptions>. • Obtaining a GitHub user profile and checking the profile's user login.
`BasicTests`	Contains a test method for routing and content type.
`IntegrationTests`	Contains the integration tests for the Index page using custom `WebApplicationFactory` class.
`Helpers/Utilities`	• `Utilities.cs` contains the `InitializeDbForTests` method used to seed the database with test data. • `HtmlHelpers.cs` provides a method to return an AngleSharp `IHtmlDocument` for use by the test methods. • `HttpClientExtensions.cs` provide overloads for `SendAsync` to submit requests to the SUT.

The test framework is xUnit. Integration tests are conducted using the Microsoft.AspNetCore.TestHost, which includes the TestServer. Because the Microsoft.AspNetCore.Mvc.Testing package is used to configure the test host and test server, the `TestHost` and `TestServer` packages don't require direct package references in the test app's project file or developer configuration in the test app.

Integration tests usually require a small dataset in the database prior to the test execution. For example, a delete test calls for a database record deletion, so the database must have at least one record for the delete request to succeed.

The sample app seeds the database with three messages in `Utilities.cs` that tests can use when they execute:

C#

```
public static void InitializeDbForTests(ApplicationDbContext db)
{
    db.Messages.AddRange(GetSeedingMessages());
    db.SaveChanges();
}

public static void ReinitializeDbForTests(ApplicationDbContext db)
{
    db.Messages.RemoveRange(db.Messages);
    InitializeDbForTests(db);
}

public static List<Message> GetSeedingMessages()
{
    return new List<Message>()
    {
        new Message(){ Text = "TEST RECORD: You're standing on my scarf." },
        new Message(){ Text = "TEST RECORD: Would you like a jelly baby?" },
        new Message(){ Text = "TEST RECORD: To the rational mind, " +
            "nothing is inexplicable; only unexplained." }
    };
}
```

The SUT's database context is registered in `Program.cs`. The test app's `builder.ConfigureServices` callback is executed *after* the app's `Program.cs` code is executed. To use a different database for the tests, the app's database context must be replaced in `builder.ConfigureServices`. For more information, see the Customize WebApplicationFactory section.

ASP.NET Core load/stress testing

Article • 03/07/2024

Load testing and stress testing are important to ensure a web app is performant and scalable. Load and stress testing have different goals even though they often share similar tests.

Load tests: Test whether the app can handle a specified load of users for a certain scenario while still satisfying the response goal. The app is run under normal conditions.

Stress tests: Test app stability when running under extreme conditions, often for a long period of time. The tests place high user load, either spikes or gradually increasing load on the app, or they limit the app's computing resources.

Stress tests determine if an app under stress can recover from failure and gracefully return to expected behavior. Under stress, the app is run at abnormally high stress.

Azure Load Testing is a fully managed load-testing service that enables you to generate high-scale load. The service simulates traffic for apps, regardless of where they're hosted. Azure Load Testing Preview enables you to use existing Apache JMeter scripts to generate high-scale load.

Visual Studio 2019 load testing has been deprecated. The corresponding Azure DevOps cloud-based load testing service has been closed.

Third-party tools

The following list contains third-party web performance tools with various feature sets:

- Apache JMeter
- ApacheBench (ab)
- Gatling
- jmeter-dotnet-dsl
- k6
- Locust
- West Wind WebSurge
- Netling
- Vegeta
- NBomber

Load and stress test with release builds

Load and stress tests should be done in release and production mode and not in debug and development mode. Release configurations are fully optimized with minimal logging. Debug configuration is not optimized. Development mode enables more information logging that can impact performance.

Test ASP.NET Core middleware

Article • 01/11/2024

By Chris Ross

Middleware can be tested in isolation with TestServer. It allows you to:

- Instantiate an app pipeline containing only the components that you need to test.
- Send custom requests to verify middleware behavior.

Advantages:

- Requests are sent in-memory rather than being serialized over the network.
- This avoids additional concerns, such as port management and HTTPS certificates.
- Exceptions in the middleware can flow directly back to the calling test.
- It's possible to customize server data structures, such as HttpContext, directly in the test.

Set up the TestServer

In the test project, create a test:

- Build and start a host that uses TestServer.
- Add any required services that the middleware uses.
- Add a package reference to the project for the Microsoft.AspNetCore.TestHost NuGet package.
- Configure the processing pipeline to use the middleware for the test.

```
C#

[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
```

```
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    ...
}
```

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at **Package consumption workflow (NuGet documentation)**. Confirm correct package versions at **NuGet.org**.

Send requests with HttpClient

Send a request using HttpClient:

C#

```
[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();
```

```
    var response = await host.GetTestClient().GetAsync("/");

    ...
}
```

Assert the result. First, make an assertion the opposite of the result that you expect. An initial run with a false positive assertion confirms that the test fails when the middleware is performing correctly. Run the test and confirm that the test fails.

In the following example, the middleware should return a 404 status code (*Not Found*) when the root endpoint is requested. Make the first test run with `Assert.NotEqual( ... );`, which should fail:

C#

```
[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    var response = await host.GetTestClient().GetAsync("/");

    Assert.NotEqual(HttpStatusCode.NotFound, response.StatusCode);
}
```

Change the assertion to test the middleware under normal operating conditions. The final test uses `Assert.Equal( ... );`. Run the test again to confirm that it passes.

C#

```
[Fact]
public async Task MiddlewareTest_ReturnsNotFoundForRequest()
{
    using var host = await new HostBuilder()
```

```
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    var response = await host.GetTestClient().GetAsync("/");

    Assert.Equal(HttpStatusCode.NotFound, response.StatusCode);
}
```

Send requests with HttpContext

A test app can also send a request using SendAsync(Action<HttpContext>, CancellationToken). In the following example, several checks are made when `https://example.com/A/Path/?and=query` is processed by the middleware:

C#

```
[Fact]
public async Task TestMiddleware_ExpectedResponse()
{
    using var host = await new HostBuilder()
        .ConfigureWebHost(webBuilder =>
        {
            webBuilder
                .UseTestServer()
                .ConfigureServices(services =>
                {
                    services.AddMyServices();
                })
                .Configure(app =>
                {
                    app.UseMiddleware<MyMiddleware>();
                });
        })
        .StartAsync();

    var server = host.GetTestServer();
    server.BaseAddress = new Uri("https://example.com/A/Path/");

    var context = await server.SendAsync(c =>
```

```
    {
        c.Request.Method = HttpMethods.Post;
        c.Request.Path = "/and/file.txt";
        c.Request.QueryString = new QueryString("?and=query");
    });

    Assert.True(context.RequestAborted.CanBeCanceled);
    Assert.Equal(HttpProtocol.Http11, context.Request.Protocol);
    Assert.Equal("POST", context.Request.Method);
    Assert.Equal("https", context.Request.Scheme);
    Assert.Equal("example.com", context.Request.Host.Value);
    Assert.Equal("/A/Path", context.Request.PathBase.Value);
    Assert.Equal("/and/file.txt", context.Request.Path.Value);
    Assert.Equal("?and=query", context.Request.QueryString.Value);
    Assert.NotNull(context.Request.Body);
    Assert.NotNull(context.Request.Headers);
    Assert.NotNull(context.Response.Headers);
    Assert.NotNull(context.Response.Body);
    Assert.Equal(404, context.Response.StatusCode);
    Assert.Null(context.Features.Get<IHttpResponseFeature>().ReasonPhrase);
}
```

SendAsync permits direct configuration of an HttpContext object rather than using the HttpClient abstractions. Use SendAsync to manipulate structures only available on the server, such as HttpContext.Items or HttpContext.Features.

As with the earlier example that tested for a *404 - Not Found* response, check the opposite for each `Assert` statement in the preceding test. The check confirms that the test fails correctly when the middleware is operating normally. After you've confirmed that the false positive test works, set the final `Assert` statements for the expected conditions and values of the test. Run it again to confirm that the test passes.

Add request routes

Additional routes can be added by configuration using the test `HttpClient`:

C#

```
    [Fact]
    public async Task TestWithEndpoint_ExpectedResponse ()
    {
        using var host = await new HostBuilder()
            .ConfigureWebHost(webBuilder =>
            {
                webBuilder
                    .UseTestServer()
                    .ConfigureServices(services =>
                    {
                        services.AddRouting();
```

```
                    })
                    .Configure(app =>
                    {
                        app.UseRouting();
                        app.UseMiddleware<MyMiddleware>();
                        app.UseEndpoints(endpoints =>
                        {
                            endpoints.MapGet("/hello", () =>
                                TypedResults.Text("Hello Tests"));
                        });
                    });
            })
            .StartAsync();

        var client = host.GetTestClient();

        var response = await client.GetAsync("/hello");

        Assert.True(response.IsSuccessStatusCode);
        var responseBody = await response.Content.ReadAsStringAsync();
        Assert.Equal("Hello Tests", responseBody);
```

Additional routes can also be added using the approach `server.SendAsync`.

TestServer limitations

TestServer:

- Was created to replicate server behaviors to test middleware.
- Does ***not*** try to replicate all HttpClient behaviors.
- Attempts to give the client access to as much control over the server as possible, and with as much visibility into what's happening on the server as possible. For example it may throw exceptions not normally thrown by `HttpClient` in order to directly communicate server state.
- Doesn't set some transport specific headers by default as those aren't usually relevant to middleware. For more information, see the next section.
- Ignores the `Stream` position passed through StreamContent. HttpClient sends the entire stream from the start position, even when positioning is set. For more information, see this GitHub issue.

Content-Length and Transfer-Encoding headers

TestServer does ***not*** set transport related request or response headers such as Content-Length or Transfer-Encoding. Applications should avoid depending on these headers because their usage varies by client, scenario, and protocol. If `Content-Length`

and `Transfer-Encoding` are necessary to test a specific scenario, they can be specified in the test when composing the HttpRequestMessage or HttpContext. For more information, see the following GitHub issues:

- dotnet/aspnetcore#21677
- dotnet/aspnetcore#18463
- dotnet/aspnetcore#13273

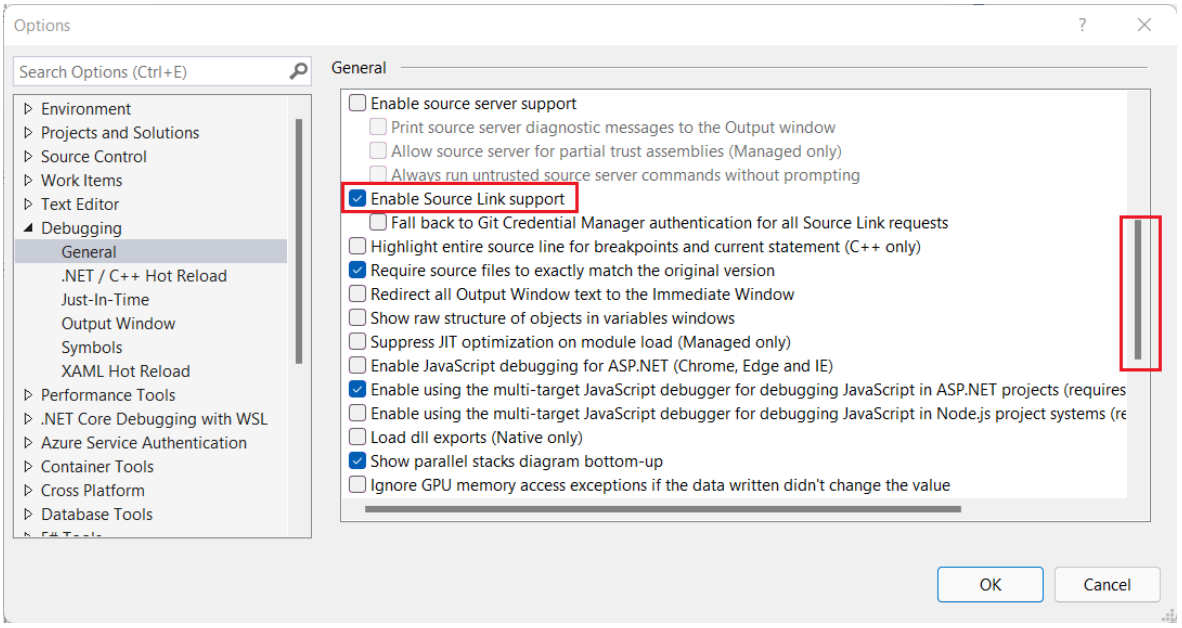
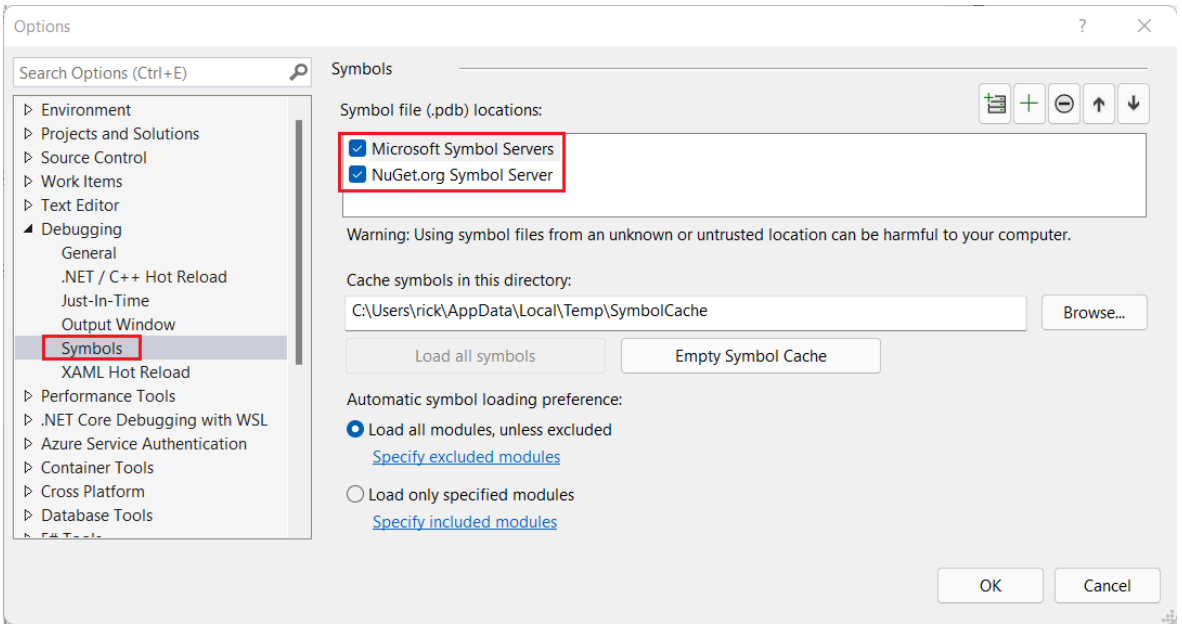
Debug .NET and ASP.NET Core source code with Visual Studio



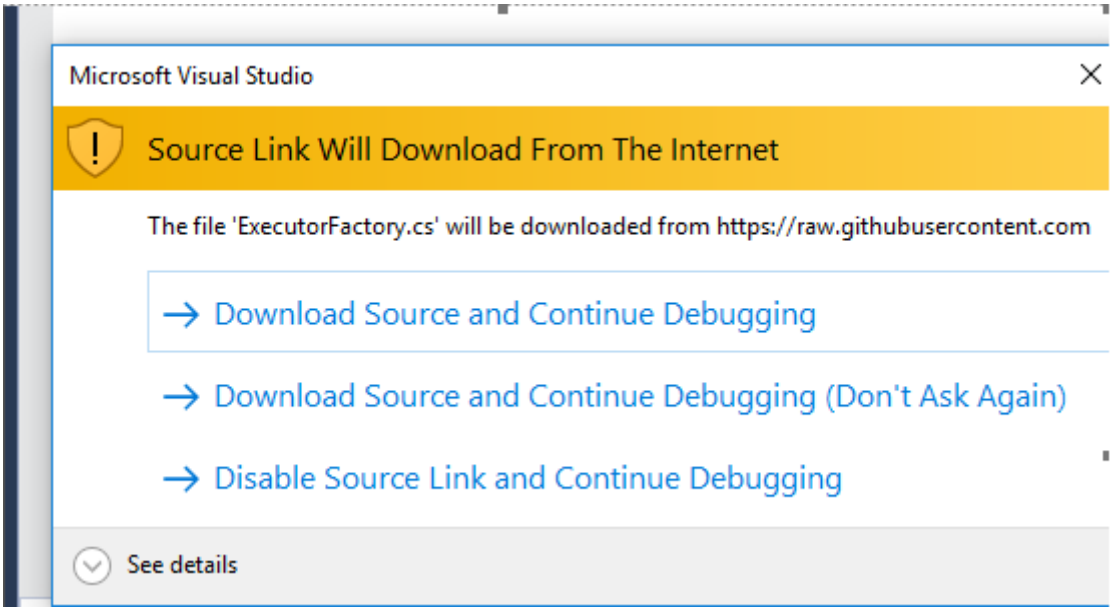
Article • 09/18/2024

To debug .NET and ASP.NET Core source code in Visual Studio:

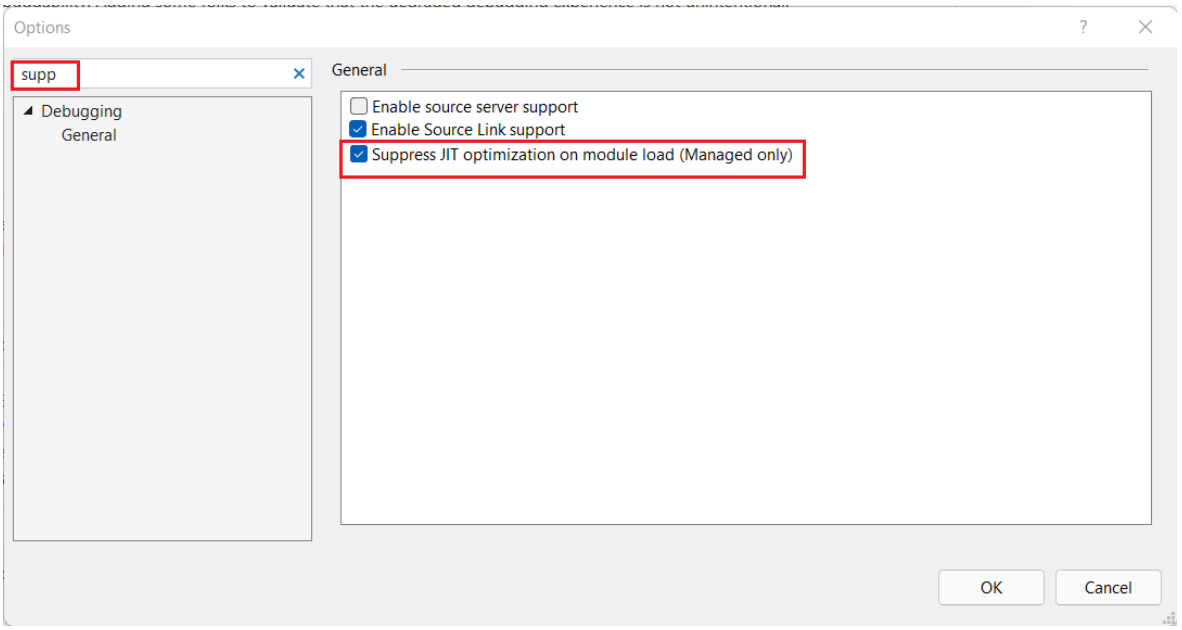


- In **Tools -> Options -> Debugging -> General**, un-check **Enable Just My Code**.

- Verify **Enable Source Link support** is checked.



- In **Tool -> Options -> Debugging -> Symbols**, enable **Microsoft Symbol Servers**.



When you step into any .NET or ASP.NET Core code, Visual Studio displays the source code. For example:

- Set a break point in `OnGet` in `Pages/Privacy.cshtml.cs` and select the **Privacy** link.
- Select one of the **Download Source and Continue Debugging** options.

The preceding instructions work for basic stepping into functions, but the optimized .NET code often removes local variables and functions. To disable optimizations and allow better source debugging:

- In **Tools -> Options -> Debugging -> General**, enable **Suppress JIT optimization on module load (Managed only)**:

- Add the environment variable and value `COMPlus_ReadyToRun=0` to the `Properties/launchSettings.json` file:

JSON

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:10892",
      "sslPort": 44315
    }
  },
  "profiles": {
    "WebApplication18": {
      "commandName": "Project",
      "dotnetRunMessages": true,
      "launchBrowser": true,
      "applicationUrl": "https://localhost:7045;http://localhost:5045",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development",
        "COMPlus_ReadyToRun": "0"
      }
    },
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development",
        "COMPlus_ReadyToRun": "0"
      }
    }
  }
}
```

If you have debugged an app before with the previous version of .NET, delete the `%TEMP%/SymbolCache` directory as it can have old PDBs that are out of date.

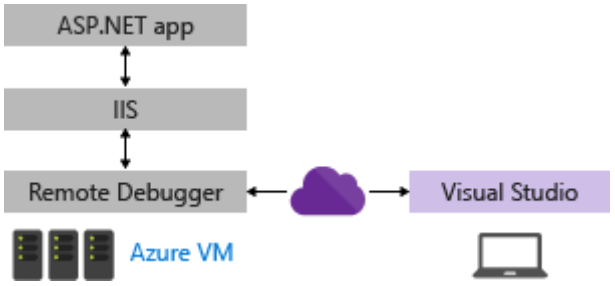
Remote Debug ASP.NET Core on IIS using an Azure VM from Visual Studio



Article • 04/23/2024

This guide explains how to set up and configure a Visual Studio ASP.NET Core app, deploy it to IIS using an Azure VM, and attach the remote debugger from Visual Studio.

For IIS scenarios, Linux isn't supported.

To debug IIS on an Azure VM, follow the steps in this article. Using this method, you can use a customized configuration of IIS, but the setup and deployment steps are more complicated. If you don't need to customize IIS for your scenario, you might choose simpler methods to host and debug the app in Azure App Service instead.

For an Azure VM, you must deploy your app from Visual Studio to Azure and you also need to manually install the IIS role and the remote debugger, as shown in the following illustration.

> ⚠ **Warning**
>
> Be sure to delete the Azure resources that you create when you have completed the steps in this tutorial. That way you can avoid incurring unnecessary charges.

These procedures have been tested on these server configurations:

- Windows Server 2022 and IIS 10
- Windows Server 2019 and IIS 10
- Windows Server 2016 and IIS 10

Prerequisites

Visual Studio 2019 or later versions is required to follow the steps shown in this article.

Network requirements

Debugging between two computers connected through a proxy isn't supported. Debugging over a high latency or low bandwidth connection, such as dialup Internet, or over the Internet across countries/regions isn't recommended and might fail or be unacceptably slow. For a complete list of requirements, see Requirements.

App already running in IIS on the Azure VM?

This article includes steps on setting up a basic configuration of IIS on Windows server and deploying the app from Visual Studio. These steps are included to make sure that the server has the required components installed, that the app can run correctly, and that you're ready to remote debug.

- If your app is running in IIS and you just want to download the remote debugger and start debugging, go to Download and Install the remote tools on Windows Server.
- If you want help ensuring your app is set up, deployed, and running correctly in IIS so that you can debug, follow all the steps in this article.
    - Before you begin, follow all the steps described in Create a Windows Virtual Machine, which includes steps to install the IIS web server.
    - Make sure you open port 80 in the Azure Network security group. When you verify that port 80 is open, also open the correct port for the remote debugger (4026, 4024, or 4022). That way, you don't have to open it later. If you're using Web Deploy, also open port 8172.

Create the ASP.NET Core application on the Visual Studio computer

1. Create a new ASP.NET Core web application.

   In Visual Studio, choose **File** > **Start window** to open the Start window, and then choose **Create a new project**. In the search box, type **web app**, then choose **C#** as the language, then choose **ASP.NET Core Web Application (Model-View-Controller)**, and then choose **Next**. On the next screen, name the project **MyASPApp**, and then choose **Next**.

   Choose either the recommended target framework or .NET 8, and then choose **Create**. The version must match the version installed on the server.

2. Open the *HomeController.cs* file in the Controllers folder and set a breakpoint in the `return View;` statement in the `Privacy` method.

   In older templates, open the *Privacy.cshtml.cs* file and set a breakpoint in the `OnGet` method.

Update browser security settings on Windows Server

If you're using an older version of Windows Server, you might need to add some domains as trusted sites to enable you to download some of the web server components. Add the trusted sites by going to **Internet Options** > **Security** > **Trusted Sites** > **Sites**. Add the following domains.

- microsoft.com
- go.microsoft.com
- download.microsoft.com
- iis.net

When you download the software, you might get requests to grant permission to load various web site scripts and resources. Some of these resources aren't required, but to simplify the process, select **Add** when prompted.

Install ASP.NET Core on Windows Server

1. Install the .NET Core Hosting Bundle on the hosting system. The bundle installs the .NET Core Runtime, .NET Core Library, and the ASP.NET Core Module. For more in-depth instructions, see Publishing to IIS.

   For the current .NET Core hosting bundle, install the ASP.NET Core Hosting Bundle.

   > **Note**
   >
   > If you previously installed IIS, the ASP.NET Core IIS Module gets installed with ASP.NET Core. Otherwise, install the ASP.NET Core IIS Module manually.

   For .NET Core 2, install the .NET Core Windows Server Hosting.

   > **Note**

If the system doesn't have an Internet connection, obtain and install the *Microsoft Visual C++ 2015 Redistributable* before installing the .NET Core Windows Server Hosting bundle.

2. Restart the system (or execute **net stop was /y** followed by **net start w3svc** from a command prompt to pick up a change to the system PATH).

Choose a deployment option

If you need help deploying the app to IIS, consider these options:

- Deploy by creating a publish settings file in IIS and importing the settings in Visual Studio. In some scenarios, this approach is a fast way to deploy your app. When you create the publish settings file, permissions are automatically set up in IIS.
- Deploy by publishing to a local folder and copying the output by a preferred method to a prepared app folder on IIS.

(Optional) Deploy using a publish settings file

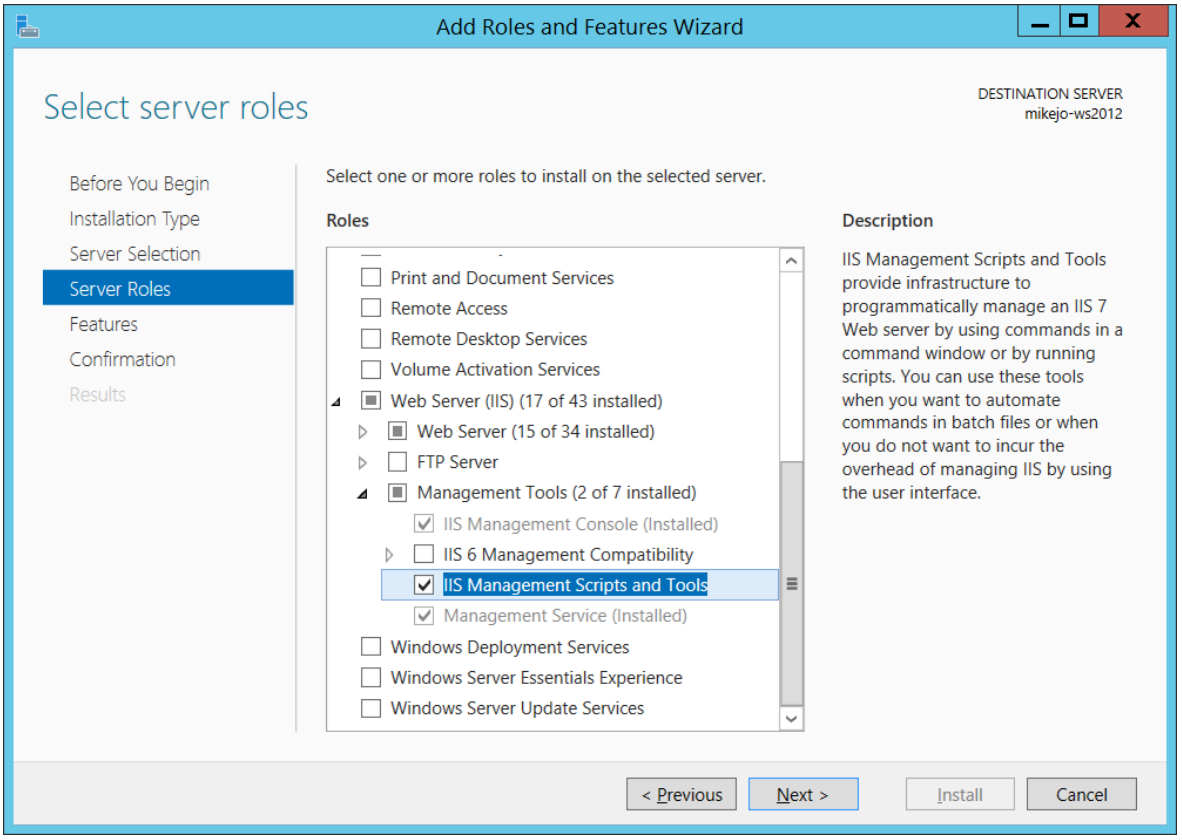
You can use this option create a publish settings file and import it into Visual Studio.

> **Note**
>
> This deployment method uses Web Deploy, which must be installed on the server. If you want to configure Web Deploy manually instead of importing the settings, you can install Web Deploy 3.6 instead of Web Deploy 3.6 for Hosting Servers. However, if you configure Web Deploy manually, you will need to make sure that an app folder on the server is configured with the correct values and permissions (see Configure ASP.NET Web site).

Configure the ASP.NET Core web site

1. In IIS Manager, in the left pane under **Connections**, select **Application Pools**. Open **DefaultAppPool** and set the **.NET CLR version** to **No Managed Code**. This is required for ASP.NET Core. The Default Web Site uses the DefaultAppPool.

2. Stop and restart the DefaultAppPool.



Install and configure Web Deploy on Windows Server

Web Deploy provides additional configuration features that enable the creation of the publish settings file from the UI.

> **Note**
>
> The Web Platform Installer reached End-of-Life on 7/1/22. For more information, see Web Platform Installer - End of support and sunsetting the product/application feed. You can directly install Web Deploy 4.0 to create the publish settings file.

1. If you did not already install **IIS Management Scripts and Tools**, install it now.

   Go to **Select server roles** > **Web Server (IIS)** > **Management Tools**, and then select the **IIS Management Scripts and Tools** role, click **Next**, and then install the role.

   The scripts and tools are required to enable the generation of the publish settings file.

   Make sure you also install the **Management Service** and **IIS Management Console** (they may be already installed).

2. On Windows Server, download Web Deploy 4.0.

3. Run the Web Deploy installation program, and make sure you select **Complete** installation instead of a typical installation.

With a complete installation, you get the components you need to generate a publish settings file. (If you choose **Custom** instead, you can see the list of components, as shown in the following illustration.)

4. (Optional) Verify that Web Deploy is running correctly by opening **Control Panel** > **System and Security** > **Administrative Tools** > **Services**, and then make sure that:

   - **Web Deployment Agent Service** is running (the service name is different in older versions).
   - **Web Management Service** is running.

   If one of the agent services is not running, restart the **Web Deployment Agent Service**.

   If the Web Deployment Agent Service is not present at all, go to **Control Panel** > **Programs** > **Uninstall a program**, find **Microsoft Web Deploy <version>**. Choose to **Change** the installation and make sure that you choose **Will be installed to the local hard drive** for the Web Deploy components. Complete the change installation steps.

Create the publish settings file in IIS on Windows Server

1. Close and reopen the IIS Management Console to show updated configuration options in the UI.

2. In IIS, right-click the **Default Web Site**, choose **Deploy** > **Configure Web Deploy Publishing**.

If you don't see the **Deploy** menu, see the preceding section to verify that Web Deploy is running.

3. In the **Configure Web Deploy Publishing** dialog box, examine the settings.

4. Click **Setup**.

   In the **Results** panel, the output shows that access rights are granted to the specified user, and that a file with a *.publishsettings* file extension has been generated in the location shown in the dialog box.

```xml
<?xml version="1.0" encoding="utf-8"?>
<publishData>
  <publishProfile
    publishUrl="https://myhostname:8172/msdeploy.axd"
    msdeploySite="Default Web Site"
    destinationAppUrl="http://myhostname:80/"
    mySQLDBConnectionString=""
    SQLServerDBConnectionString=""
    profileName="Default Settings"
```

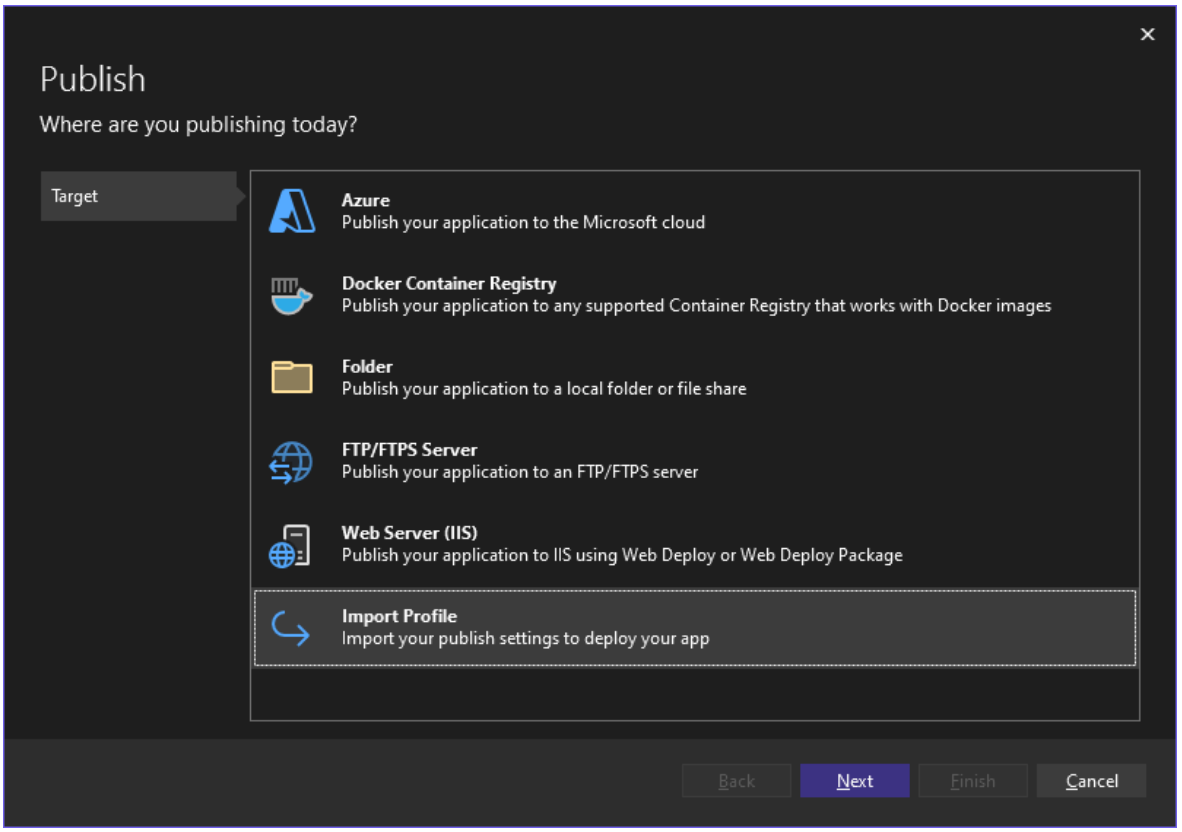
```
    publishMethod="MSDeploy"
    userName="myhostname\myusername" />
</publishData>
```

Depending on your Windows Server and IIS configuration, you see different values in the XML file. Here are a few details about the values that you see:

- The *msdeploy.axd* file referenced in the `publishUrl` attribute is a dynamically generated HTTP handler file for Web Deploy. (For testing purposes, `http://myhostname:8172` generally works as well.)
- The `publishUrl` port is set to port 8172, which is the default for Web Deploy.
- The `destinationAppUrl` port is set to port 80, which is the default for IIS.
- If, in later steps, you are unable to connect to the remote host from Visual Studio using the host name, test the server's IP address in place of the host name.

> **Note**
>
> If you are publishing to IIS running on an Azure VM, you must open an inbound port for Web Deploy and IIS in the Network Security group. For detailed information, see Open ports to a virtual machine.

5. Copy this file to the computer where you are running Visual Studio.



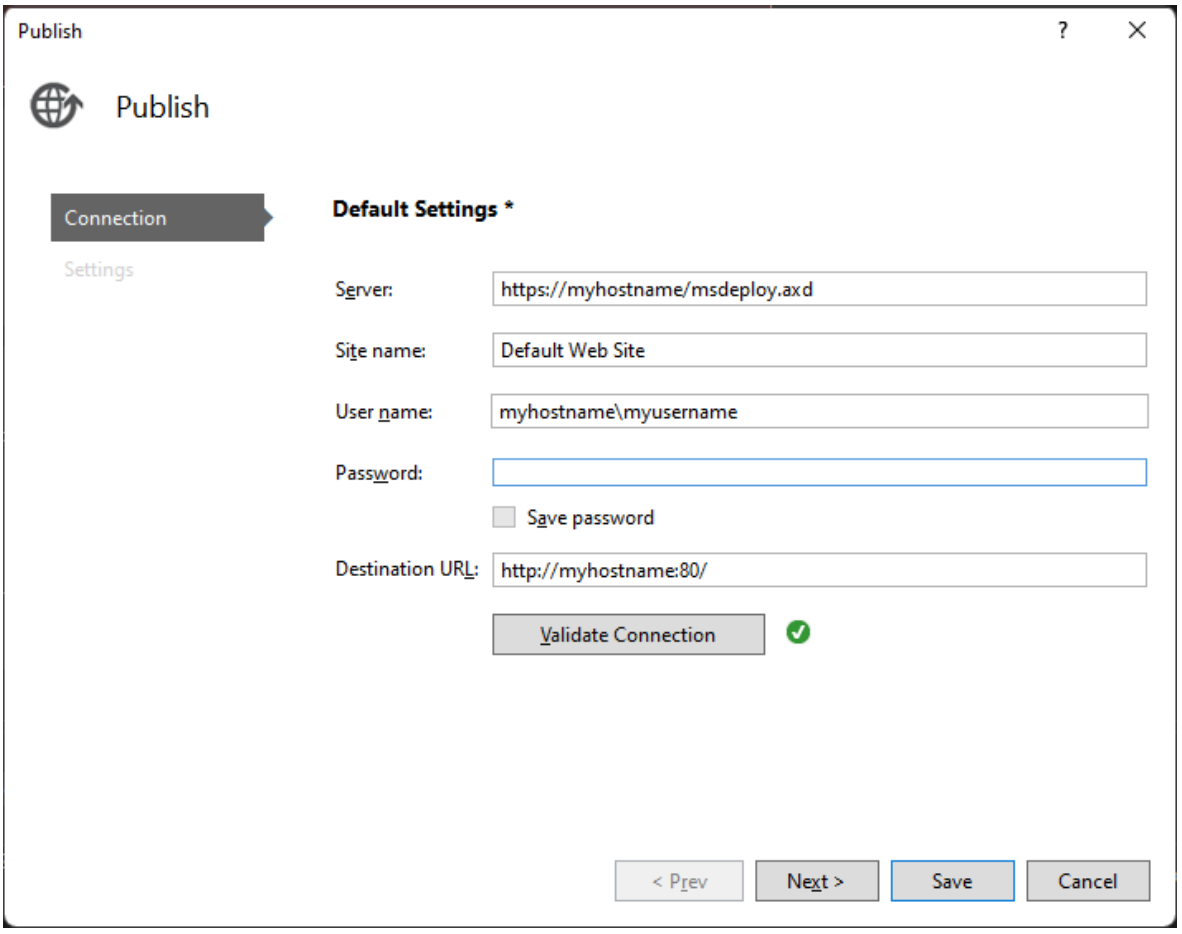
Import the publish settings in Visual Studio and deploy

1. On the computer where you have the ASP.NET project open in Visual Studio, right-click the project in Solution Explorer, and choose **Publish**.

   If you have previously configured any publishing profiles, the **Publish** pane appears. Click **New** or **Create new profile**.

2. Select the option to import a profile.

   In the **Publish** dialog box, click **Import Profile**.



3. Navigate to the location of the publish settings file that you created in the previous section.

4. In the **Import Publish Settings File** dialog, navigate to and select the profile that you created in the previous section, and click **Open**.

   Click **Finish** to save the publishing profile, and then click **Publish**.

   Visual Studio begins the deployment process, and the Output window shows progress and results.

   If you get an any deployment errors, click **More Actions** > **Edit** to edit settings. Modify settings and click **Validate** to test new settings. If the host name is not found, try the IP address instead of the host name in both the **Server** and **Destination URL** fields.

> **Note**
>
> If you restart an Azure VM, the IP address might change.

After the app deploys successfully, it should start automatically.

- If the app doesn't start after deployment, start the app in IIS to verify that it runs correctly.
- For ASP.NET Core, make sure the Application pool field for the **DefaultAppPool** is set to **No Managed Code**.

When you're ready, switch to a debug configuration.

> **Important**
>
> If you choose to debug a Release configuration, you disable debugging in the *web.config* file when you publish.

1. Select **More Options** > **Edit** to edit the profile, and then select **Settings**.
2. Select **Save** and then republish the app.
3. Select a **Debug** configuration, and then select **Remove additional files at destination** under the **File Publish** options.

(Optional) Deploy by publishing to a local folder

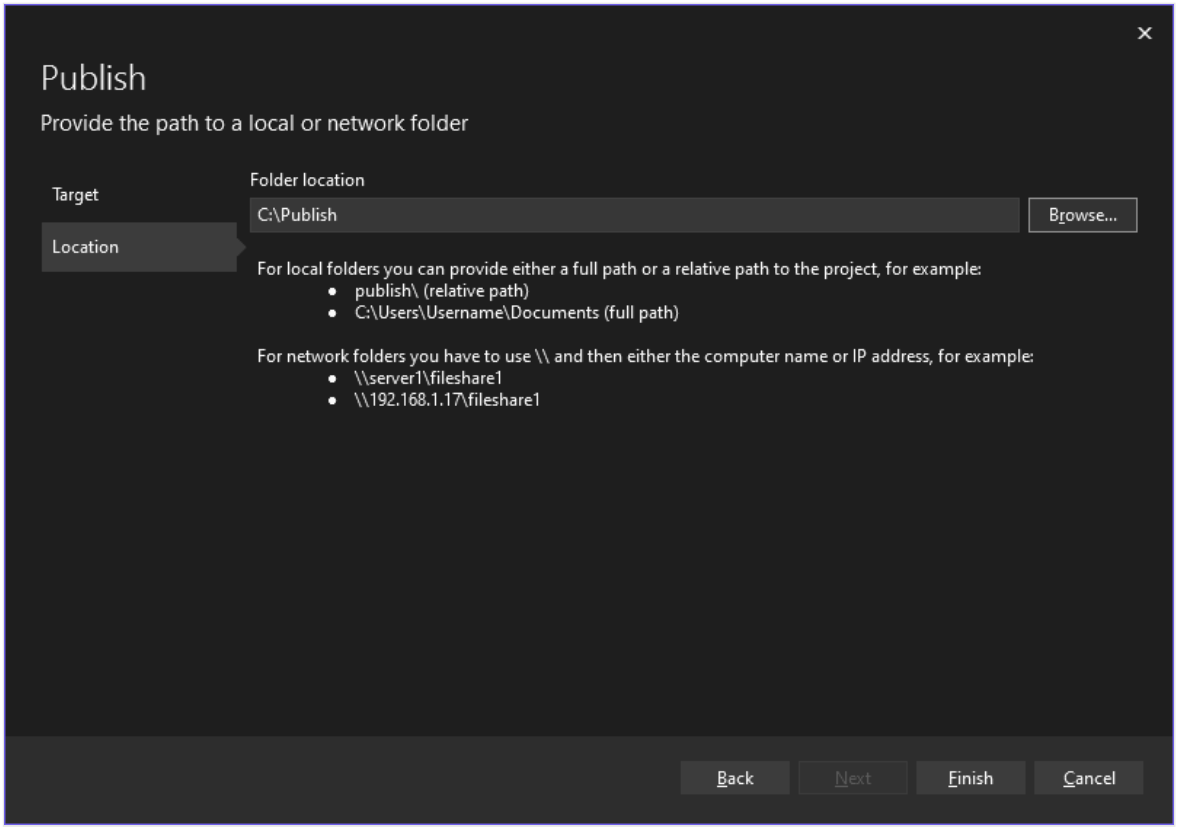
You can use this option to deploy your app if you want to copy the app to IIS using PowerShell, RoboCopy, or you want to manually copy the files.

Configure the ASP.NET Core Web site on the Windows Server computer

If you're importing publish settings, you can skip this section.

1. Open the **Internet Information Services (IIS) Manager** and go to **Sites**.
2. Right-click the **Default Web Site** node and select **Add Application**.
3. Set the **Alias** field to **MyASPApp** and the Application pool field to **No Managed Code**. Set the **Physical path** to **C:\Publish** (where you later deploy the ASP.NET Core project).
4. With the site selected in the IIS Manager, choose **Edit Permissions**, and make sure that IUSR, IIS_IUSRS, or the user configured for the Application Pool is an authorized user with Read & Execute rights.

   If you don't see one of these users with access, go through steps to add IUSR as a user with Read & Execute rights.

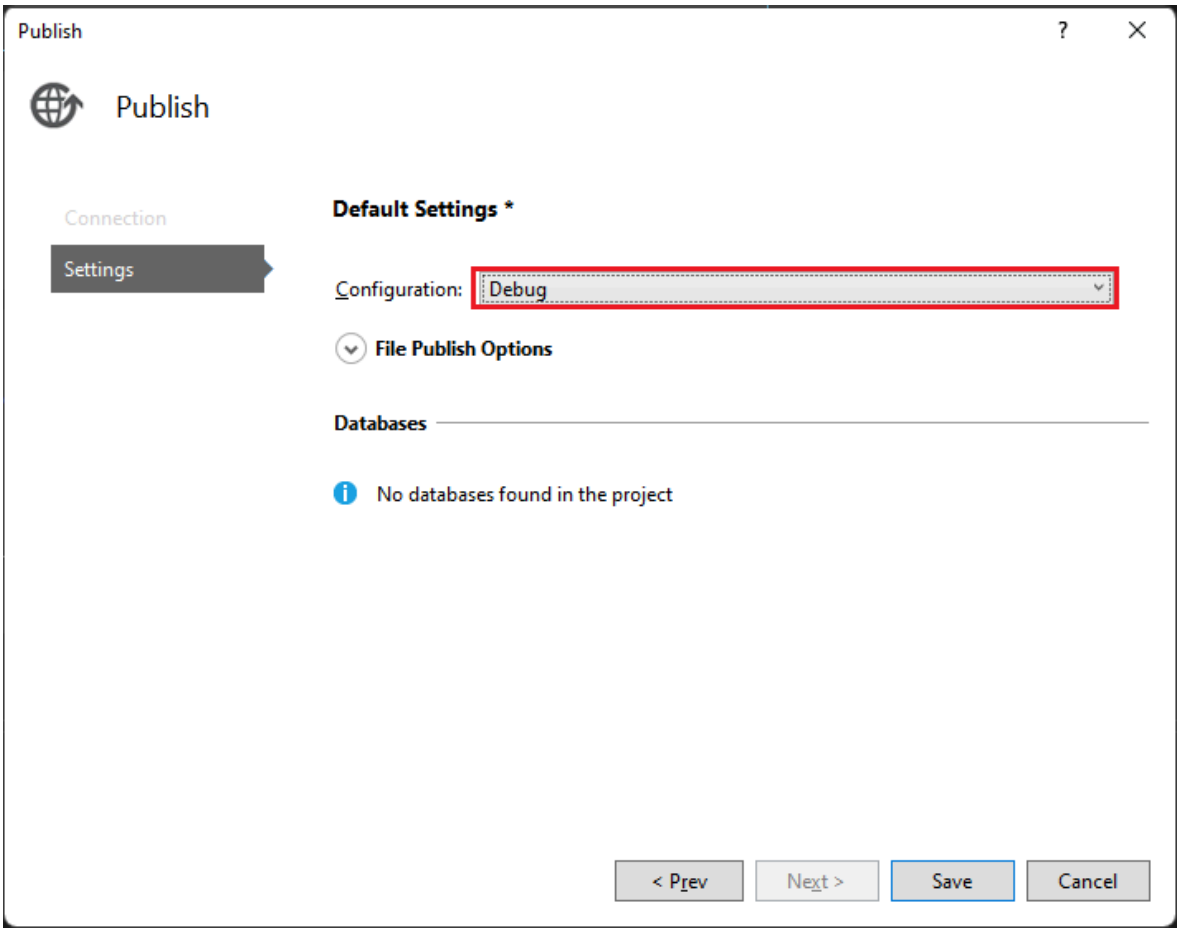


(Optional) Publish and Deploy the app by publishing to a local folder from Visual Studio

If you're not using Web Deploy, you must publish and deploy the app using the file system or other tools. You can start by creating a package using the file system, and then either deploy the package manually or use other tools like PowerShell, Robocopy, or XCopy. In this section, we assume you're manually copying the package if you aren't using Web Deploy.

1. In the **Solution Explorer**, right-click the project node and select **Publish** (for Web Forms, **Publish Web App**).

   If you have previously configured any publishing profiles, the **Publish** pane appears. Click **New profile**.



2. In the **Publish** dialog box, select **Folder**, click **Browse**, and create a new folder, **C:\Publish**.

   Click **Finish** to save the publish profile.

3. Switch to a debug configuration.

   Choose **Edit** to edit the profile, and then choose **Settings**. Choose a **Debug** configuration, and then choose **Remove additional files at destination** under the **File Publish** options.

> ⓘ **Note**
>
> If you use a Release build, you disable debugging in the *web.config* file when you publish.

4. Click **Publish**.

   The application publishes a **Debug** configuration of the project to the local folder. Progress shows in the Output window.

5. Copy the ASP.NET project directory from the Visual Studio computer to the local directory configured for the ASP.NET app (in this example, **C:\Publish**) on the Windows Server computer. In this tutorial, we assume you are copying manually, but you can use other tools like PowerShell, Xcopy, or Robocopy.

   > ⊗ **Caution**
   >
   > If you need to make changes to the code or rebuild, you must republish and repeat this step. The executable you copied to the remote machine must exactly match your local source and symbols. If you do not do this you will

receive a `cannot find or open the PDB file` warning in Visual Studio when you attempt to debug the process.

6. On the Windows Server, verify that you can run the app correctly by opening the app in your browser.

   If the app doesn't run correctly, there may be a mismatch between the version of ASP.NET installed on your server and your Visual Studio machine, or you may have an issue with your IIS or Web site configuration. Recheck earlier steps.

Download and Install the remote tools on Windows Server

Download the version of the remote tools that matches your version of Visual Studio.

On the remote device or server that you want to debug on, rather than the Visual Studio machine, download and install the correct version of the remote tools from the links in the following table.

- Download the most recent update of the remote tools for your version of Visual Studio. Earlier remote tools versions aren't compatible with later Visual Studio versions. (For example, if you are using Visual Studio 2019, download the latest update of the remote tools for Visual Studio 2019. In this scenario, do not download the remote tools for Visual Studio 2022.)
- Download the remote tools with the same architecture as the machine you're installing them on. For example, if you want to debug x86 applications on a remote computer running an x64 operating system, install the x64 remote tools. To debug x86, ARM, or x64 applications on an ARM64 operating system, install the ARM64 remote tools.

Expand table

Version	Link	Notes
Visual Studio 2022	Remote tools	Compatible with all Visual Studio 2022 versions. Download the version matching your device operating system (x86, x64, or ARM64). On older versions of Windows Server, see Unblock the file download for help downloading the remote tools.
Visual Studio 2019	Remote tools	Compatible with all Visual Studio 2019 versions. Download the version matching your device operating system (x86, x64, or ARM64). On older versions of Windows Server, see Unblock the file download for help downloading the remote tools.

Version	Link	Notes
Visual Studio 2017	Remote tools	Compatible with all Visual Studio 2017 versions. Download the version matching your device operating system (x86, x64, or ARM64). On Windows Server, see Unblock the file download for help downloading the remote tools.
Visual Studio 2015	Remote tools	Remote tools for Visual Studio 2015 are available from My.VisualStudio.com. If prompted, join the free Visual Studio Dev Essentials program, or sign in with your Visual Studio subscription ID. On Windows Server, see Unblock the file download for help downloading the remote tools.
Visual Studio 2013	Remote tools	Download page in Visual Studio 2013 documentation
Visual Studio 2012	Remote tools	Download page in Visual Studio 2012 documentation

You can run the remote debugger by copying *msvsmon.exe* to the remote computer, rather than installing the remote tools. However, the Remote Debugger Configuration Wizard (*rdbgwiz.exe*) is available only when you install the remote tools. You may need to use the wizard for configuration if you want to run the remote debugger as a service. For more information, see (Optional) Configure the remote debugger as a service.

> **Note**
>
> - To debug Windows 10 or later apps on ARM devices, use ARM64, which is available with the latest version of the remote tools.
> - To debug Windows 10 apps on Windows RT devices, use ARM, which is available only in the Visual Studio 2015 remote tools download.
> - To debug x64 apps on an ARM64 operating system, run the x64 msvsmon.exe that is installed with the ARM64 remote tools.

Set up the remote debugger on Windows Server

1. On the remote computer, find and start the **Remote Debugger** from the **Start** menu.

   If you don't have administrative permissions on the remote computer, right-click the **Remote Debugger** app and select **Run as administrator**. Otherwise, just start it

normally.

If you are planning to attach to a process which is running as an administrator, or is running under a different user account (such as IIS), right-click the **Remote Debugger** app and select **Run as administrator**. For more information, see Run the remote debugger as an administrator.

2. The first time you start the remote debugger (or before you have configured it), the **Remote Debugging Configuration** wizard appears.

   In most scenarios, choose **Next** until you get to the **Configure the Windows Firewall** page of the wizard.

3. Select at least one network type you want to use the remote tools on. If the computers are connected through a domain, you must choose the first item. If the computers are connected through a workgroup or homegroup, choose the second or third item as appropriate.

   Next, select **Finish** to start the remote debugger.

4. When configuration is complete, the **Remote Debugger** window appears.

The remote debugger is now waiting for a connection. Use the server name and port number shown to set the remote connection configuration in Visual Studio.

To stop the remote debugger, select **File** > **Exit**. You can restart it from the **Start** menu, or from the command line:

Windows Command Prompt

```
<Remote debugger installation directory>\msvsmon.exe
```

> **Note**
>
> If you need to add permissions for additional users, change the authentication mode, or port number for the remote debugger, see Configure the remote debugger.

Attach to the ASP.NET Core application from the Visual Studio computer

Starting in Visual Studio 2022 version 17.10 Preview 2, the Attach to Process dialog box has changed. If you need instructions that match the older dialog box, switch to the Visual Studio 2019 view (upper left version selector in the article).

1. On the Visual Studio computer, open the solution that you're trying to debug (**MyASPApp** if you're following all the steps in this article).

2. In Visual Studio, select **Debug** > **Attach to Process** (Ctrl + Alt + P).

   > **Tip**
   >
   > In Visual Studio 2017 and later versions, you can reattach to the same process you previously attached to by using **Debug** > **Reattach to Process...** (Shift +

Alt + P).

3. Set the **Connection Type** to **Remote (Windows)**.

   The **Connection Target** option appears.

   Set the **Connection Target** to **<remote computer name>** and press **Enter**.

   Verify that Visual Studio adds the required port to the computer name, which appears in the format: **<remote computer name>:port**

   On Visual Studio 2022, you should see **<remote computer name>:4026**

   The port is required. If you don't see the port number, add it manually.

4. Select **Refresh**.

   You should see some processes appear in the **Available Processes** window.

   If you don't see any processes, try using the IP address instead of the remote computer name (the port is required). You can use `ipconfig` in a command line to get the IPv4 address.

   If you want to use the **Find** button, you might need to open outbound UDP port 3702 on the server.

5. Check **Show processes from all users**.

6. Type the first letter of your process name to quickly find your app.

   - If you're using the in-process hosting model on IIS, select the correct **w3wp.exe** process. Starting in .NET Core 3, this process is the default.
   - Otherwise, select the **dotnet.exe** process. (This is the out-of-process hosting model.)

   If you have multiple processes showing *w3wp.exe* or *dotnet.exe*, check the **User Name** column. In some scenarios, the **User Name** column shows your app pool name, such as **IIS APPPOOL\DefaultAppPool**. If you see the App Pool, but it's not unique, create a new named App Pool for the app instance you want to debug, and then you can find it easily in the **User Name** column.

7. Select **Attach**.

8. Open the remote computer's website. In a browser, go to **http://<remote computer name>**.

   You should see the ASP.NET web page.

9. In the running ASP.NET application, select the link to the **Privacy** page.

   The breakpoint should be hit in Visual Studio.

   If you're unable to attach or hit the breakpoint, see Troubleshoot remote debugging.

Troubleshooting IIS deployment

- If you can't connect to the host using the host name, try the IP address instead.
- Make sure the required ports are open on the remote server.
- For ASP.NET Core, you need to make sure that the Application pool field for the **DefaultAppPool** is set to **No Managed Code**.
- Verify that the version of ASP.NET used in your app is the same as the version you installed on the server. For your app, you can view and set the version in the **Properties** page. To set the app to a different version, that version must be installed.
- If the app tried to open, but you see a certificate warning, choose to trust the site. If you already closed the warning, you can edit the publishing profile, a *.pubxml

file, in your project and add the following element (for test only):
`<AllowUntrustedCertificate>true</AllowUntrustedCertificate>`

- After it's deployed, start the app in IIS to test that it deployed correctly.
- Check the Output window in Visual Studio for status information, and check your error messages.

Open required ports on Windows Server

In most setups, required ports are opened by the installation of ASP.NET and the remote debugger. However, if you're troubleshooting deployment issues and the app is hosted behind a firewall, you might need to verify that the correct ports are open.

On an Azure VM, you must open ports through:

- The Network security group.
- The firewall on Windows Server

Required ports:

- 80 - Required for IIS
- 4026 - Required for remote debugging from Visual Studio 2022 (see Remote Debugger Port Assignments for more information).
- UDP 3702 - (Optional) The Discovery port enables you to the **Find** button when attaching to the remote debugger in Visual Studio. This must be an outbound port (outbound rule).

In addition, these ports should already be opened by the ASP.NET Core installation:

- 8172 - (Optional) Required for Web Deploy to deploy the app from Visual Studio

Debug exceptions in .NET applications using Snapshot Debugger

Article • 09/11/2024

When enabled, Snapshot Debugger automatically collects a debug snapshot of the source code and variables when an exception occurs in your live .NET application. The Snapshot Debugger in Application Insights:

- Monitors system-generated logs from your web app.
- Collects snapshots on your top-throwing exceptions.
- Provides information you need to diagnose issues in production.

Learn more about the Snapshot Debugger and Snapshot Uploader processes.

Supported applications and environments

This section lists the applications and environments that are supported.

Applications

Snapshot collection is available for:

- .NET Framework 4.6.2 and newer versions.
- .NET 6.0 or later on Windows.

Environments

The following environments are supported:

- Azure App Service
- Azure Functions
- Azure Cloud Services running OS family 4 or later
- Azure Service Fabric running on Windows Server 2012 R2 or later
- Azure Virtual Machines and Azure Virtual Machine Scale Sets running Windows Server 2012 R2 or later
- On-premises virtual or physical machines running Windows Server 2012 R2 or later or Windows 8.1 or later

> **Note**

Client applications (for example, WPF, Windows Forms, or UWP) aren't supported.

Prerequisites for using Snapshot Debugger

Packages and configurations

- Include the Snapshot Collector NuGet package in your application.
- Configure collection parameters in ApplicationInsights.config.

Permissions

- Verify you're added to the Application Insights Snapshot Debugger role for the target **Application Insights Snapshot**.

How Snapshot Debugger works

The Snapshot Debugger is implemented as an Application Insights telemetry processor. When your application runs, the Snapshot Debugger telemetry processor is added to your application's system-generated logs pipeline.

> **Important**
>
> Snapshots might contain personal data or other sensitive information in variable and parameter values. Snapshot data is stored in the same region as your Application Insights resource.

Snapshot Debugger process

The Snapshot Debugger process starts and ends with the `TrackException` method. A process snapshot is a suspended clone of the running process, so that your users experience little to no interruption. In a typical scenario:

1. Your application throws the TrackException.
2. The Snapshot Debugger monitors exceptions as they're thrown by subscribing to the AppDomain.CurrentDomain.FirstChanceException event.
3. A counter is incremented for the problem ID.

- When the counter reaches the `ThresholdForSnapshotting` value, the problem ID is added to a collection plan.

> ⓘ **Note**
>
> The `ThresholdForSnapshotting` default minimum value is 1. With this value, your app has to trigger the same exception *twice* before a snapshot is created.

4. The exception event's problem ID is computed and compared against the problem IDs in the collection plan.

5. If there's a match between problem IDs, a **snapshot** of the running process is created.

   - The snapshot is assigned a unique identifier and the exception is stamped with that identifier.

   > ⓘ **Note**
   >
   > The snapshot creation rate is limited by the `SnapshotsPerTenMinutesLimit` setting. By default, the limit is one snapshot every 10 minutes.

6. After the `FirstChanceException` handler returns, the thrown exception is processed as normal.

7. The exception reaches the `TrackException` method again and is reported to Application Insights, along with the snapshot identifier.

> ⓘ **Note**
>
> Set `IsEnabledInDeveloperMode` to `true` if you want to generate snapshots while you debug in Visual Studio.

Snapshot Uploader process

While the Snapshot Debugger process continues to run and serve traffic to users with little interruption, the snapshot is handed off to the Snapshot Uploader process. In a typical scenario, the Snapshot Uploader:

1. Creates a minidump.

2. Uploads the minidump to Application Insights, along with any relevant symbol (*.pdb*) files.

> ⓘ **Note**
>
> No more than 50 snapshots per day can be uploaded.

If you enabled the Snapshot Debugger but you aren't seeing snapshots, see the Troubleshooting guide.

Upgrading Snapshot Debugger

Snapshot Debugger auto-upgrades via the built-in, preinstalled Application Insights site extension.

Manually adding an Application Insights site extension to keep Snapshot Debugger up-to-date is deprecated.

Overhead

The Snapshot Debugger is designed for use in production environments. The default settings include rate limits to minimize the impact on your applications.

However, you may experience small CPU, memory, and I/O overhead associated with the Snapshot Debugger, such as:

- When an exception is thrown in your application
- If the exception handler decides to create a snapshot
- When `TrackException` is called

There is **no additional cost** for storing data captured by Snapshot Debugger.

See example scenarios in which you may experience Snapshot Debugger overhead.

Limitations

This section discusses limitations for the Snapshot Debugger.

- **Data retention**

  Debug snapshots are stored for 15 days. The default data retention policy is set on a per-application basis. If you need to increase this value, you can request an

increase by opening a support case in the Azure portal. For each Application Insights instance, a maximum number of 50 snapshots are allowed per day.

- **Publish symbols**

  The Snapshot Debugger requires symbol files on the production server to:
  - Decode variables
  - Provide a debugging experience in Visual Studio

  By default, Visual Studio 2017 versions 15.2+ publishes symbols for release builds when it publishes to App Service.

  In prior versions, you must add the following line to your publish profile `.pubxml` file so that symbols are published in release mode:

  ```
  XML

  <ExcludeGeneratedDebugSymbol>False</ExcludeGeneratedDebugSymbol>
  ```

  For Azure Compute and other types, make sure that the symbol files are either:
  - In the same folder of the main application `.dll` (typically, `wwwroot/bin`), or
  - Available on the current path.

  For more information on the different symbol options that are available, see the Visual Studio documentation. For best results, we recommend that you use *Full*, *Portable*, or *Embedded*.

- **Optimized builds**

  In some cases, local variables can't be viewed in release builds because of optimizations applied by the JIT compiler.

  However, in App Service, the Snapshot Debugger can deoptimize throwing methods that are part of its collection plan.

  > **Tip**
  >
  > Install the Application Insights Site extension in your instance of App Service to get deoptimization support.

Next steps

Enable the Application Insights Snapshot Debugger for your application:

- Azure App Service
- Azure Functions
- Azure Cloud Services
- Azure Service Fabric
- Azure Virtual Machines and Virtual Machine Scale Sets
- On-premises virtual or physical machines

Debug live ASP.NET Azure apps using the Snapshot Debugger

Article • 10/20/2022

The Snapshot Debugger takes a snapshot of your in-production apps when code that you're interested in executes. To instruct the debugger to take a snapshot, you set snappoints and logpoints in your code. The debugger lets you see exactly what went wrong, without impacting traffic of your production application. The Snapshot Debugger can help you dramatically reduce the time it takes to resolve issues that occur in production environments.

Snappoints and logpoints are similar to breakpoints, but unlike breakpoints, snappoints don't halt the application when hit. Typically, capturing a snapshot at a snappoint takes 10-20 milliseconds.

In this tutorial, you will:

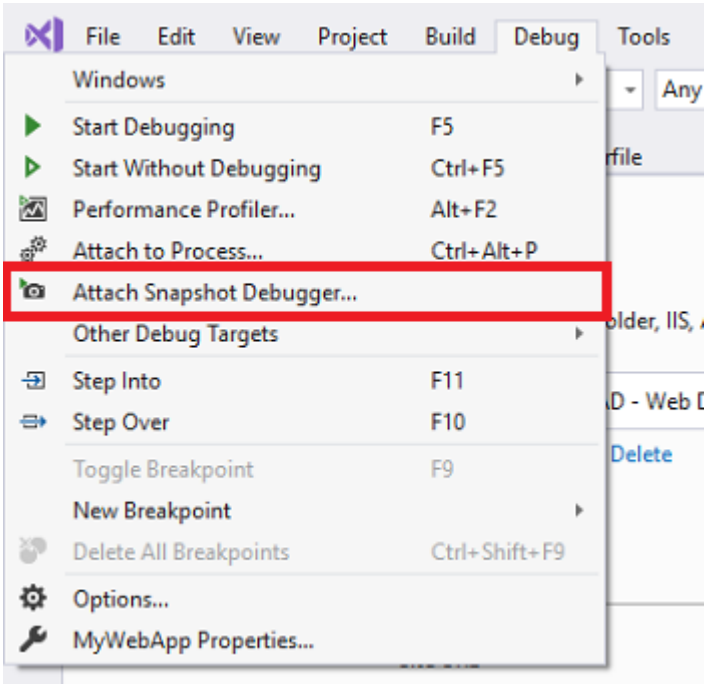
- ✓ Start the Snapshot Debugger
- ✓ Set a snappoint and view a snapshot
- ✓ Set a logpoint

Prerequisites

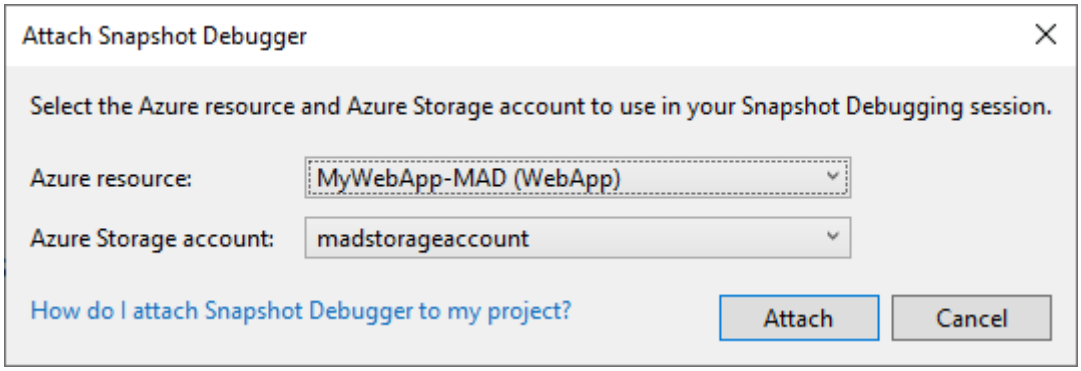
- Snapshot Debugger is only available starting in Visual Studio 2017 Enterprise version 15.5 or higher with the **Azure development workload**. (Under the **Individual components** tab, you find it under **Debugging and testing** > **Snapshot debugger**.)

  If it's not already installed, install Visual Studio 2019. If you're updating from a previous Visual Studio installation, run the Visual Studio Installer and check the Snapshot Debugger component in the **ASP.NET and web development workload**.

- Basic or higher Azure App Service plan.



- Snapshot collection is available for the following web apps running in Azure App Service:
  - ASP.NET applications running on .NET Framework 4.6.1 or later.
  - ASP.NET Core applications running on .NET Core 2.0 or later on Windows.



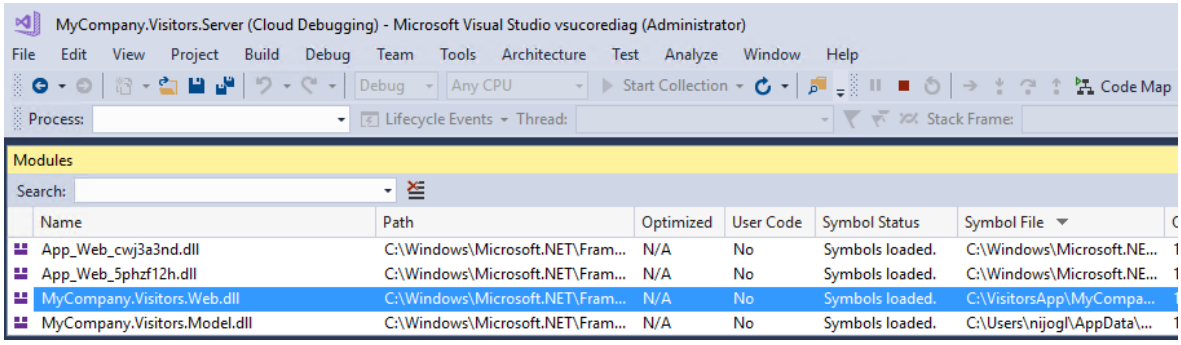
Open your project and start the Snapshot Debugger

1. Open the project you would like to snapshot debug.

   > **ⓘ Important**
   >
   > To snapshot debug, you need to open the *same version of source code* that is published to your Azure App Service.

2. Choose **Debug** > **Attach Snapshot Debugger...**. Select the Azure App Service your project is deployed to and an Azure storage account, and then click **Attach**. Snapshot Debugger also supports Azure Kubernetes Service and Azure Virtual Machines (VM) & Virtual Machine Scale Sets.

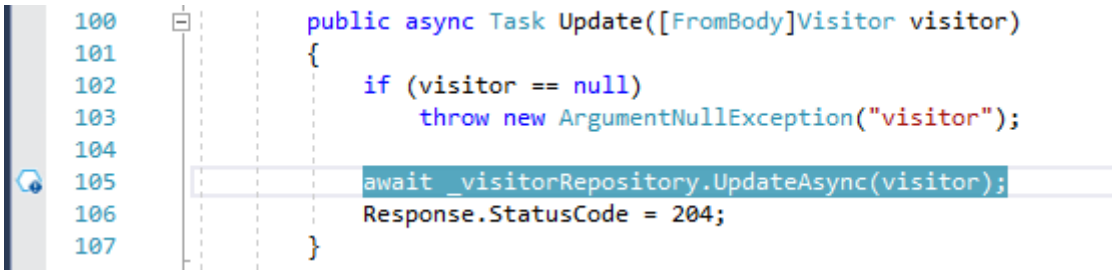
> **ⓘ Important**



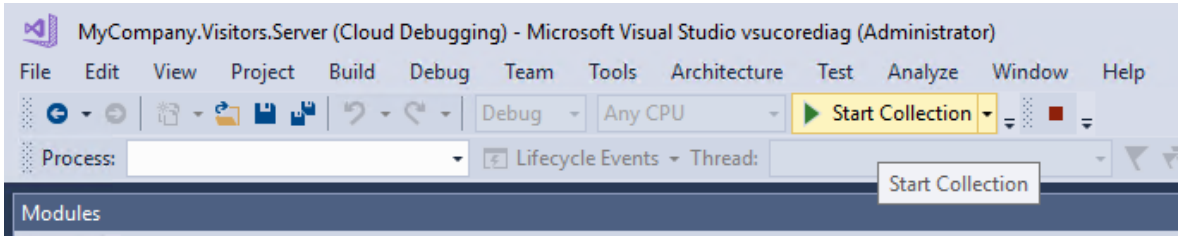
The first time you select **Attach Snapshot Debugger**, you're prompted to install the Snapshot Debugger site extension on your Azure App Service. This installation requires a restart of your Azure App Service.

> **Note**
>
> (Visual Studio 2019 version 16.2 and above) Snapshot Debugger has enabled Azure cloud support. Make sure that both the Azure resource and Azure Storage account you select are from the same cloud. Please contact your Azure administrator if you have questions about your enterprise's Azure compliance configurations.

Visual Studio is now in snapshot debugging mode.



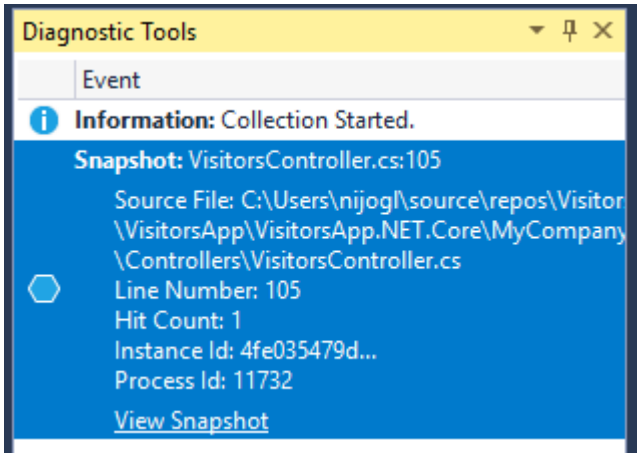
The **Modules** window shows you when all the modules have loaded for the Azure App Service (choose **Debug** > **Windows** > **Modules** to open this window).



Set a snappoint

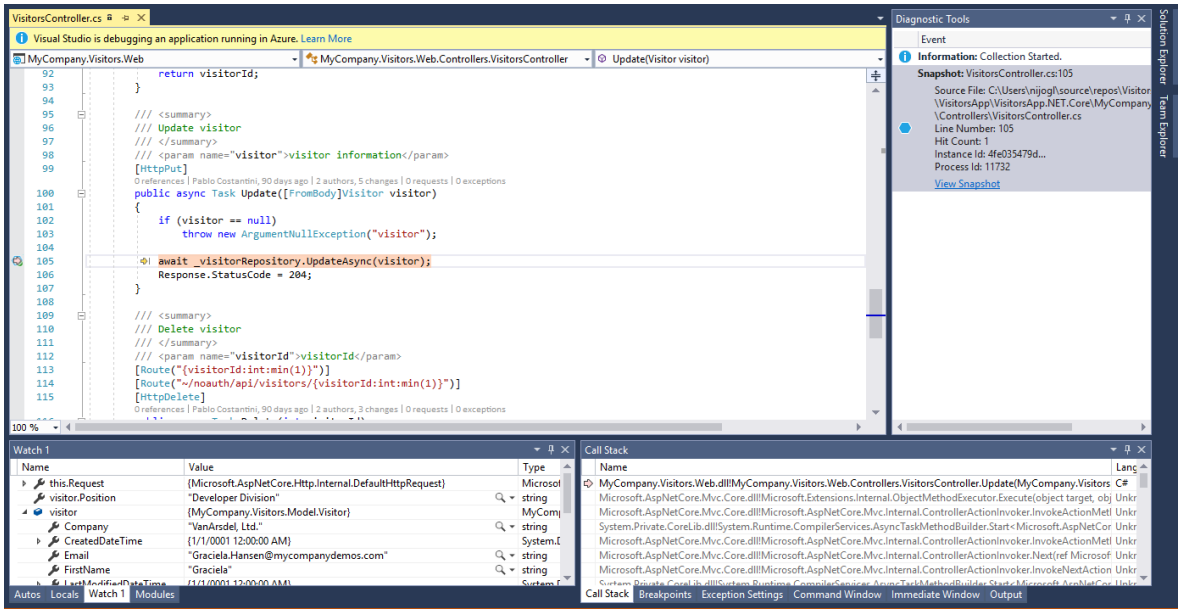
1. In the code editor, click the left gutter next to a line of code you're interested in to set a snappoint. Make sure it's code that you know will execute.

2. Click **Start Collection** to turn on the snappoint.



> **Tip**
>
> You can't step when viewing a snapshot, but you can place multiple snappoints in your code to follow execution at different lines of code. If you have multiple snappoints in your code, the Snapshot Debugger makes sure that the corresponding snapshots are from the same end-user session. The Snapshot Debugger does this even if there are many users hitting your app.

Take a snapshot



Once a snappoint is set, you can either manually generate a snapshot by going to the browser view of your web site and running the line of code marked or wait for your users to generate one from their usage of the site.

Inspect snapshot data

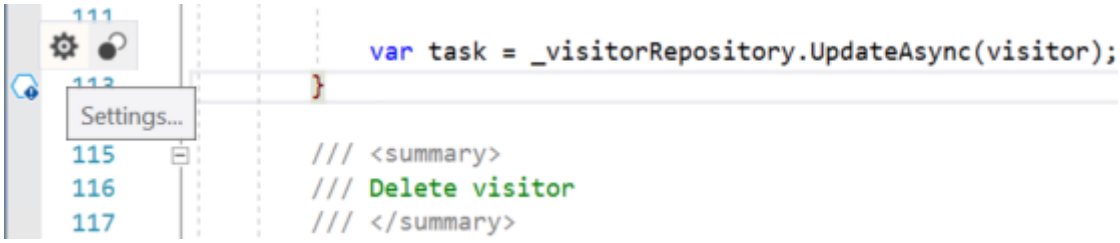
1. When the snappoint is hit, a snapshot appears in the Diagnostic Tools window. To open this window, choose **Debug** > **Windows** > **Show Diagnostic Tools**.

2. Double-click the snappoint to open the snapshot in the code editor.

From this view, you can hover over variables to view DataTips, use the **Locals**, **Watches**, and **Call Stack** windows, and also evaluate expressions.

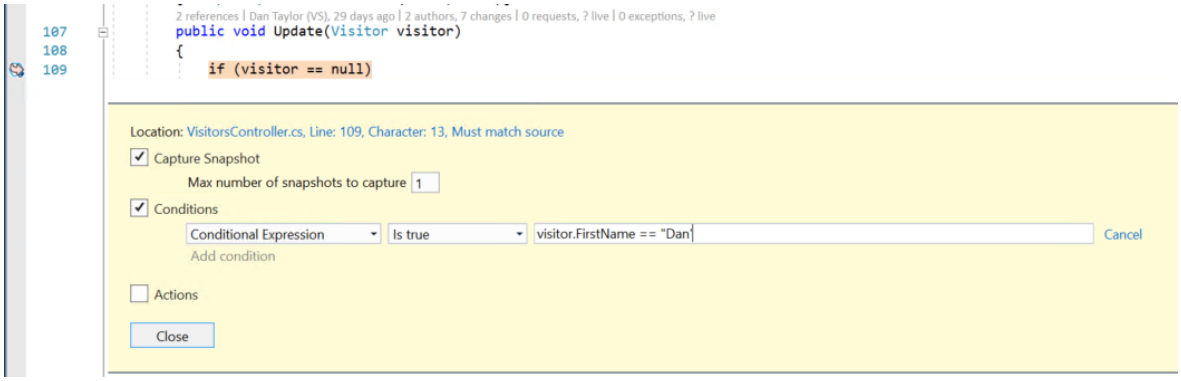
The website itself is still live and end users aren't affected. Only one snapshot is captured per snappoint by default: after a snapshot is captured the snappoint turns off. If you want to capture another snapshot at the snappoint, you can turn the snappoint back on by clicking **Update Collection**.

You can also add more snappoints to your app and turn them on with the **Update Collection** button.



Need help? See the Troubleshooting and known issues and FAQ for snapshot debugging pages.

Set a conditional snappoint



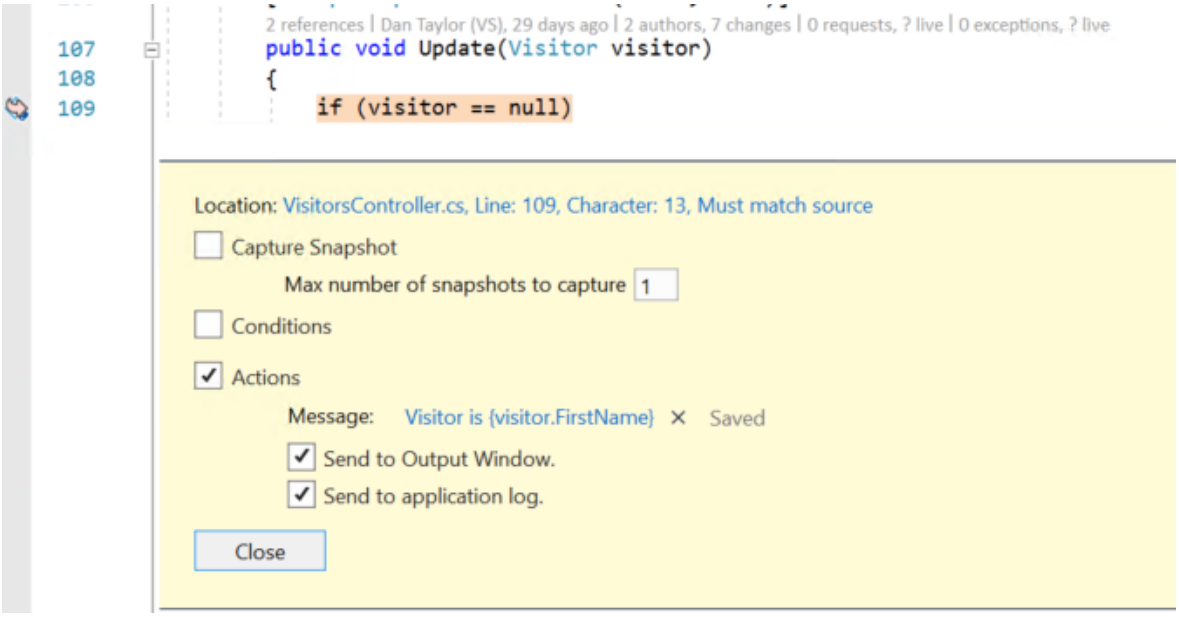
If it's difficult to recreate a particular state in your app, consider using a conditional snappoint. Conditional snappoints help you control when to take a snapshot such as when a variable contains a particular value that you want to inspect. You can set conditions using expressions, filters, or hit counts.

To create a conditional snappoint

1. Right-click a snappoint icon (the hollow sphere) and choose **Settings**.

2. In the snappoint settings window, type an expression.

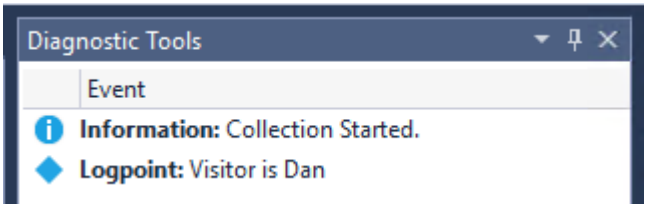
In the preceding illustration, the snapshot is only taken for the snappoint when `visitor.FirstName == "Dan"`.



Set a logpoint

In addition to taking a snapshot when a snappoint is hit, you can also configure a snappoint to log a message (that is, create a logpoint). You can set logpoints without having to redeploy your app. Logpoints are executed virtually and cause no impact or side effects to your running application.

To create a logpoint



1. Right-click a snappoint icon (the blue hexagon) and choose **Settings**.

2. In the snappoint settings window, select **Actions**.

3. In the **Message** field, you can enter the new log message you want to log. You can also evaluate variables in your log message by placing them inside curly braces.

   If you choose **Send to Output Window**, when the logpoint is hit, the message appears in the Diagnostic Tools window.

   If you choose **Send to application log**, when the logpoint is hit, the message appears anywhere that you can see messages from `System.Diagnostics.Trace` (or `ILogger` in .NET Core), such as App Insights.

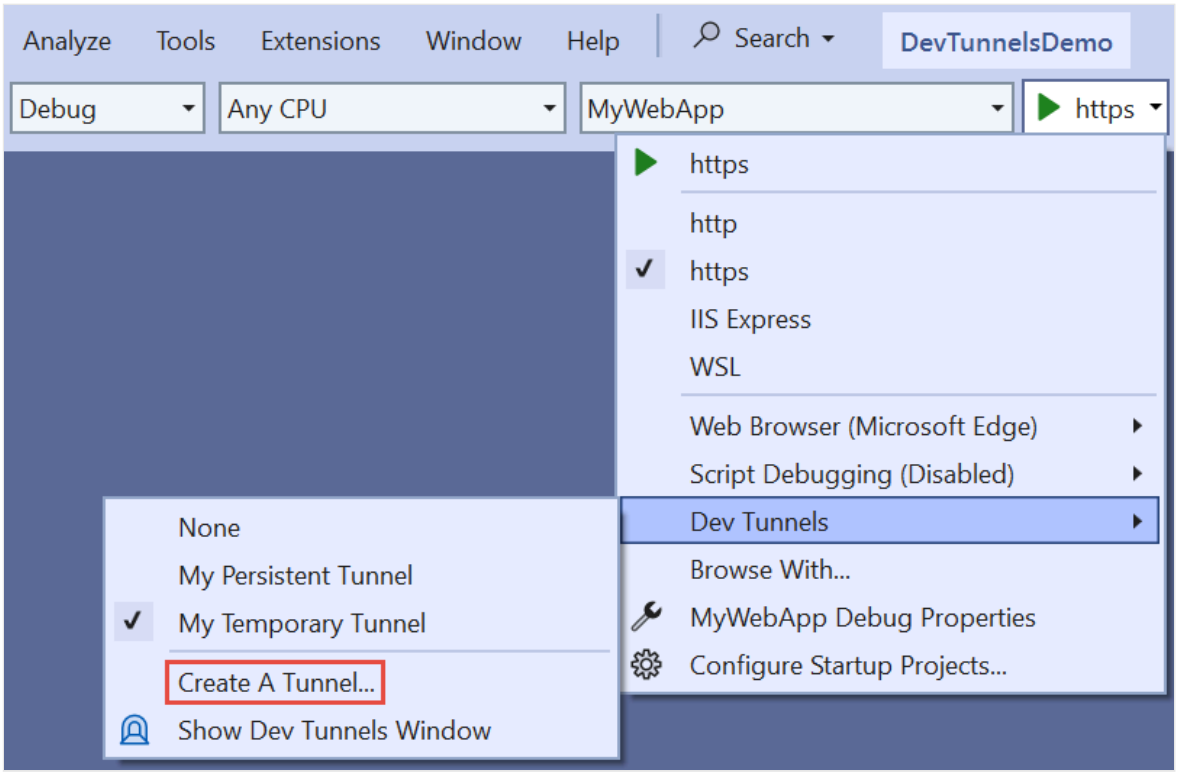
Use dev tunnels in Visual Studio to debug your web APIs

Article • 11/14/2023

To quickly debug and test your web APIs within Microsoft Power Automate or Power Apps, use *dev tunnels* in Visual Studio. Dev tunnels enables ad-hoc connections between machines that can't directly connect to each other. Once you enable this feature, you'll see that debugging (F5) automatically creates a dev tunnel URL that you can use to connect to Power Apps or Power Automate.



Prerequisites

- Download Visual Studio 2022 Preview version 17.6 or later with the **ASP.NET and web development workload** installed. You need to sign in to Visual Studio to create and use dev tunnels. The feature isn't available in Visual Studio for Mac.
- One of the following Power Platform environments:
  - Power Automate
  - Power Apps

> **Note**
>
> If you need help getting started with Microsoft Power Platform, go to Create a developer environment.

Step 1: Configure your ASP.NET Core project in Visual Studio

1. In the debug dropdown menu, select **Dev Tunnels** > **Create A Tunnel**.

2. The tunnel creation dialog opens and you can configure dev tunnels. Make sure to set authentication type to **Public**.

   To learn more, go to How to use dev tunnels in Visual Studio 2022 with ASP.NET Core apps.

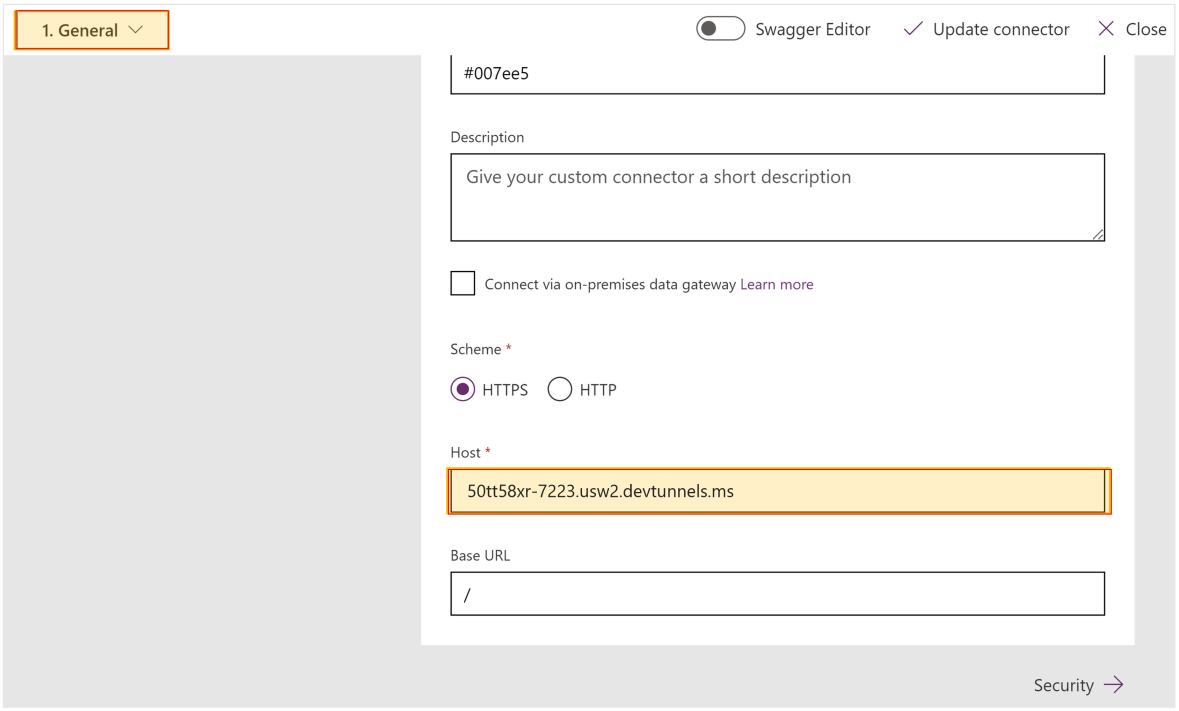
3. Select **OK**. Visual Studio displays confirmation of tunnel creation. The tunnel is now enabled and appears in the debug dropdown **Dev Tunnels** flyout.

4. Select **F5** (**Debug** > **Start Debugging**), or the **Start Debugging** button to see the dev tunnel URL.

URL with and without dev tunnels

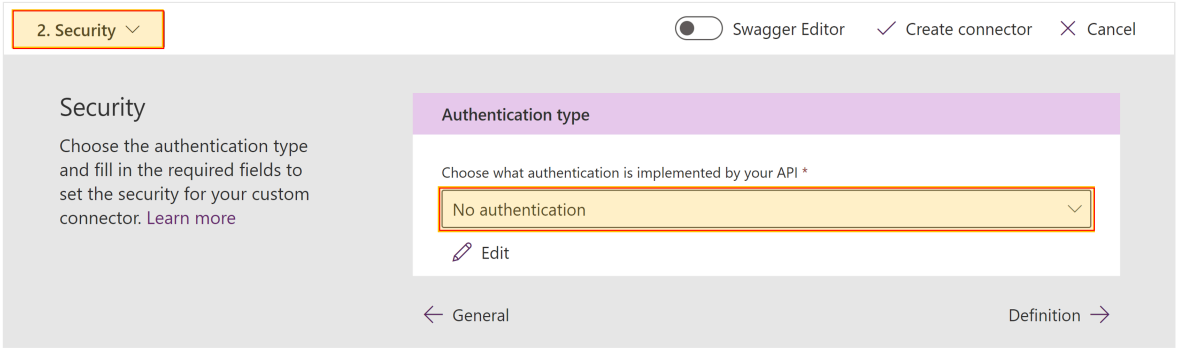
To learn more, go to Use a tunnel.

- **Before debugging:** `https://localhost:7223/swagger/index.html`
- **After debugging:** `https://50tt58xr-7223.usw2.devtunnels.ms/swagger/indexf.html`



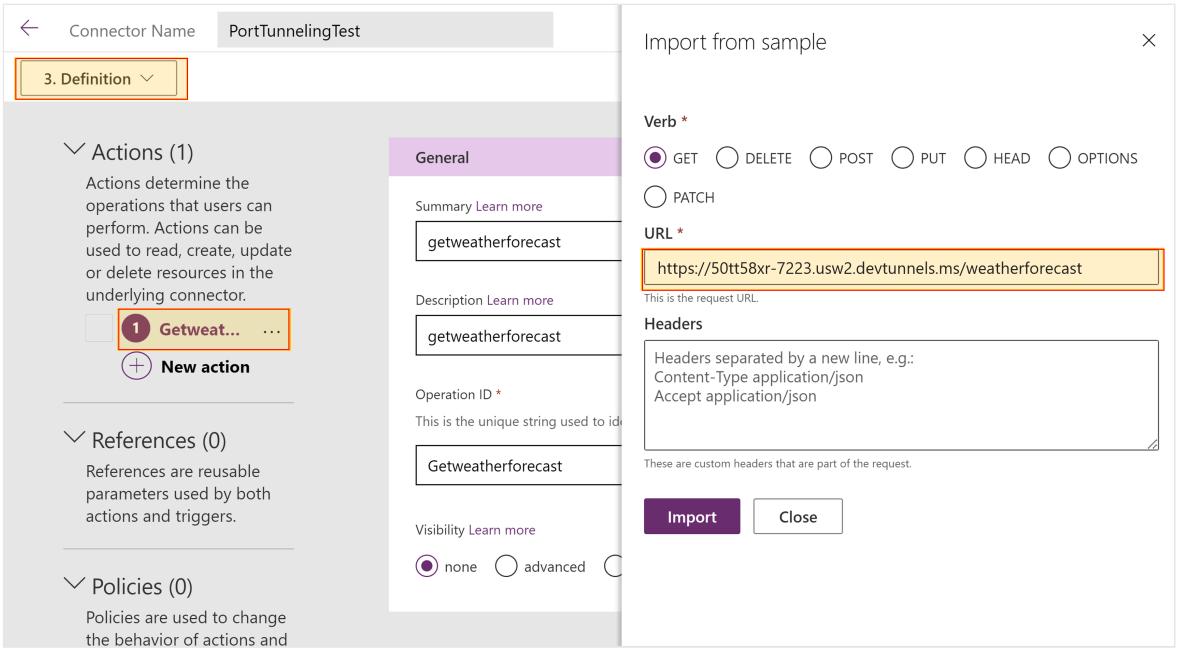
Step 2: Create a custom connector for your web API using the dev tunnel URL

A custom connector is a wrapper around a REST API and allows Power Automate or Power Apps solutions to communicate with your web API. There are many ways to



create a custom connector. The following sections explain how to use the dev tunnel URL and create a custom connector from scratch, or with API Management.

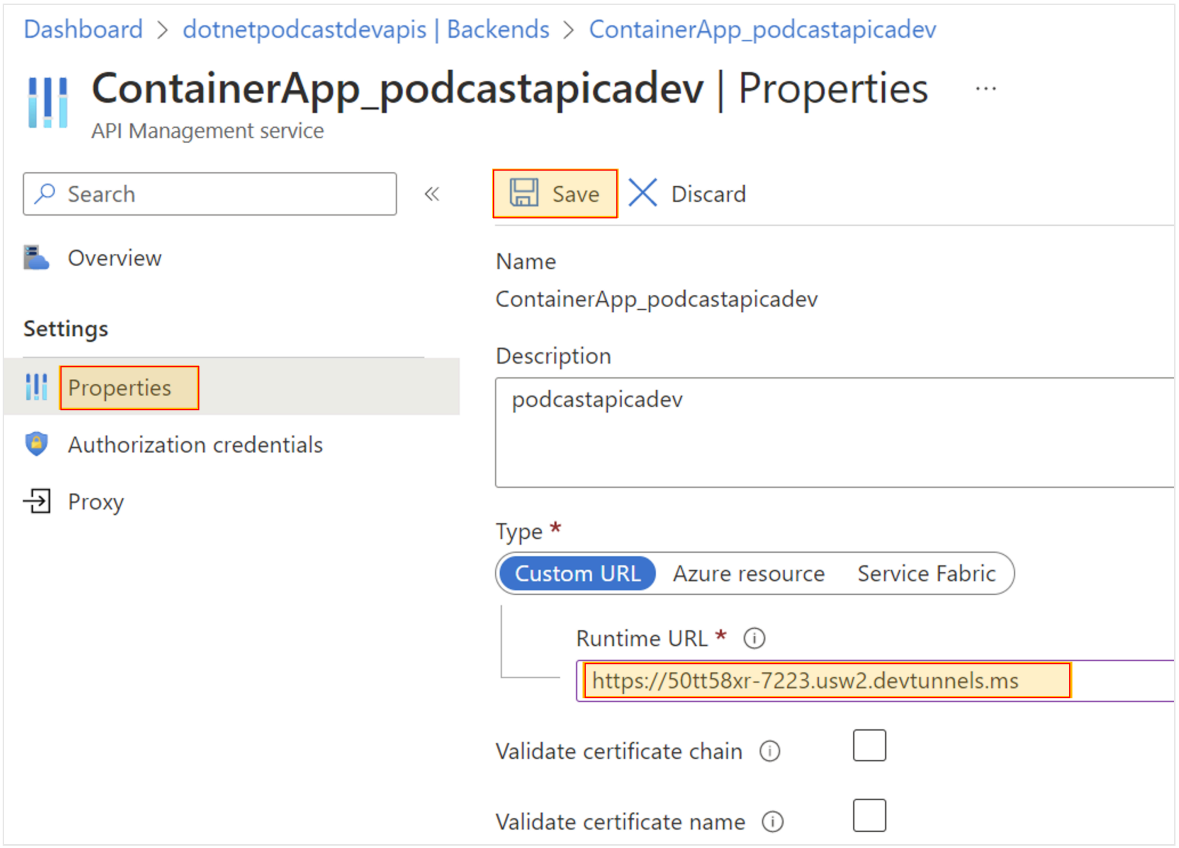
Create a custom connector from scratch



1. On the **General** tab, post the dev tunnel URL into the **Host** field.

2. On the **Security** tab, select **No authentication** from the dropdown menu.

3. On the **Definition** tab, define your HTTP methods by adding actions. For the URL action, use the dev tunnel base URL + /actionName. For an example, go to How to use dev tunnels.

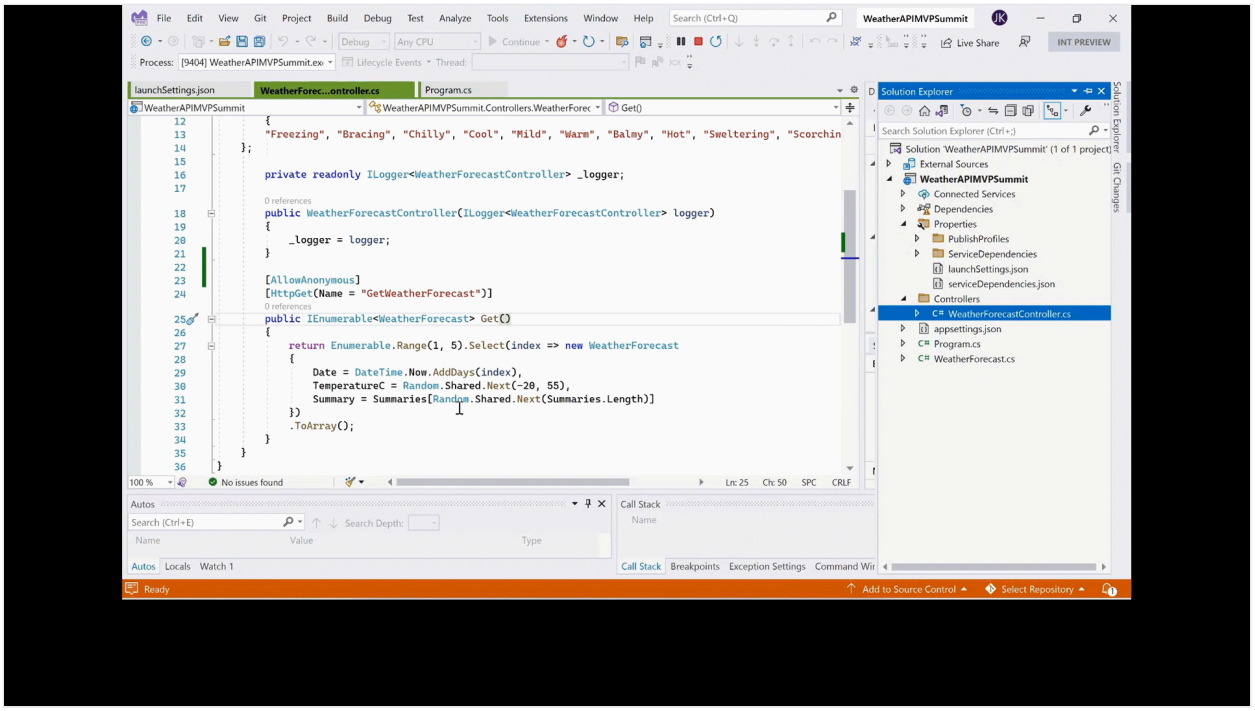


4. You can now test your custom connector. To do this, select the **Test** tab. After adding your connection, you can test your web API.

   For instructions, go to Create a custom connector from scratch.

Create a custom connector with API Management

1. Go to your Azure API Management instance in the Azure portal.
2. Modify the runtime URL of your API in the menu under **Backends** and select your API instance.
3. On the **Properties** tab, replace the **Runtime URL** with the dev tunnel URL and select **Save**.



4. On the **Power Platform** tab, you can now create a custom connector. For instructions, go to Export APIs from Azure API Management to the Power Platform.

Step 3: Add the custom connector to Power Apps or Power Automate

To debug your web API, use a custom connector from a Power Apps app or a Power Automate flow.

When your custom connector is integrated in your Power Platform solution, you can set a *breakpoint*, and debug your Power Apps app or Power Automate flow.

> **Note**
>
> Breakpoints are the most basic and essential feature of reliable debugging. A breakpoint indicates where Visual Studio should suspend your running code so you review the values of variables, behavior of memory, or if a branch of code is getting run.

Provide feedback

We greatly appreciate feedback on issues with our connector platform, or new feature ideas. To provide feedback, go to Submit issues or get help with connectors and select your feedback type.

Troubleshoot and debug ASP.NET Core projects

Article • 09/17/2024

By Rick Anderson

The following links provide troubleshooting guidance:

- Troubleshoot ASP.NET Core on Azure App Service and IIS
- Common error troubleshooting for Azure App Service and IIS with ASP.NET Core
- NDC Conference (London, 2018): Diagnosing issues in ASP.NET Core Applications
- ASP.NET Blog: Troubleshooting ASP.NET Core Performance Problems

.NET Core SDK warnings

Both the 32-bit and 64-bit versions of the .NET Core SDK are installed

In the **New Project** dialog for ASP.NET Core, you may see the following warning:

> Both 32-bit and 64-bit versions of the .NET Core SDK are installed. Only templates from the 64-bit versions installed at 'C:\Program Files\dotnet\sdk\' are displayed.

This warning appears when both 32-bit (x86) and 64-bit (x64) versions of the .NET Core SDK are installed. Common reasons both versions may be installed include:

- You originally downloaded the .NET Core SDK installer using a 32-bit machine but then copied it across and installed it on a 64-bit machine.
- The 32-bit .NET Core SDK was installed by another application.
- The wrong version was downloaded and installed.

Uninstall the 32-bit .NET Core SDK to prevent this warning. Uninstall from **Control Panel** > **Programs and Features** > **Uninstall or change a program**. If you understand why the warning occurs and its implications, you can ignore the warning.

The .NET Core SDK is installed in multiple locations

In the **New Project** dialog for ASP.NET Core, you may see the following warning:

> The .NET Core SDK is installed in multiple locations. Only templates from the SDKs installed at 'C:\Program Files\dotnet\sdk\' are displayed.

You see this message when you have at least one installation of the .NET Core SDK in a directory outside of *C:\Program Files\dotnet\sdk*. Usually this happens when the .NET Core SDK has been deployed on a machine using copy/paste instead of the MSI installer.

Uninstall all 32-bit .NET Core SDKs and runtimes to prevent this warning. Uninstall from **Control Panel** > **Programs and Features** > **Uninstall or change a program**. If you understand why the warning occurs and its implications, you can ignore the warning.

No .NET Core SDKs were detected

- In the Visual Studio **New Project** dialog for ASP.NET Core, you may see the following warning:

  > No .NET Core SDKs were detected, ensure they are included in the environment variable `PATH`.

- When executing a `dotnet` command, the warning appears as:

  > It was not possible to find any installed dotnet SDKs.

These warnings appear when the environment variable `PATH` doesn't point to any .NET Core SDKs on the machine. To resolve this problem:

- Install the .NET Core SDK. Obtain the latest installer from .NET Downloads.
- Verify that the `PATH` environment variable points to the location where the SDK is installed (`C:\Program Files\dotnet\` for 64-bit/x64 or `C:\Program Files (x86)\dotnet\` for 32-bit/x86). The SDK installer normally sets the `PATH`. Always install the same bitness SDKs and runtimes on the same machine.

Missing SDK after installing the .NET Core Hosting Bundle

Installing the .NET Core Hosting Bundle modifies the `PATH` when it installs the .NET Core runtime to point to the 32-bit (x86) version of .NET Core (`C:\Program Files (x86)\dotnet\`). This can result in missing SDKs when the 32-bit (x86) .NET Core `dotnet` command is used (No .NET Core SDKs were detected). To resolve this problem, move

`C:\Program Files\dotnet\` to a position before `C:\Program Files (x86)\dotnet\` on the `PATH`.

Obtain data from an app

If an app is capable of responding to requests, you can obtain the following data from the app using middleware:

- Request: Method, scheme, host, pathbase, path, query string, headers
- Connection: Remote IP address, remote port, local IP address, local port, client certificate
- Identity: Name, display name
- Configuration settings
- Environment variables

Place the following middleware code at the beginning of the `Startup.Configure` method's request processing pipeline. The environment is checked before the middleware is run to ensure that the code is only executed in the Development environment.

To obtain the environment, use either of the following approaches:

- Inject the `IHostingEnvironment` into the `Startup.Configure` method and check the environment with the local variable. The following sample code demonstrates this approach.

- Assign the environment to a property in the `Startup` class. Check the environment using the property (for example, `if (Environment.IsDevelopment())`).

C#

```
public void Configure(IApplicationBuilder app, IHostingEnvironment env,
    IConfiguration config)
{
    if (env.IsDevelopment())
    {
        app.Run(async (context) =>
        {
            var sb = new StringBuilder();
            var nl = System.Environment.NewLine;
            var rule = string.Concat(nl, new string('-', 40), nl);
            var authSchemeProvider = app.ApplicationServices
                .GetRequiredService<IAuthenticationSchemeProvider>();

            sb.Append($"Request{rule}");
            sb.Append($"{DateTimeOffset.Now}{nl}");
```

```
            sb.Append($"{context.Request.Method} {context.Request.Path}
{nl}");
            sb.Append($"Scheme: {context.Request.Scheme}{nl}");
            sb.Append($"Host: {context.Request.Headers["Host"]}{nl}");
            sb.Append($"PathBase: {context.Request.PathBase.Value}{nl}");
            sb.Append($"Path: {context.Request.Path.Value}{nl}");
            sb.Append($"Query: {context.Request.QueryString.Value}{nl}
{nl}");

            sb.Append($"Connection{rule}");
            sb.Append($"RemoteIp: {context.Connection.RemoteIpAddress}
{nl}");
            sb.Append($"RemotePort: {context.Connection.RemotePort}{nl}");
            sb.Append($"LocalIp: {context.Connection.LocalIpAddress}{nl}");
            sb.Append($"LocalPort: {context.Connection.LocalPort}{nl}");
            sb.Append($"ClientCert: {context.Connection.ClientCertificate}
{nl}{nl}");

            sb.Append($"Identity{rule}");
            sb.Append($"User: {context.User.Identity.Name}{nl}");
            var scheme = await authSchemeProvider
                .GetSchemeAsync(IISDefaults.AuthenticationScheme);
            sb.Append($"DisplayName: {scheme?.DisplayName}{nl}{nl}");

            sb.Append($"Headers{rule}");
            foreach (var header in context.Request.Headers)
            {
                sb.Append($"{header.Key}: {header.Value}{nl}");
            }
            sb.Append(nl);

            sb.Append($"WebSockets{rule}");
            if (context.Features.Get<IHttpUpgradeFeature>() != null)
            {
                sb.Append($"Status: Enabled{nl}{nl}");
            }
            else
            {
                sb.Append($"Status: Disabled{nl}{nl}");
            }

            sb.Append($"Configuration{rule}");
            foreach (var pair in config.AsEnumerable())
            {
                sb.Append($"{pair.Path}: {pair.Value}{nl}");
            }
            sb.Append(nl);

            sb.Append($"Environment Variables{rule}");
            var vars = System.Environment.GetEnvironmentVariables();
            foreach (var key in vars.Keys.Cast<string>().OrderBy(key => key,
                StringComparer.OrdinalIgnoreCase))
            {
                var value = vars[key];
                sb.Append($"{key}: {value}{nl}");
```

```
            }

            context.Response.ContentType = "text/plain";
            await context.Response.WriteAsync(sb.ToString());
        });
    }
}
```

Debug ASP.NET Core apps

The following links provide information on debugging ASP.NET Core apps.

- Debugging ASP Core on Linux
- Debugging .NET Core on Unix over SSH
- Quickstart: Debug ASP.NET with the Visual Studio debugger
- See this GitHub issue for more debugging information.

Troubleshoot ASP.NET Core on Azure App Service and IIS

Article • 09/27/2024

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, the ASP.NET Core project default server is Kestrel. Visual studio can be configured to use IIS Express. A *502.5 - Process Failure* or a *500.30 - Start Failure* that occurs when debugging locally with IIS Express can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:

    - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
    - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.
    - When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.

3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module (ANCM) for IIS.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

This error also may occur when the .NET Core Hosting Bundle isn't installed or is corrupted. Installing or repairing the installation of the .NET Core Hosting Bundle (for IIS) or Visual Studio (for IIS Express) may fix the problem.

500.0 In-Process Handler Load Failure

The worker process fails. The app doesn't start.

An unknown error occurred loading ASP.NET Core Module components. Take one of the following actions:

- Contact Microsoft Support (select **Developer Tools** then **ASP.NET Core**).
- Ask a question on Stack Overflow.
- File an issue on our GitHub repository.

500.30 In-Process Startup Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core CLR in-process, but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

Common failure conditions:

- The app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine.
- Using Azure Key Vault, lack of permissions to the Key Vault. Check the access policies in the targeted Key Vault to ensure that the correct permissions are granted.

500.31 ANCM Failed to Find Native Dependencies

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core runtime in-process, but it fails to start. The most common cause of this startup failure is when the `Microsoft.NETCore.App` or `Microsoft.AspNetCore.App` runtime isn't installed. If the app is deployed to target ASP.NET Core 3.0 and that version doesn't exist on the machine, this error occurs. An example error message follows:

```
```

```
The specified framework 'Microsoft.NETCore.App', version '3.0.0' was not
found.
  - The following frameworks were found:
      2.2.1 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview5-27626-15 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27713-13 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27714-15 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27723-08 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
```

The error message lists all the installed .NET Core versions and the version requested by the app. To fix this error, either:

- Install the appropriate version of .NET Core on the machine.
- Change the app to target a version of .NET Core that's present on the machine.
- Publish the app as a self-contained deployment.

When running in development (the `ASPNETCORE_ENVIRONMENT` environment variable is set to `Development`), the specific error is written to the HTTP response. The cause of a process startup failure is also found in the Application Event Log.

500.32 ANCM Failed to Load dll

The worker process fails. The app doesn't start.

The most common cause for this error is that the app is published for an incompatible processor architecture. If the worker process is running as a 32-bit app and the app was published to target 64-bit, this error occurs.

To fix this error, either:

- Republish the app for the same processor architecture as the worker process.
- Publish the app as a framework-dependent deployment.

500.33 ANCM Request Handler Load Failure

The worker process fails. The app doesn't start.

The app didn't reference the `Microsoft.AspNetCore.App` framework. Only apps targeting the `Microsoft.AspNetCore.App` framework can be hosted by the ASP.NET Core Module.

To fix this error, confirm that the app is targeting the `Microsoft.AspNetCore.App` framework. Check the `.runtimeconfig.json` to verify the framework targeted by the app.

500.34 ANCM Mixed Hosting Models Not Supported

The worker process can't run both an in-process app and an out-of-process app in the same process.

To fix this error, run apps in separate IIS application pools.

500.35 ANCM Multiple In-Process Applications in same Process

The worker process can't run multiple in-process apps in the same process.

To fix this error, run apps in separate IIS application pools.

500.36 ANCM Out-Of-Process Handler Load Failure

The out-of-process request handler, *aspnetcorev2_outofprocess.dll*, isn't next to the *aspnetcorev2.dll* file. This indicates a corrupted installation of the ASP.NET Core Module.

To fix this error, repair the installation of the .NET Core Hosting Bundle (for IIS) or Visual Studio (for IIS Express).

500.37 ANCM Failed to Start Within Startup Time Limit

ANCM failed to start within the provided startup time limit. By default, the timeout is 120 seconds.

This error can occur when starting a large number of apps on the same machine. Check for CPU/Memory usage spikes on the server during startup. You may need to stagger the startup process of multiple apps.

500.38 ANCM Application DLL Not Found

ANCM failed to locate the application DLL, which should be next to the executable.

This error occurs when hosting an app packaged as a single-file executable using the in-process hosting model. The in-process model requires that the ANCM load the .NET Core app into the existing IIS process. This scenario isn't supported by the single-file

deployment model. Use **one** of the following approaches in the app's project file to fix this error:

1. Disable single-file publishing by setting the `PublishSingleFile` MSBuild property to `false`.
2. Switch to the out-of-process hosting model by setting the `AspNetCoreHostingModel` MSBuild property to `OutOfProcess`.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.

2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:

    - If deploying a 32-bit (x86) app, set the value to `True`.
    - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Failed to start application (ErrorCode '0x800701b1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/3/ROOT', ErrorCode '0x800701b1'.
```

The app failed to start because a Windows Service failed to load.

One common service that needs to be enabled is the "null" service. The following command enables the `null` Windows Service:

Windows Command Prompt

```
sc.exe start null
```

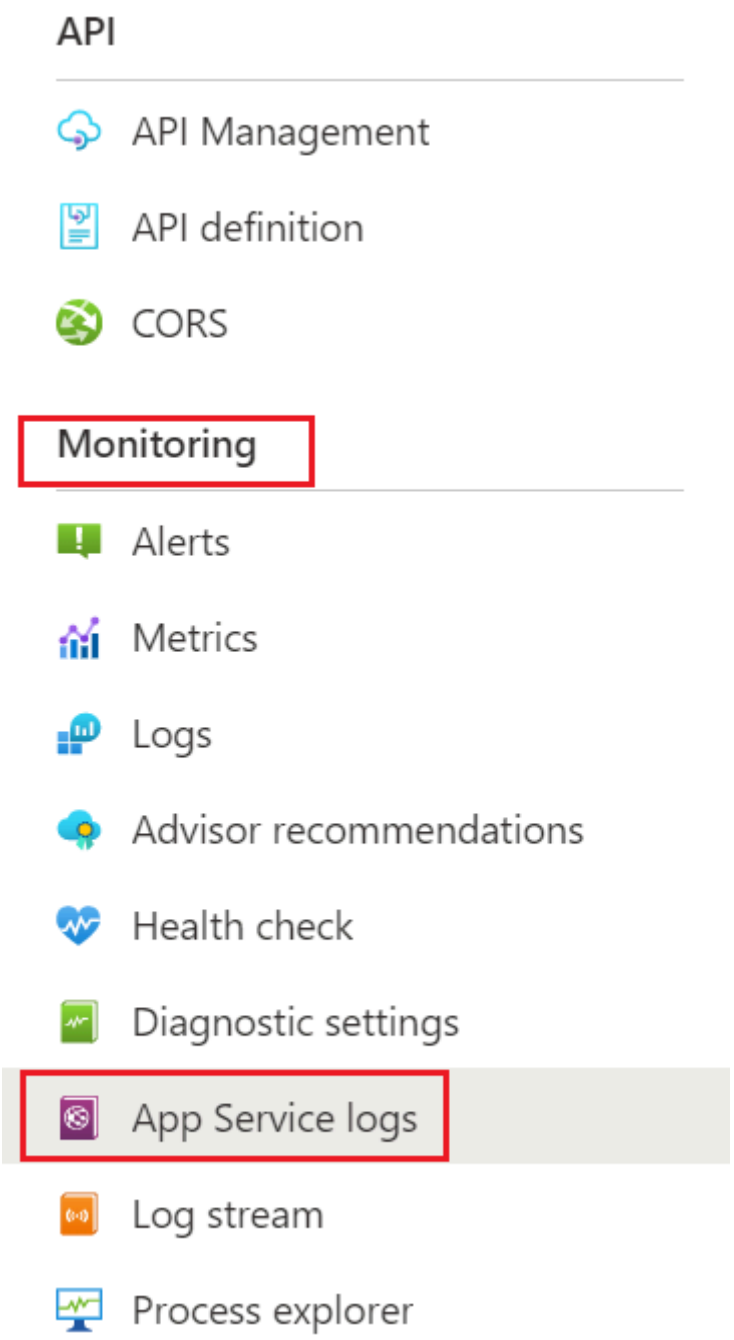
Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

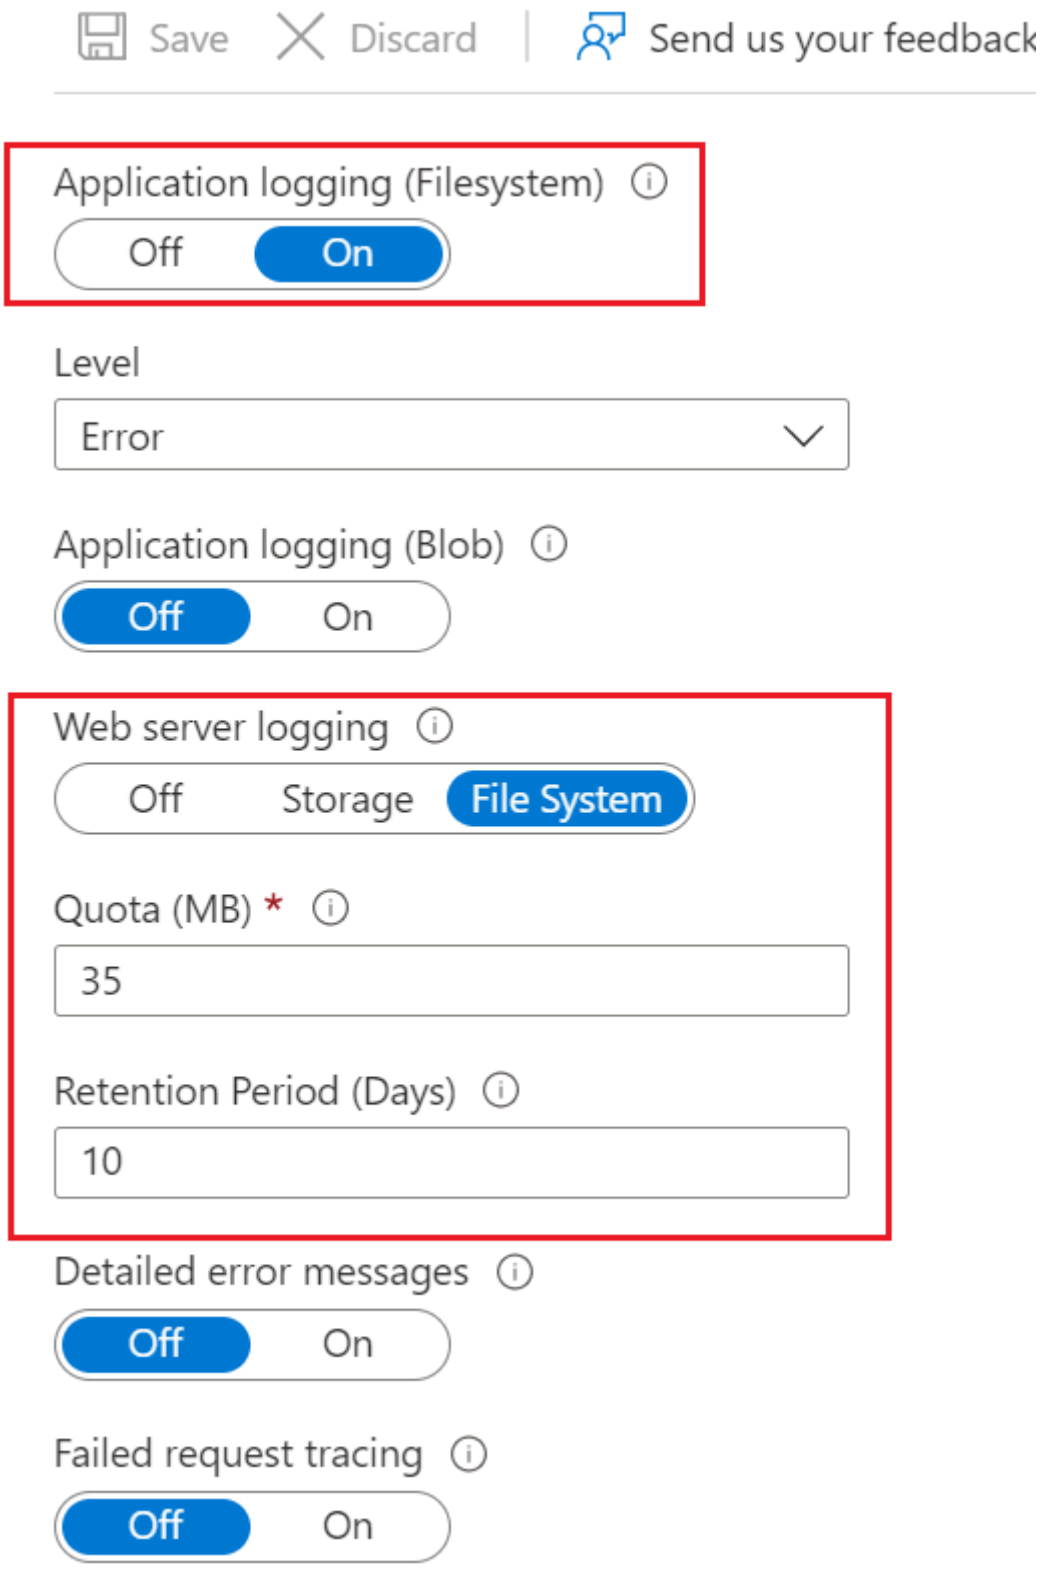
The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service



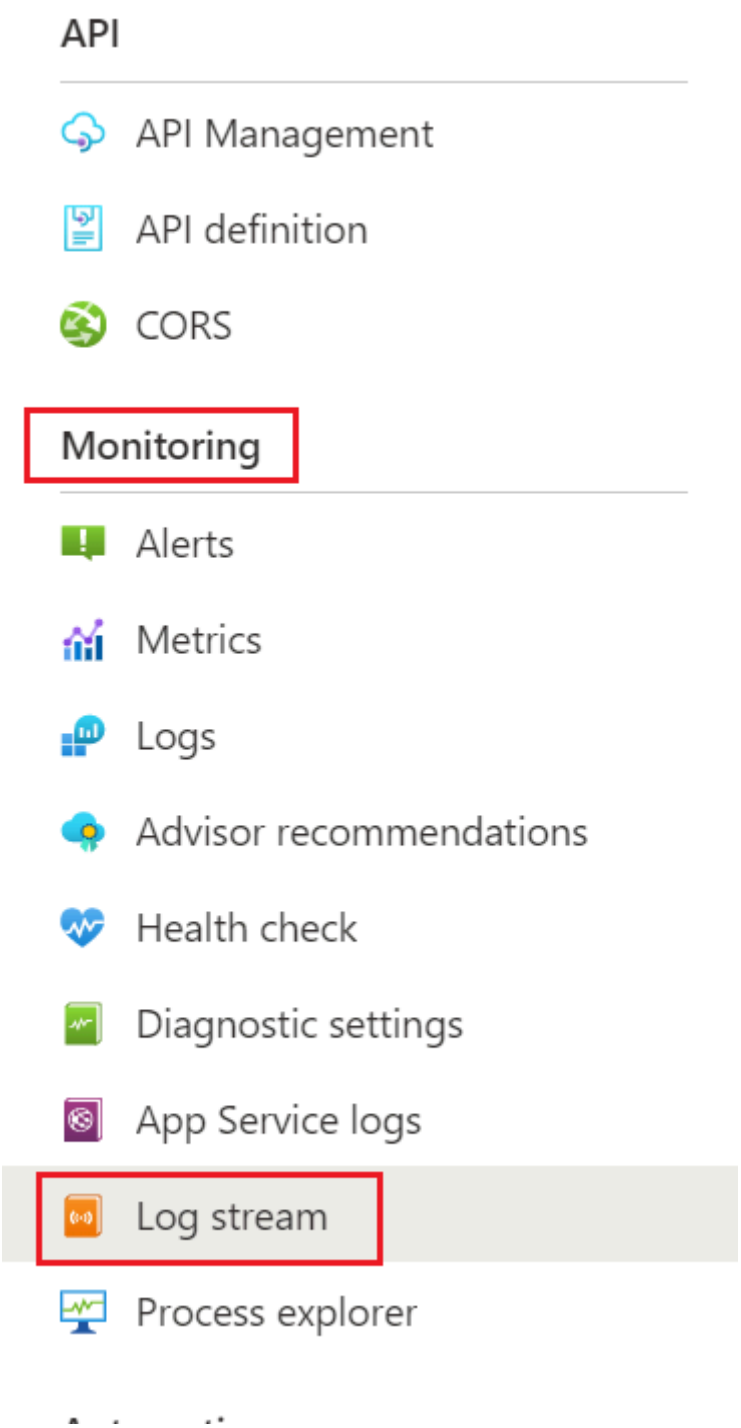
> **Important**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Azure App Services Log stream

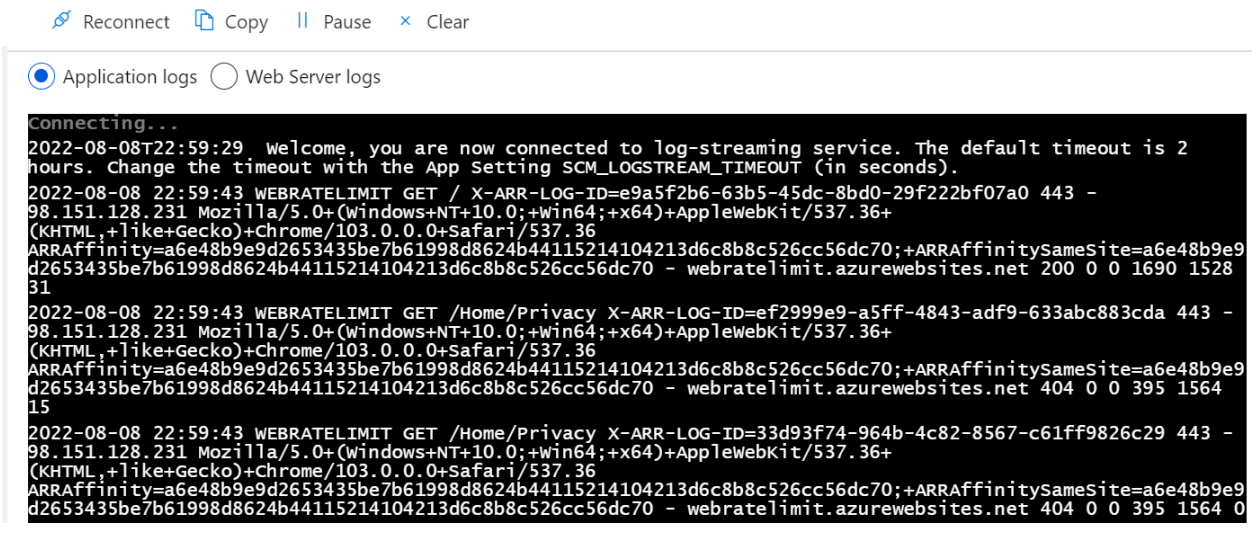


The Azure App Services Log streams logging information as it occurs. To view streaming logs:

1. In the Azure portal, open the app in **App Services**.



2. In the left pane, navigate to **Monitoring** > **App Service Logs**.



3. Select **File System** for **Web Server Logging**. Optionally enable **Application logging**.

4. In the left pane, navigate to **Monitoring** > **Log stream**, and then select **Application logs** or **Web Server Logs**.

The following images shows the application logs output:

Streaming logs have some latency and might not display immediately.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.
2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go** → button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the `eventlog.xml` file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go** → button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:

- If the app is a framework-dependent deployment:

  .NET CLI

  ```
  dotnet .\{ASSEMBLY NAME}.dll
  ```

- If the app is a self-contained deployment:

  Console

  ```
  {ASSEMBLY NAME}.exe
  ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:

  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

- If the app is a self-contained deployment:

  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

> ⚠ **Warning**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. In the Azure Portal, navigate to the web app.
2. In the **App Service** blade, enter **kudu** in the search box.
3. Select **Advanced Tools** > **Go**.
4. Select **Debug console** > **CMD**.
5. Navigate to *site/wwwroot*
6. Select the pencil icon to edit the *web.config* file.
7. In the `<aspNetCore />` element, set `stdoutLogEnabled="true"` and select **Save**.

Disable stdout logging when troubleshooting is complete by setting `stdoutLogEnabled="false"`.

For more information, see ASP.NET Core Module (ANCM) for IIS.

ASP.NET Core Module debug log (Azure App Service)

The ASP.NET Core Module debug log provides additional, deeper logging from the ASP.NET Core Module. To enable and view stdout logs:

1. To enable the enhanced diagnostic log, perform either of the following:

- Follow the instructions in Enhanced diagnostic logs to configure the app for an enhanced diagnostic logging. Redeploy the app.
- Add the `<handlerSettings>` shown in Enhanced diagnostic logs to the live app's *web.config* file using the Kudu console:
  a. Open **Advanced Tools** in the **Development Tools** area. Select the **Go**→ button. The Kudu console opens in a new browser tab or window.
  b. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
  c. Open the folders to the path **site** > **wwwroot**. Edit the *web.config* file by selecting the pencil button. Add the `<handlerSettings>` section as shown in Enhanced diagnostic logs. Select the **Save** button.

2. Open **Advanced Tools** in the **Development Tools** area. Select the **Go**→ button. The Kudu console opens in a new browser tab or window.
3. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
4. Open the folders to the path **site** > **wwwroot**. If you didn't supply a path for the *aspnetcore-debug.log* file, the file appears in the list. If you supplied a path, navigate to the location of the log file.
5. Open the log file with the pencil button next to the file name.

Disable debug logging when troubleshooting is complete:

To disable the enhanced debug log, perform either of the following:

- Remove the `<handlerSettings>` from the *web.config* file locally and redeploy the app.
- Use the Kudu console to edit the *web.config* file and remove the `<handlerSettings>` section. Save the file.

For more information, see Log creation and redirection with the ASP.NET Core Module.

> ⚠ **Warning**
>
> Failure to disable the debug log can lead to app or server failure. There's no limit on log file size. Only use debug logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or nonresponsive app (Azure App Service)

When an app responds slowly or doesn't respond to a request, see Troubleshoot slow web app performance issues in Azure App Service.

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.
2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.
4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go**→ button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.

5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> ⚠ **Warning**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`).

`stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.

4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.
3. Save the file.

For more information, see ASP.NET Core Module (ANCM) for IIS.

> ⚠ **Warning**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (IIS)

Add the following handler settings to the app's *web.config* file to enable ASP.NET Core Module debug log:

XML

```
<aspNetCore ...>
  <handlerSettings>
    <handlerSetting name="debugLevel" value="file" />
    <handlerSetting name="debugFile" value="c:\temp\ancm.log" />
  </handlerSettings>
</aspNetCore>
```

Confirm that the path specified for the log exists and that the app pool's identity has write permissions to the location.

For more information, see Log creation and redirection with the ASP.NET Core Module.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

XML

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="InProcess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development"
/>
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or non-responding app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.

2. Run the EnableDumps PowerShell script:

   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     Console

     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     Console

     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.

4. After the crash has occurred, run the DisableDumps PowerShell script:

   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     Console

     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     Console

     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> ⚠ **Warning**
>
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App doesn't respond, fails during startup, or runs normally

When an app stops responding but doesn't crash, fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

Common error troubleshooting for Azure App Service and IIS with ASP.NET Core

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This topic describes the most common errors and provides troubleshooting advice when hosting ASP.NET Core apps on Azure Apps Service and IIS.

See Troubleshoot ASP.NET Core on Azure App Service and IIS information on common app startup errors and instructions on how to diagnose errors.

Collect the following information:

- Browser behavior such as status code and error message.
- Application Event Log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS

    1. Select **Start** on the **Windows** menu, type *Event Viewer*, and press **Enter**.
    2. After the **Event Viewer** opens, expand **Windows Logs** > **Application** in the sidebar.

- ASP.NET Core Module stdout and debug log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS: Follow the instructions in the Log creation and redirection and Enhanced diagnostic logs sections of the ASP.NET Core Module topic.

Compare error information to the following common errors. If a match is found, follow the troubleshooting advice.

The list of errors in this topic isn't exhaustive. If you encounter an error not listed here, open a new issue using the **Content feedback** button at the bottom of this topic with detailed instructions on how to reproduce the error.

> ⓘ **Important**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

OS upgrade removed the 32-bit ASP.NET Core Module

Application Log: The Module DLL **C:\WINDOWS\system32\inetsrv\aspnetcore.dll** failed to load. The data is the error.

Troubleshooting:

Non-OS files in the **C:\Windows\SysWOW64\inetsrv** directory aren't preserved during an OS upgrade. If the ASP.NET Core Module is installed prior to an OS upgrade and then any app pool is run in 32-bit mode after an OS upgrade, this issue is encountered. After an OS upgrade, repair the ASP.NET Core Module. See Install the .NET Core Hosting bundle. Select **Repair** when the installer is run.

Missing site extension, 32-bit (x86) and 64-bit (x64) site extensions installed, or wrong process bitness set

Applies to apps hosted by Azure App Services.

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found. Failed to start application '/LM/W3SVC/1416782824/ROOT', ErrorCode '0x8000ffff'.

- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff. Could not find inprocess request handler. It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.

Troubleshooting:

- If running the app on a preview runtime, install either the 32-bit (x86) **or** 64-bit (x64) site extension that matches the bitness of the app and the app's runtime version. **Don't install both extensions or multiple runtime versions of the extension.**
  - ASP.NET Core {RUNTIME VERSION} (x86) Runtime
  - ASP.NET Core {RUNTIME VERSION} (x64) Runtime

  Restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and both the 32-bit (x86) and 64-bit (x64) site extensions are installed, uninstall the site extension that doesn't match the bitness of the app. After removing the site extension, restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and the site extension's bitness matches that of the app, confirm that the preview site extension's *runtime version* matches the app's runtime version.
- Confirm that the app's **Platform** in **Application Settings** matches the bitness of the app.

For more information, see Deploy ASP.NET Core apps to Azure App Service.

An x86 app is deployed but the app pool isn't enabled for 32-bit apps

- **Browser:** HTTP Error 500.30 - ANCM In-Process Start Failure

- **Application Log:** Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' hit unexpected managed exception, exception code = '0xe0434352'. Please check the stderr logs for more information. Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' failed to load clr and managed application. CLR worker thread exited prematurely

- **ASP.NET Core Module stdout Log:** The log file is created but empty.

- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8007023e

This scenario is trapped by the SDK when publishing a self-contained app. The SDK produces an error if the RID doesn't match the platform target (for example, `win10-x64` RID with `<PlatformTarget>x86</PlatformTarget>` in the project file).

Troubleshooting:

For an x86 framework-dependent deployment (`<PlatformTarget>x86</PlatformTarget>`), enable the IIS app pool for 32-bit apps. In IIS Manager, open the app pool's **Advanced Settings** and set **Enable 32-Bit Applications** to **True**.

Platform conflicts with RID

- **Browser:** HTTP Error 502.5 - Process Failure

- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ', ErrorCode = '0x80004005 : ff.

- **ASP.NET Core Module stdout Log:** Unhandled Exception: System.BadImageFormatException: Could not load file or assembly '{ASSEMBLY}.dll'. An attempt was made to load a program with an incorrect format.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

- If this exception occurs for an Azure Apps deployment when upgrading an app and deploying newer assemblies, manually delete all files from the prior deployment. Lingering incompatible assemblies can result in a `System.BadImageFormatException` exception when deploying an upgraded app.

URI endpoint wrong or stopped website

- **Browser:** ERR_CONNECTION_REFUSED **--OR--** Unable to connect
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm the correct URI endpoint for the app is in use. Check the bindings.
- Confirm that the IIS website isn't in the *Stopped* state.

CoreWebEngine or W3SVC server features disabled

OS Exception: The IIS 7.0 CoreWebEngine and W3SVC features must be installed to use the ASP.NET Core Module.

Troubleshooting:

Confirm that the proper role and features are enabled. See IIS Configuration.

Incorrect website physical path or app missing

- **Browser:** 403 Forbidden - Access is denied **--OR--** 403.14 Forbidden - The Web server is configured to not list the contents of this directory.
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Check the IIS website **Basic Settings** and the physical app folder. Confirm that the app is in the folder at the IIS website **Physical path**.

Incorrect role, ASP.NET Core Module not installed, or incorrect permissions

- **Browser:** 500.19 Internal Server Error - The requested page cannot be accessed because the related configuration data for the page is invalid. --**OR**-- This page can't be displayed
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm that the proper role is enabled. See IIS Configuration.
- Open **Programs & Features** or **Apps & features** and confirm that **Windows Server Hosting** is installed. If **Windows Server Hosting** isn't present in the list of installed programs, download and install the .NET Core Hosting Bundle.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.
- Make sure that the **Application Pool** > **Process Model** > **Identity** is set to **ApplicationPoolIdentity** or the custom identity has the correct permissions to access the app's deployment folder.
- If you uninstalled the ASP.NET Core Hosting Bundle and installed an earlier version of the hosting bundle, the *applicationHost.config* file doesn't include a section for the ASP.NET Core Module. Open *applicationHost.config* at *%windir%/System32/inetsrv/config* and find the `<configuration><configSections>` `<sectionGroup name="system.webServer">` section group. If the section for the ASP.NET Core Module is missing from the section group, add the section element:

  ```
  XML
  <section name="aspNetCore" overrideModeDefault="Allow" />
  ```

  Alternatively, install the latest version of the ASP.NET Core Hosting Bundle. The latest version is backwards-compatible with supported ASP.NET Core apps.

Incorrect processPath, missing PATH variable, Hosting Bundle not installed, system/IIS not restarted, VC++ Redistributable not installed, or dotnet.exe access violation

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"{...}" ', ErrorCode = '0x80070002 : 0. Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed to start application '/LM/W3SVC/2/ROOT', ErrorCode '0x8007023e'.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** Event Log: 'Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed HRESULT returned: 0x8007023e

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Check the *processPath* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's `dotnet` for a framework-dependent deployment (FDD) or `.\{ASSEMBLY}.exe` for a self-contained deployment (SCD).
- For an FDD, *dotnet.exe* might not be accessible via the PATH settings. Confirm that *C:\Program Files\dotnet* exists in the System PATH settings.
- For an FDD, *dotnet.exe* might not be accessible for the user identity of the app pool. Confirm that the app pool user identity has access to the *C:\Program Files\dotnet* directory. Confirm that there are no deny rules configured for the app pool user identity on the *C:\Program Files\dotnet* and app directories.
- An FDD may have been deployed and .NET Core installed without restarting IIS. Either restart the server or restart IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.
- An FDD may have been deployed without installing the .NET Core runtime on the hosting system. If the .NET Core runtime hasn't been installed, run the **.NET Core Hosting Bundle installer** on the system.

Current .NET Core Hosting Bundle installer (direct download)

For more information, see Install the .NET Core Hosting Bundle.

If a specific runtime is required, download the runtime from the .NET Downloads page and install it on the system. Complete the installation by restarting the system or restarting IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.

Incorrect arguments of <aspNetCore> element

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed to start application '/LM/W3SVC/3/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed HRESULT returned: 0x8000ffff

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

- Examine the *arguments* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's either (a) `.\{ASSEMBLY}.dll` for a framework-dependent deployment (FDD); or (b) not present, an empty string (`arguments=""`), or a list of the app's arguments (`arguments="{ARGUMENT_1}, {ARGUMENT_2}, ... {ARGUMENT_X}"`) for a self-contained deployment (SCD).

Missing .NET Core shared framework

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.

Failed to start application '/LM/W3SVC/5/ROOT', ErrorCode '0x8000ffff'.

- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.
- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8000ffff

Troubleshooting:

For a framework-dependent deployment (FDD), confirm that the correct runtime installed on the system.

Stopped Application Pool

- **Browser:** 503 Service Unavailable
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Confirm that the Application Pool isn't in the *Stopped* state.

Sub-application includes a <handlers> section

- **Browser:** HTTP Error 500.19 - Internal Server Error
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.
- **ASP.NET Core Module Debug Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.

Troubleshooting:

Confirm that the sub-app's *web.config* file doesn't include a `<handlers>` section or that the sub-app doesn't inherit the parent app's handlers.

The parent app's `<system.webServer>` section of *web.config* is placed inside of a `<location>` element. The InheritInChildApplications property is set to `false` to indicate that the settings specified within the <location> element aren't inherited by apps that reside in a subdirectory of the parent app. For more information, see ASP.NET Core Module (ANCM) for IIS.

stdout log path incorrect

- **Browser:** The app responds normally.
- **Application Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module debug Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core

Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.

Troubleshooting:

- The `stdoutLogFile` path specified in the `<aspNetCore>` element of *web.config* doesn't exist. For more information, see ASP.NET Core Module: Log creation and redirection.
- The app pool user doesn't have write access to the stdout log path.

Application configuration general issue

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure **--OR--** HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Variable
- **ASP.NET Core Module stdout Log:** The log file is created but empty or created with normal entries until the point of the app failing.
- **ASP.NET Core Module Debug Log:** Variable

Troubleshooting:

The process failed to start, most likely due to an app configuration or programming issue.

Code analysis in ASP.NET Core apps

Article • 07/08/2024

.NET compiler platform analyzers inspect application code for code quality and style issues. This document lists diagnostics for ASP.NET Core. For information on .NET diagnostics, see Overview of .NET source code analysis.

The following list contains the diagnostics for ASP.NET Core. Not all of the diagnostics shown are available in older versions of ASP.NET Core.

Diagnostic ID:

- ASP0000
- ASP0001
- ASP0003
- ASP0004
- ASP0005
- ASP0006
- ASP0007
- ASP0008
- ASP0009
- ASP0010
- ASP0011
- ASP0012
- ASP0013
- ASP0014
- ASP0015
- ASP0016
- ASP0017
- ASP0018
- ASP0019
- ASP0020
- ASP0021
- ASP0022
- ASP0023
- ASP0024
- ASP0025
- ASP0026
- BL0001
- BL0002
- BL0003

- BL0004
- BL0005
- BL0006

ASP0000: Do not call 'IServiceCollection.BuildServiceProvider' in 'ConfigureServices'

Article • 06/18/2024

Expand table

	Value
Rule ID	ASP0000
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

A call to BuildServiceProvider was detected in the application start up code.

Rule description

Calling 'BuildServiceProvider' from application code results in more than one copy of singleton services being created which might result in incorrect application behavior. Consider alternatives such as dependency injecting services as parameters to 'Configure'.

How to fix violations

Remove the call to `BuildServiceProvider` from the application startup code.

When to suppress warnings

It is safe to suppress this rule if updating the application to remove the call to `BuildServiceProvider` is non-trivial and you have thoroughly tested the application to ensure multiple singleton services are not added.

ASP0001: Authorization middleware is incorrectly configured

Article • 06/18/2024

Expand table

	Value
Rule ID	ASP0001
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

An out of order call to UseAuthorization was detected in the application start up code.

Rule description

For authorization to be effective for endpoint routes, the call to `UseAuthorization` should appear between the calls to `UseRouting` and `UseEndpoints`. In the absence of this, the fallback policy, if configured, will be used to authorize all requests.

Consider the following code:

C#

```
app.UseStaticFiles();
app.UseAuthorization();

app.UseRouting();
app.UseEndpoints(endpoints =>
{
    endpoints.MapDefaultControllerRoute();
});
```

The call to `UseAuthorization` appears before `UseRouting` and consequently is not endpoint aware.

How to fix violations

Change the order in which the call to `UseAuthorization` and `UseRouting` are performed.

C#

```
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.UseEndpoints(endpoints =>
{
    endpoints.MapDefaultControllerRoute();
});
```

When to suppress warnings

It is safe to suppress this rule if the call to `UseAuthorization` is intended to authorize the fallback policy on all outgoing requests, or is meant to authorize resources not routed using endpoint routing.

ASP0003: Do not use model binding attributes with route handlers

Article • 09/28/2022

Expand table

	Value
Rule ID	ASP0003
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

A route handler delegate includes a parameter that has a [Bind] attribute.

Rule description

Route handler endpoints only support a subset of MVC attributes such as [FromRoute], [FromBody], etc. Unsupported attributes are ignored and result in unexpected binding behavior. For example, the following code results in an analyzer warning:

C#

```
app.MapGet("/todos/{id}", ([Bind] int id) => new Todo { Id = id });
```

How to fix violations

To fix a violation of this rule, make sure that the endpoint uses one of the allowed model binding attributes.

C#

```
app.MapGet("/todos/{id}", ([FromRoute] int id) => new Todo { Id = id });
```

When to suppress warnings

Do ***not*** suppress a warning from this rule. An incorrect model binding setup can result in unexpected behavior when resolving parameters at runtime.

Provide product feedback

ASP0004: Do not use action results with route handlers

Article • 09/28/2022

Expand table

	Value
Rule ID	ASP0004
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

A route handler delegate returns a value that implements IActionResult.

Rule description

Route handler endpoints do not support executing MVC's `IActionResult` instances. Returning an `IActionResult` that doesn't implement `IResult` results in serializing the result instance rather than executing the result.

C#

```
app.MapGet("/todos/{id}", (int id) => new JsonResult(new Todo { .. }));
```

How to fix violations

To fix a violation of this rule, make sure that endpoint's route handler returns an IResult type by using the Results extension methods.

C#

```
app.MapGet("/todos/{id}", (int id) => Results.Json(new Todo { .. }));
```

When to suppress warnings

Do ***not*** suppress a warning from this rule. Returning an `IActionResult` that doesn't implement `IResult` results in serializing the result instance rather than executing the result.

Collaborate with us on GitHub

The source for this content can be found on GitHub, where you can also create and review issues and pull requests. For more information, see our contributor guide.

ASP.NET Core feedback

ASP.NET Core is an open source project. Select a link to provide feedback:

Open a documentation issue

Provide product feedback

ASP0005: Do not place attribute on method called by route handler lambda

Article • 09/28/2022

Expand table

	Value
Rule ID	ASP0005
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

An attribute was applied to a method definition instead of the route handler in a route handler endpoint.

Rule description

When an endpoint is declared, attributes should be applied to the delegate parameter in order to be effective. For example, the Authorize attribute in the following code sample isn't set on the registered endpoint:

C#

```
app.MapGet("/todos/{id}", GetTodoById);

[Authorize]
Todo GetTodoById(int id)
{
  ...
}
```

The attribute must be placed on the route handler parameter as shown in the following code:

C#

```
app.MapGet("/todos/{id}", [Authorize] GetTodoById);
```

```
Todo GetTodoById(int id)
{
  ...
}
```

How to fix violations

To fix a violation of this rule, make sure that endpoint attributes are applied to the route handler parameter:

C#

```
app.MapGet("/todos/{id}", [Authorize] (int id) => {});
app.MapGet("/users/{id}", [Authorize] GetUserById);
```

When to suppress warnings

Do not suppress a warning from this rule. Misplaced attributes can result in unexpected behavior at runtime.

Collaborate with us on GitHub

The source for this content can be found on GitHub, where you can also create and review issues and pull requests. For more information, see our contributor guide.

ASP0006: Do not use non-literal sequence numbers

Article • 10/30/2022

Expand table

	Value
Rule ID	ASP0006
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

An invocation on a method in RenderTreeBuilder containing a sequence number that isn't a literal as a parameter.

Rule description

Blazor's UI diffing algorithm relies on sequence numbers to determine which elements have changed. Computing the sequence number dynamically or using a counter can result in poor diffing performance. Instead, use a literal sequence number that maps to the source code line for the element. For example, the following code produces an error:

C#

```
using Microsoft.AspNetCore.Components.Rendering;
var builder = new RenderTreeBuilder();
var seqNum = 1;
builder.OpenElement(seqNum, "div");
builder.CloseElement();
```

How to fix violations

To fix a violation of this rule, make sure that calls to methods on the RenderTreeBuilder class that take a sequence number as a parameter use a literal sequence number.

C#

```
using Microsoft.AspNetCore.Components.Rendering;
var builder = new RenderTreeBuilder();
builder.OpenElement(0, "div");
builder.CloseElement();
```

When to suppress warnings

Do ***not*** suppress a warning from this rule. Using a non-literal sequence number can result in performance degradation.

Collaborate with us on GitHub

The source for this content can be found on GitHub, where you can also create and review issues and pull requests. For more information, see our contributor guide.

ASP0007: Route parameter and argument optionality is mismatched

Article • 09/28/2022

Expand table

	Value
Rule ID	ASP0007
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

A route parameter is declared as required in the Delegate definition but is marked as optional in the endpoint route.

Rule description

When an endpoint is declared, optionality of parameters can be declared in both the route template and in the route handler arguments. When a parameter is declared as optional in the handler, it must also be declared as optional in the route template. For example, GET `/todos` fails to resolve a match for the following code:

C#

```
app.MapGet("/todos/{id}", (int? id) => {});
```

The preceding code fails to match GET `/todos` because the `id` parameter was not provided, even though it is treated as optional in the route handler.

How to fix violations

To fix a violation of this rule, make sure that the optionality in the route template and the delegate match. For example, for the following code sample:

C#

```
app.MapGet("/todos/{id}", (int? id) => {});
```

If the parameter is intended to be required, make the type non-nullable by removing the `?` from `int?`:

C#

```
app.MapGet("/todos/{id}", (int id) => {});
```

If the parameter is intended to be optional, then the nullable value type operator `?` should be applied:

C#

```
app.MapGet("/todos/{id?}", (int? id) => {});
```

When to suppress warnings

Do ***not*** suppress a warning from this rule. Mismatched parameter optionality can result in unexpected behavior with routing at runtime.

ASP0008: Do not use ConfigureWebHost with WebApplicationBuilder.Host

Article • 09/28/2022

Expand table

	Value
Rule ID	ASP0008
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

`ConfigureWebHost` can't be used with the `Host` property on `WebApplicationBuilder`.

Rule description

The `WebApplicationBuilder` doesn't support configuring the `WebHost` before build using the `ConfigureWebHost` extension method.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Host.ConfigureWebHost(webHostBuilder => {

webHostBuilder.UseContentRoot(Path.Combine(Directory.GetCurrentDirectory(),
"myContentRoot"));
});

var app = builder.Build();

app.Run();
```

How to fix violations

To fix a violation of this rule, configure the `WebHost` directly on the `WebApplicationBuilder`. For example, instead of setting the content root path via `ConfigureWebHost`.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Host.ConfigureWebHost(webHostBuilder =>
{

webHostBuilder.UseContentRoot(Path.Combine(Directory.GetCurrentDirectory(),
"myContentRoot"));
});

var app = builder.Build();

app.Run();
```

Configure the content root path directly on the `WebApplicationBuilder.WebHost`.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.UseContentRoot(Path.Combine(Directory.GetCurrentDirectory(),
"foobar"));

var app = builder.Build();

app.Run();
```

When to suppress warnings

Do ***not*** suppress a warning from this rule. A misconfigured application can result in unexpected behavior at runtime.

ASP0009: Do not use Configure with WebApplicationBuilder.WebHost

Article • 09/28/2022

Expand table

	Value
Rule ID	ASP0009
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

`Configure` can't be used with the `WebHost` property on `WebApplicationBuilder`.

Rule description

The `WebApplicationBuilder` doesn't support configuring the `WebHost` before build using the `Configure` extension method.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.Configure(webHostBuilder => {

webHostBuilder.UseContentRootPath(Path.Combine(Directory.GetCurrentDirectory
(), "myContentRoot"));
});

var app = builder.Build();

app.Run();
```

How to fix violations

To fix a violation of this rule, configure the `WebHost` directly on the `WebApplicationBuilder`. For example, instead of setting the content root path via

`Configure`.

```C#
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.Configure(webHostBuilder =>
{

webHostBuilder.UseContentRoot(Path.Combine(Directory.GetCurrentDirectory(),
"myContentRoot"));
});

var app = builder.Build();

app.Run();
```

Configure the content root path directly on the `WebApplicationBuilder`.

```C#
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.UseContentRoot(Path.Combine(Directory.GetCurrentDirectory(),
"myContentRoot"));

var app = builder.Build();

app.Run();
```

ASP0010: Do not use UseStartup with WebApplicationBuilder.WebHost

Article • 06/18/2024

Expand table

	Value
Rule ID	ASP0010
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

`UseStartup` can't be used with `WebApplicationBuilder.WebHost`.

Rule description

The `WebApplicationBuilder` doesn't support configuration via a `Startup` class.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.UseStartup<Startup>();

var app = builder.Build();

app.Run();
```

How to fix violations

To fix a violation of this rule, leverage the `Configuration` and `Services` properties on the `WebApplicationBuilder` to modify configuration and DI directly, without the need for a startup class.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication();

var app = builder.Build();

app.Run();
```

When to suppress warnings

Do ***not*** suppress a warning from this rule. A misconfigured application can result in unexpected behavior at runtime.

ASP0011: Suggest using builder.Logging over Host.ConfigureLogging or WebHost.ConfigureLogging

Article • 09/28/2022

Expand table

	Value
Rule ID	ASP0011
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

`ConfigureLogging` isn't the recommended strategy for configuring logging in a minimal API application.

Rule description

`ConfigureLogging` isn't the recommended strategy for configuring logging in a minimal API application.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Host.ConfigureLogging(logging =>
{
    logging.AddJsonConsole();
})

var app = builder.Build();

app.Run();
```

How to fix violations

To fix a violation of this rule, use the `Logging` property on the `WebApplicationBuilder` to modify the logging configuration directly without the need for an additional `ConfigureLogging` call.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Logging.AddJsonConsole();

var app = builder.Build();

app.Run();
```

When to suppress warnings

ASP0013: Suggest switching from using Configure methods to WebApplicationBuilder.Configuration

Article • 02/13/2024

Expand table

	Value
Rule ID	ASP0013
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

Configure isn't the recommended strategy for reading and writing to configuration in a minimal API app. `Configure` was designed to be used with Web Host or .NET Generic Host. In a minimal API app, WebApplicationBuilder.Configuration should be used to modify configuration directly.

Rule description

`Configure` isn't the recommended strategy for configuring logging in a minimal API app.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Host.ConfigureAppConfiguration(builder =>
{
    builder.AddJsonFile("customAppSettings.json");
})

var app = builder.Build();

app.Run();
```

How to fix violations

To fix a violation of this rule, use WebApplicationBuilder.Configuration to modify application configuration directly without the need for an additional ConfigureAppConfiguration call.

```C#
var builder = WebApplication.CreateBuilder(args);

builder.Configuration.AddJsonFile("customAppSettings.json");

var app = builder.Build();

app.Run();
```

When to suppress warnings

Do ***not*** suppress a warning from this rule.

ASP0014: Suggest using top level route registrations

Article • 02/23/2023

Expand table

	Value
Rule ID	ASP0014
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

Routes can be registered directly at the top-level of a minimal API application.

Rule description

Routes can be registered directly at the top-level of a minimal API application and don't need to be nested within a `UseEndpoints` call.

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.UseEndpoints(endpoints =>
{
    endpoints.MapGet("/", () => "Hello World!");
});

app.Run();
```

How to fix violations

To fix a violation of this rule, register the endpoints directly on the `WebApplication`.

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

When to suppress warnings

Warnings from this rule can be suppressed if the target `UseEndpoints` invocation is invoked without any mappings as a strategy to organize middleware ordering.

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

#pragma warning disable ASP0014
app.UseEndpoints(e => {});
#pragma warning restore ASP0014

app.Run();
```

ASP0015: Suggest using IHeaderDictionary properties

Article • 11/28/2022

Expand table

	Value
Rule ID	ASP0015
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

IHeaderDictionary properties are the recommended strategy for accessing headers.

Rule description

`IHeaderDictionary` properties are recommended for accessing headers. Accessing headers using an indexer as in the example below is not recommended.

C#

```
var app = WebApplication.Create();

app.MapGet("/", (HttpContext context) => context.Request.Headers[""content-
type""]);

app.Run();
```

How to fix violations

To fix a violation of this rule, use the property specified in the analyzer message to access the header specified in the message or apply the associated codefix.

C#

```
var app = WebApplication.Create();
app.MapGet("/", (HttpContext context) =>
```

```
context.Request.Headers.ContentType);
app.Run();
```

When to suppress warnings

Do not suppress a warning from this rule.

ASP0016: Do not return a value from RequestDelegate

Article • 11/28/2022

Expand table

	Value
Rule ID	ASP0016
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

A method used to create a RequestDelegate returns `Task<T>`. `RequestDelegate` discards this value.

Rule description

Do not return a value `Delegate`s provided to APIs that expect `RequestDelegate`. For example, the following sample returns a `Task<string>` where the `string` value of the `Task` will be discarded.

C#

```
var app = WebApplication.Create();
app.Use(next =>
{
    return new RequestDelegate((HttpContext context) =>
    {
        return Task.FromResult(""hello world"");
    });
});
```

How to fix violations

To fix a violation of this rule, change the return type to non-generic `Task` or, if the delegate is a route handler, cast it to `Delegate` so the return value is written to the

response.

When to suppress warnings

Do not suppress a warning from this rule.

ASP0018: Unused route parameter

Article • 06/20/2024

Expand table

	Value
Rule ID	ASP0018
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

A route parameter is specified but not used.

Rule description

A route parameter is specified but not used. In the example below, the `id` parameter is defined in the route but not in the route handler.

C#

```
var app = WebApplication.Create();

app.MapGet("/{id}", () => ...);
```

How to fix violations

To fix a violation of this rule, remove the route parameter or add code that uses the parameter.

C#

```
var app = WebApplication.Create();

app.MapGet("/{id}", (string id) => ...);
```

When to suppress warnings

In general, do ***not*** suppress a warning from this rule without validating the route parameter is used. Currently properties within the bound model for FromRoute attributes may not be analyzed. For more information, see GitHub issue #54212.

ASP0019: Suggest using IHeaderDictionary.Append or the indexer

Article • 11/28/2022

Expand table

	Value
Rule ID	ASP0019
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

`IDictionary.Add` isn't recommended for setting or appending headers. IDictionary.Add throws an `ArgumentException` when attempting to add a duplicate key.

Rule description

`IDictionary.Add` isn't recommended for setting or appending headers.

How to fix violations

To fix a violation of this rule, use `IHeaderDictionary.Append` or the indexer to append or set headers.

When to suppress warnings

Do not suppress a warning from this rule.

ASP0020: Complex types referenced by route parameters must be parsable

Article • 03/27/2023

Expand table

	Value
Rule ID	ASP0020
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

A route parameter is a complex type that isn't parsable.

Rule description

This diagnostic is emitted when a route parameter is a complex type that isn't parsable.

How to fix violations

To fix a violation of this rule, define a `bool TryParse(string, IFormatProvider, out T)` method, where `T` is the complex type identified in the error message. As an alternative, implement IParsable<TSelf>.

When to suppress warnings

Do not suppress a warning from this rule.

ASP0021: The return type of the BindAsync method must be `ValueTask<T>`.

Article • 03/27/2023

Expand table

	Value
Rule ID	ASP0021
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

An implementation of the BindAsync method has a return type that isn't ValueTask<TResult>.

Rule description

This diagnostic is emitted when an implementation of the `BindAsync` method has a return type that isn't `ValueTask<T>`.

How to fix violations

To fix a violation of this rule, define a `ValueTask<T>` return type for `BindAsync` and consider implementing IBindableFromHttpContext<TSelf> to enforce implementation.

When to suppress warnings

Do not suppress a warning from this rule.

ASP0022: Route conflict detected between route handlers

Article • 11/08/2023

Expand table

	Value
Rule ID	ASP0022
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

An HTTP request matches multiple routes, resulting in an ambiguous match error.

Rule description

This diagnostic is emitted when a route conflict is detected.

How to fix violations

To fix a violation of this rule, change the route's pattern, HTTP method, or route constraints.

When to suppress warnings

Do not suppress a warning from this rule.

Notes

ASP0023 warns on route conflicts in ASP.NET Core MVC apps, this analyzer warns on route conflicts in minimal API apps.

This analyzer is intentionally conservative about duplicate routes it reports to avoid false positives:

- The analyzer only reports duplicate routes declared in the same code block in a method. Duplicate routes in different branches of an `if` statement aren't reported because the analyzer can't statically determine which will be used at runtime.
- The analyzer only reports duplicate routes with known metadata. Unknown methods called on a route handler might add new metadata that is then used to customize how the route is matched.

ASP0025: Use AddAuthorizationBuilder to register authorization services and construct policies.

Article • 05/15/2023

Expand table

	Value
Rule ID	ASP0025
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

The use of AddAuthorization can be converted to the new AddAuthorizationBuilder.

Rule description

Use `AddAuthorizationBuilder` to register authorization services and construct policies.

How to fix violations

To fix a violation of this rule, replace the usage of `AddAuthorization` with `AddAuthorizationBuilder`.

The code fix converts any usage of the setters for the following properties of AuthorizationOptions:

- DefaultPolicy
- FallbackPolicy
- InvokeHandlersAfterFailure

These setter usages are converted to equivalent method calls on AuthorizationBuilder:

- SetDefaultPolicy
- SetFallbackPolicy

- SetInvokeHandlersAfterFailure

No diagnostic is reported when the configure action passed to `AddAuthorization` uses any of the following members of `AuthorizationOptions`:

- The GetPolicy(String) method
- The DefaultPolicy getter
- The FallbackPolicy getter
- The InvokeHandlersAfterFailure getter

`AuthorizationBuilder` doesn't have equivalents for these members of `AuthorizationOptions`, so they can't be converted.

No diagnostic is reported if the configure action passed to `AddAuthorization` contains operations unrelated to `AuthorizationOptions`. The code fix would not be able to automatically map unrelated operations to the fluent API of `AddAuthorizationBuilder`.

The following example shows code that triggers this diagnostic:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorization(options =>
{
    options.AddPolicy("AtLeast21", policy =>
        policy.Requirements.Add(new MinimumAgeRequirement(21)));
});

var app = builder.Build();

app.UseAuthorization();

app.Run();
```

The following example shows the result of applying the code fix:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthorizationBuilder()
  .AddPolicy("AtLeast21", policy =>
  {
        policy.Requirements.Add(new MinimumAgeRequirement(21)));
  });

var app = builder.Build();
```

```
app.UseAuthorization();

app.Run();
```

When to suppress warnings

The severity level of this diagnostic is Information. Suppress warnings if you don't want to use the new syntax.

ASP0026: `[Authorize]` is overridden by `[AllowAnonymous]` from "farther away"

Article • 07/09/2024

Expand table

	Value
Rule ID	ASP0026
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

It seems intuitive that an `[Authorize]` attribute placed "closer" to an MVC action than an `[AllowAnonymous]` attribute would override the `[AllowAnonymous]` attribute and force authorization. However, this is not necessarily the case. What does matter is the relative order of the attributes.

The following code shows examples where a closer `[Authorize]` attribute gets overridden by an `[AllowAnonymous]` attribute that is farther away.

C#

```
[AllowAnonymous]
public class MyController
{
    [Authorize] // Overridden by the [AllowAnonymous] attribute on the class
    public IActionResult Private() => null;
}
```

C#

```
[AllowAnonymous]
public class MyControllerAnon : ControllerBase
{
}

[Authorize] // Overridden by the [AllowAnonymous] attribute on
MyControllerAnon
public class MyControllerInherited : MyControllerAnon
{
```

```
}

public class MyControllerInherited2 : MyControllerAnon
{
    [Authorize] // Overridden by the [AllowAnonymous] attribute on
MyControllerAnon
    public IActionResult Private() => null;
}
```

C#

```
[AllowAnonymous]
[Authorize] // Overridden by the preceding [AllowAnonymous]
public class MyControllerMultiple : ControllerBase
{
}
```

Rule description

Warning that an `[Authorize]` attribute is overridden by an `[AllowAnonymous]` attribute from "farther away."

How to fix violations

The correct action to take if you see this warning depends on the intention behind the attributes. The farther away `[AllowAnonymous]` attribute should be removed if it's unintentionally exposing the endpoint to anonymous users. If the `[AllowAnonymous]` attribute was intended to override a closer `[Authorize]` attribute, you can repeat the `[AllowAnonymous]` attribute after the `[Authorize]` attribute to clarify the intent.

C#

```
[AllowAnonymous]
public class MyController
{
    // This produces no warning because the second, "closer"
[AllowAnonymous]
    // clarifies that [Authorize] is intentionally overridden.
    // Specifying AuthenticationSchemes can still be useful
    // for endpoints that allow but don't require authenticated users.
    [Authorize(AuthenticationSchemes = "Cookies")]
    [AllowAnonymous]
    public IActionResult Privacy() => null;
}
```

When to suppress warnings

The severity level of this diagnostic is Information. You can suppress warnings if your intention is to override the `[Authorize]` attribute. However, we recommend that you make the intent clear by repeating the `[AllowAnonymous]` attribute after the `[Authorize]` attribute.

BL0001: Component parameter should have public setters

Article • 06/03/2022

Expand table

	Value
Rule ID	BL0001
Category	Usage
Fix is breaking or non-breaking	Breaking

Cause

A property on a type deriving from ComponentBase annotated with [Parameter] has a missing or non-public setters.

Rule description

Component parameters are required to have publicly accessible setters to allow the framework to assign values. All of the parameter declarations in the following example result in this diagnostic.

razor

```
@code
{
    [Parameter] int Parameter1 { get; set; }

    [Parameter] public int Parameter2 { get; }

    [Parameter] public int Parameter3 { get; private set; }
}
```

How to fix violations

- Make the property and its setter public.

razor

```
@code
{
    [Parameter] public int Parameter1 { get; set; }

    [Parameter] public int Parameter2 { get; set; }

    [Parameter] public int Parameter3 { get; set; }
}
```

- If making the property non-public is not possible, consider implementing SetParametersAsync manually.

When to suppress warnings

Do not suppress a warning from this rule.

BL0002: Component has multiple CaptureUnmatchedValues parameters

Article • 06/03/2022

Expand table

	Value
Rule ID	BL0002
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

More than one parameter on a type deriving from ComponentBase is annotated with `CaptureUnmatchedValues = true`.

Rule description

For a component, exactly one parameter is expected to have the CaptureUnmatchedValues set to `true`.

razor

```
@code
{
    [Parameter(CaptureUnmatchedValues = true)] public Dictionary<string,
object> Parameter1 { get; set; }

    [Parameter(CaptureUnmatchedValues = true)] public Dictionary<string,
object> Parameter2 { get; set; }
}
```

How to fix violations

Limit a single parameter to have `CaptureUnmatchedValues` set.

razor

```
@code
{
    [Parameter(CaptureUnmatchedValues = true)] public Dictionary<string,
object> Parameter1 { get; set; }

    [Parameter] public Dictionary<string, object> Parameter2 { get; set; }
}
```

When to suppress warnings

Do not suppress a warning from this rule.

BL0003: Component parameter with CaptureUnmatchedValues has the wrong type

Article • 06/03/2022

Expand table

	Value
Rule ID	BL0003
Category	Usage
Fix is breaking or non-breaking	Breaking

Cause

A parameter on a type deriving from ComponentBase annotated with CaptureUnmatchedValues `= true` is not assignable from `Dictionary<string, object>`

Rule description

Parameters annotated with `CaptureUnmatchedValues = true` must be able to receive a `Dictionary<string, object>` value.

razor

```
@code
{
    [Parameter(CaptureUnmatchedValues = true)] public IDictionary<string,
string> Attributes { get; set; }
}
```

How to fix violations

Change the type of the parameter to either `IDictionary<string, object>` or `Dictionary<string, object>`

razor

```
@code
{
    [Parameter(CaptureUnmatchedValues = true)] public IDictionary<string,
object> Attributes { get; set; }
}
```

When to suppress warnings

Do not suppress a warning from this rule.

BL0004: Component parameter should be public

Article • 06/03/2022

Expand table

	Value
Rule ID	BL0004
Category	Usage
Fix is breaking or non-breaking	Breaking

Cause

A property on a type deriving from ComponentBase annotated with [Parameter] is not public.

Rule description

Component parameters are required to be public and must have a public setter.

razor

```
@code
{
    [Parameter] int Parameter1 { get; set; }
}
```

How to fix violations

- Make the property and its setter public.

razor

```
@code
{
    [Parameter] public int Parameter1 { get; set; }
}
```

- If making the property non-public is not possible, consider implementing SetParametersAsync manually.

BL0005: Component parameter should not be set outside of its component

Article • 06/03/2022

Expand table

	Value
Rule ID	BL0005
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

A property on a type deriving from ComponentBase annotated with [Parameter] is being assigned to from outside the component.

Rule description

Component parameters should be assigned to as part of the component initialization or as part of `SetParametersAsync`. Assigning a value to a parameter from an external source results in the value being overwritten the next time the component renders.

How to fix violations

Consider using a distinct property to receive values from other components. Additional code can then be written to decide which of the two values to use in the component.

When to suppress warnings

Do not suppress a warning from this rule.

BL0006: Do not use RenderTree types

Article • 06/03/2022

Expand table

	Value
Rule ID	BL0006
Category	Usage
Fix is breaking or non-breaking	Non-breaking

Cause

A reference to a type in the Microsoft.AspNetCore.Components.RenderTree was found.

Rule description

Types in the `Microsoft.AspNetCore.Components.RenderTree` namespace are part of Blazor's implementation detail and are subject to breaking changes. Using these types is not recommended in user code.

How to fix violations

Remove the reference to the type.

When to suppress warnings

It is safe to suppress this rule if using this type is essential. Note that this these are subject to breaking changes between major releases.

MVC1000: Use of IHtmlHelper.Partial should be avoided

Article • 06/03/2022

Expand table

	Value
Rule ID	MVC1000
Fix is breaking or non-breaking	Non-breaking

Cause

The Partial or RenderPartial method was called or referenced.

Rule description

Rendering a partial using `IHtmlHelper.Partial` or `IHtmlHelper.RenderPartial` extension methods results in blocking calls. This may result in performance degradation and application dead locks issues due to thread pool starvation.

How to fix violations

- Use the PartialTagHelper
- Use the PartialAsync or RenderPartialAsync

When to suppress warnings

It's safe to suppress this rule if updating the application to use the suggested fixes is non-trivial. Before the validation is disabled, be sure to consider the risks of thread pool starvation to the application.

MVC1001: Filters cannot be applied to page handler methods

Article • 06/18/2024

Expand table

	Value
Rule ID	MVC1001
Fix is breaking or non-breaking	Non-breaking

Cause

An attribute implementing IFilterMetadata was applied to a Razor Page handler method.

Rule description

Razor Page handler methods are selected after MVC filter execution has started, and consequently cannot contribute filters to execute. Applying a filter to a Razor Page handler is unsupported and always incorrect.

C#

```
public class IndexModel : PageModel
{
    [MyFilter]
    public IActionResult OnGet() => Page();
}
```

How to fix violations

Remove the filter from the handler and apply it to the page model. If a filter has to be applied to a specific handler, consider using multiple Razor Pages.

C#

```
[MyFilter]
public class IndexModel : PageModel
{
```

```
    public IActionResult OnGet() => Page();
}
```

When to suppress warnings

Don't suppress warnings from this rule.

MVC1002: Route attribute cannot be applied to page handler methods

Article • 06/18/2024

Expand table

	Value
Rule ID	MVC1002
Fix is breaking or non-breaking	Non-breaking

Cause

An attribute implementing IRouteTemplateProvider was applied to a Razor Page handler method.

Rule description

Razor Page handler methods are selected after routing is completed, and consequently cannot contribute a route. Applying a route attribute such as `HttpGet` or `HttpPost` to a Razor Page handler is not supported.

C#

```
public class IndexModel : PageModel
{
    [HttpGet("/my-url")]
    public IActionResult OnGet() => Page();
}
```

How to fix violations

Remove the route attribute from the handler. Routes can be specified for a Razor Page using an `@page` directive or by using conventions. For more information, see custom routes in Razor Pages.

When to suppress warnings

Don't suppress warnings from this rule.

MVC1003: Route attributes cannot be applied to page models

Article • 06/18/2024

Expand table

	Value
Rule ID	MVC1003
Fix is breaking or non-breaking	Non-breaking

Cause

An attribute implementing IRouteTemplateProvider was applied to a Razor Page model.

Rule description

Razor Page models are identified after routing is completed, and consequently cannot contribute a route. Applying a route attribute such as `Route` to a Razor Page model is not supported.

C#

```
[Route("/my-page-route")]
public class IndexModel : PageModel
{
    public IActionResult OnGet() => Page();
}
```

How to fix violations

Remove the route attribute from the page model. Routes can be specified for a Razor Page using an `@page` directive or by using conventions. For more information, see custom routes in Razor Pages.

When to suppress warnings

Don't suppress warnings from this rule.

MVC1004: Rename model bound parameter

Article • 06/03/2022

Expand table

	Value
Rule ID	MVC1004
Fix is breaking or non-breaking	Breaking

Cause

A model bound parameter has the same name as one of its properties.

Rule description

Model binding a complex parameter with a property that has the same name may result in unexpected binding behavior. Consider renaming the parameter, or using a binding attribute to specify a different name.

Consider the following code:

C#

```
public class HomeController : Controller
{
    public IActionResult Get(SearchModel search)
    {
        ...
    }
}

public class SearcModel
{
    public string Search { get; set; }
}
```

In this model, the parameter and its property are both named `Search`, which results in model binding attempting to bind the property as `search.Search`. Naming a parameter

and its property the same prevents binding to a value without a prefix such as a query that looks like `?search=MySearchTerm`.

How to fix violations

- Rename the parameter if its prefix is not used during binding:

```
C#
```

```
public IActionResult Get(SearchModel model)
{
    ...
}
```

Renaming a parameter on a public type could be considered a breaking change since it changes a library's public API surface.

- If this is problematic, consider using a model binding attribute such as `Bind` to specify the model binding prefix:

```
C#
```

```
public IActionResult Get([Bind(Prefix = "")] SearchModel search)
{
    ...
}
```

When to suppress warnings

Warnings can be suppressed if you intend to use the parameter name as a prefix during model binding.

MVC1005: Cannot use UseMvc with Endpoint Routing

Article • 06/03/2022

Expand table

	Value
Rule ID	MVC1005
Fix is breaking or non-breaking	Non-breaking

Cause

UseMvc was invoked as part of startup.

Rule description

Using MVC via UseMvc or UseMvcWithDefaultRoute requires an explicit opt-in inside `Startup.ConfigureServices`. This is required because MVC must know whether it can rely on the authorization and CORS Middleware during initialization.

How to fix violations

If the app requires legacy IRouter support, disable EnableEndpointRoutingusing any of the following approaches in `Startup.ConfigureServices`:

C#

```
services.AddMvc(options => options.EnableEndpointRouting = false);
```

If legacy `IRouter` support is not required, replace the call to `UseMvc` with `UseEndpoints`. For more details, see the migration guide.

When to suppress warnings

Do not suppress a warning from this rule.

Collaborate with us on GitHub

The source for this content can be found on GitHub, where you can also create and review issues and pull requests. For more information, see our contributor guide.

MVC1006: Methods containing TagHelpers must be async and return Task

Article • 06/18/2024

Expand table

	Value
Rule ID	MVC1006
Fix is breaking or non-breaking	Breaking

Cause

A tag helper was defined inside a Razor function that executes synchronously

Rule description

Tag Helper execution is asynchronous. When used inside a method or a lambda within a Razor Page, the containing function must also be declared to be async.

Consider the following cshtml file:

razor

```
void Helper(string controller)
{
    <a asp-controller="@controller">Home</a>
}
```

`asp-controller` is a tag helper and will trigger this rule.

How to fix violations

Declare the function to be async and Task returning:

razor

```
async Task Helper(string controller)
{
    <a asp-controller="@controller">Home</a>
}
```

When to suppress warnings

Do not suppress a warning from this rule.

Razor Pages with Entity Framework Core in ASP.NET Core - Tutorial 1 of 8

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Tom Dykstra, Jeremy Likness, and Jon P Smith

This is the first in a series of tutorials that show how to use Entity Framework (EF) Core in an ASP.NET Core Razor Pages app. The tutorials build a web site for a fictional Contoso University. The site includes functionality such as student admission, course creation, and instructor assignments. The tutorial uses the code first approach. For information on following this tutorial using the database first approach, see this Github issue.

Download or view the completed app. Download instructions.

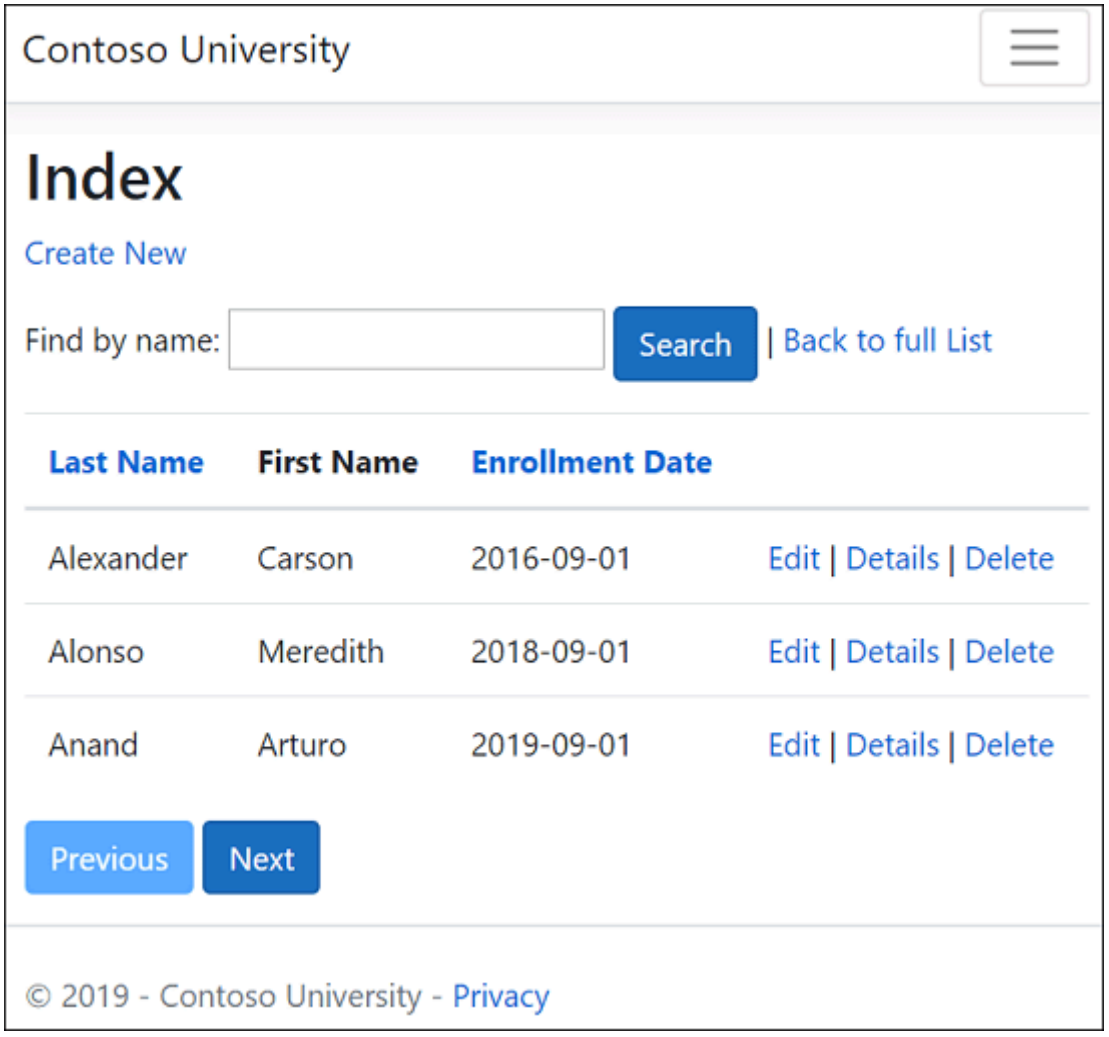
Prerequisites

- If you're new to Razor Pages, go through the Get started with Razor Pages tutorial series before starting this one.

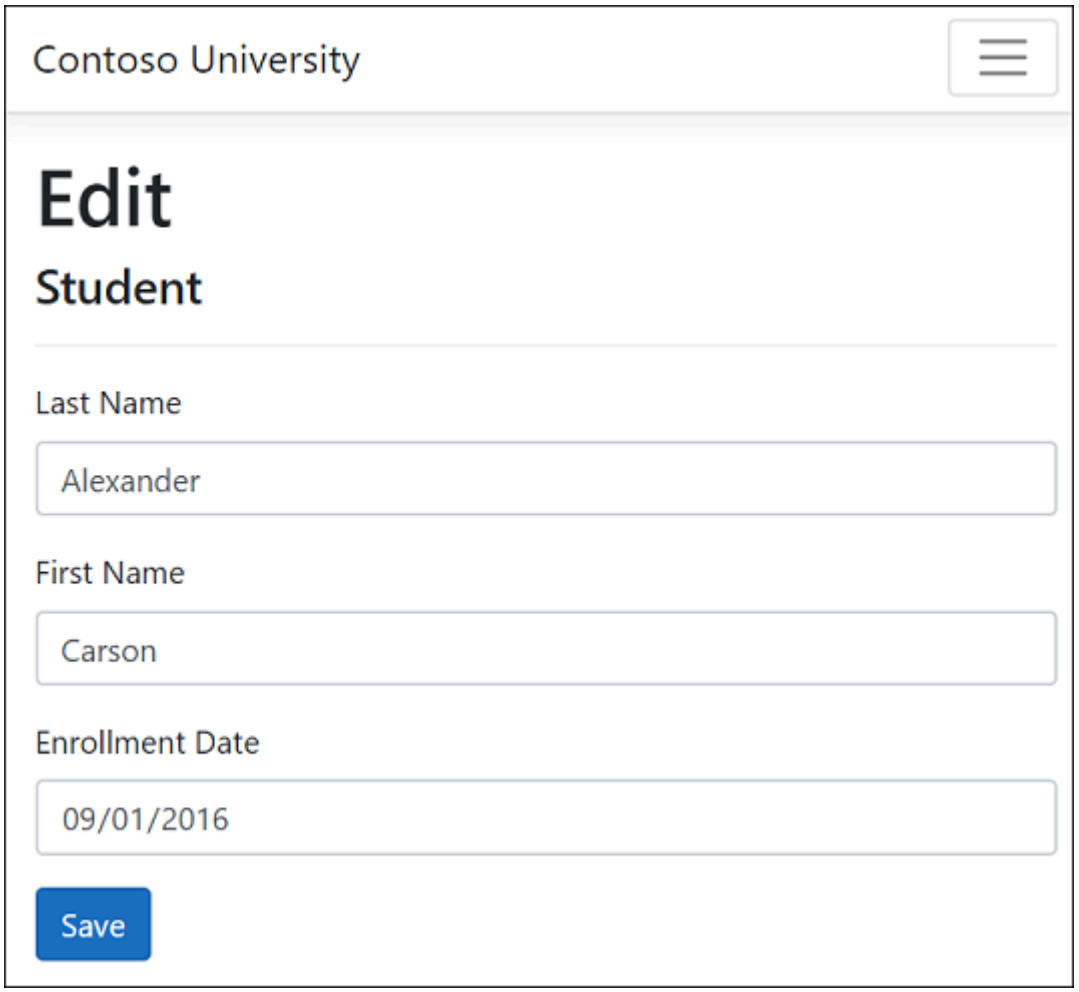
Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.
- .NET 6.0 SDK

Database engines



The Visual Studio instructions use SQL Server LocalDB, a version of SQL Server Express that runs only on Windows.



Troubleshooting

If you run into a problem you can't resolve, compare your code to the completed project. A good way to get help is by posting a question to StackOverflow.com, using the ASP.NET Core tag or the EF Core tag.

The sample app

The app built in these tutorials is a basic university web site. Users can view and update student, course, and instructor information. Here are a few of the screens created in the tutorial.

The UI style of this site is based on the built-in project templates. The tutorial's focus is on how to use EF Core with ASP.NET Core, not how to customize the UI.

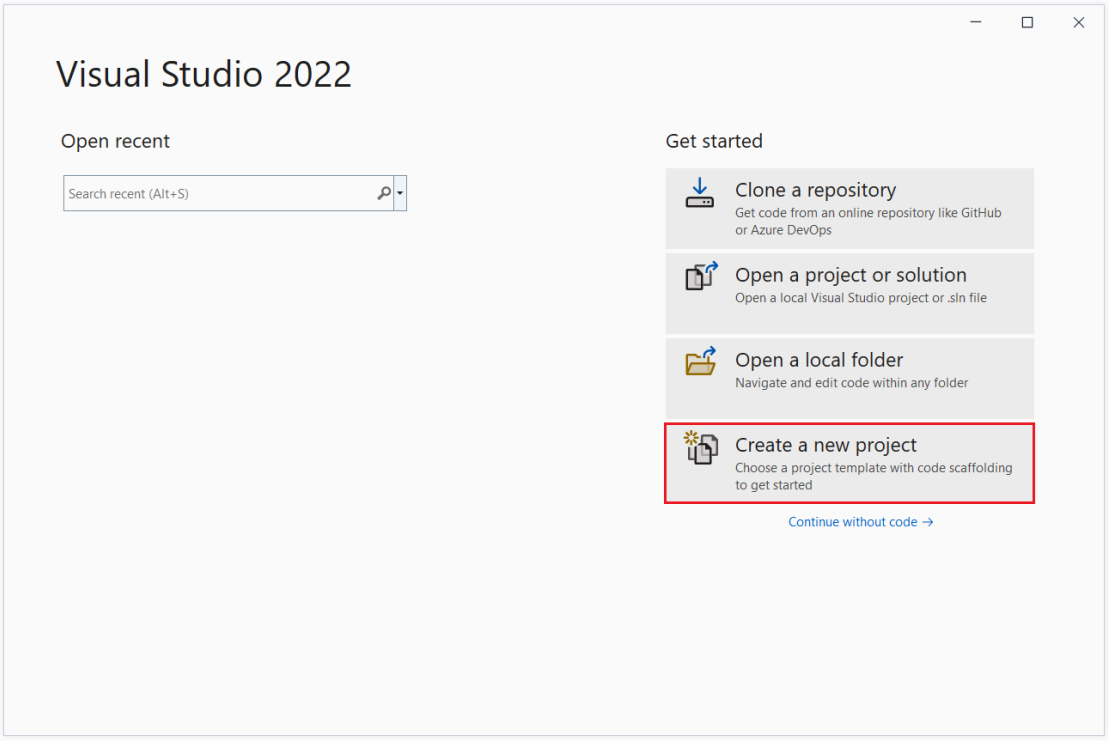
Optional: Build the sample download

This step is optional. Building the completed app is recommended when you have problems you can't solve. If you run into a problem you can't resolve, compare your code to the completed project. Download instructions.

Visual Studio

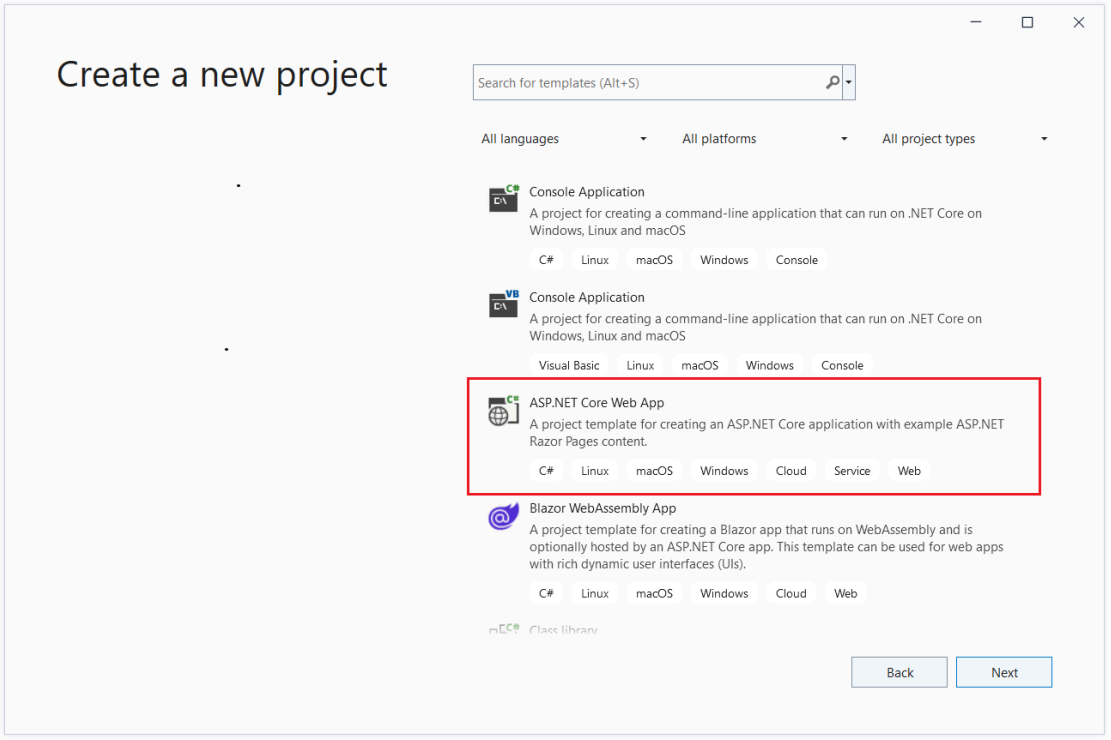
Select `ContosoUniversity.csproj` to open the project.

- Build the project.
- In Package Manager Console (PMC) run the following command:



```
PowerShell
Update-Database
```

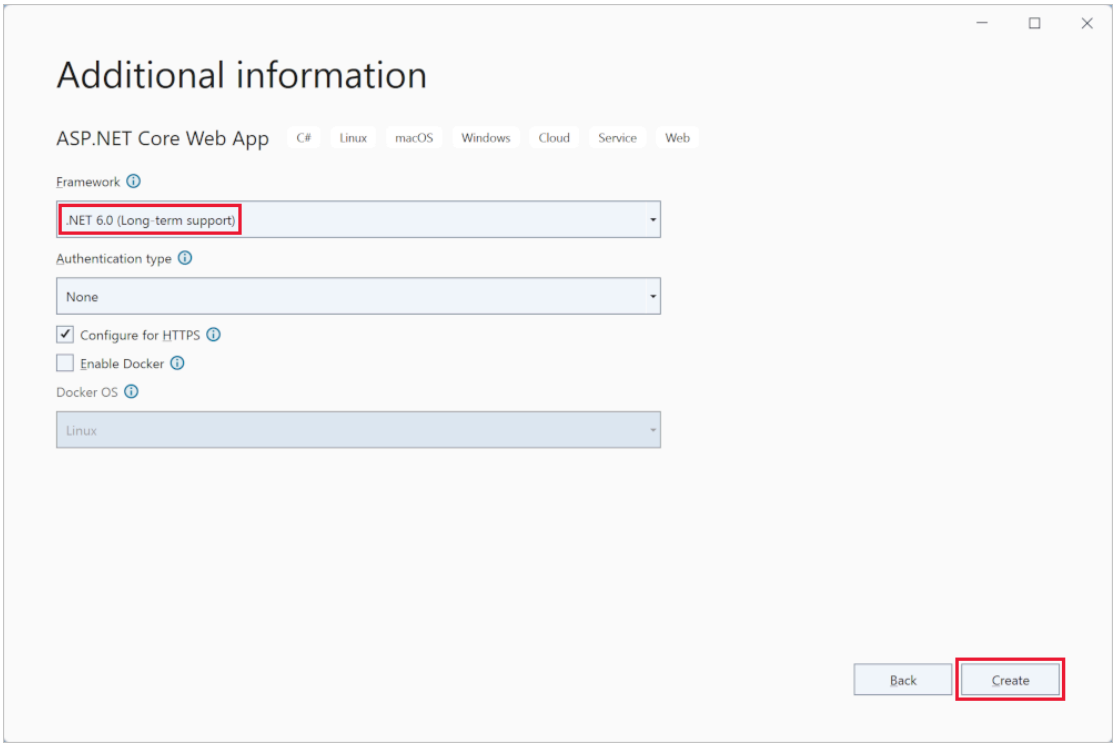
Run the project to seed the database.



Create the web app project

Visual Studio

1. Start Visual Studio 2022 and select **Create a new project**.



2. In the **Create a new project** dialog, select **ASP.NET Core Web App**, and then select **Next**.

3. In the **Configure your new project** dialog, enter `ContosoUniversity` for **Project name**. It's important to name the project *ContosoUniversity*, including matching the capitalization, so the namespaces will match when you copy and paste example code.

4. Select **Next**.

5. In the **Additional information** dialog, select **.NET 6.0 (Long-term support)** and then select **Create**.

Set up the site style

Copy and paste the following code into the `Pages/Shared/_Layout.cshtml` file:

CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Contoso University</title>

```

```
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/About">About</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Students/Index">Students</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Courses/Index">Courses</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Instructors/Index">Instructors</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
page="/Departments/Index">Departments</a>
                        </li>
                    </ul>
                </div>
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2021 - Contoso University - <a asp-area="" asp-
page="/Privacy">Privacy</a>
        </div>
    </footer>

    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>

    @await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```

The layout file sets the site header, footer, and menu. The preceding code makes the following changes:

- Each occurrence of "ContosoUniversity" to "Contoso University". There are three occurrences.
- The **Home** and **Privacy** menu entries are deleted.

- Entries are added for **About**, **Students**, **Courses**, **Instructors**, and **Departments**.

In `Pages/Index.cshtml`, replace the contents of the file with the following code:

CSHTML

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="row mb-auto">
    <div class="col-md-4">
        <div class="row no-gutters border mb-4">
            <div class="col p-4 mb-4 ">
                <p class="card-text">
                    Contoso University is a sample application that
                    demonstrates how to use Entity Framework Core in an
                    ASP.NET Core Razor Pages web app.
                </p>
            </div>
        </div>
    </div>
    <div class="col-md-4">

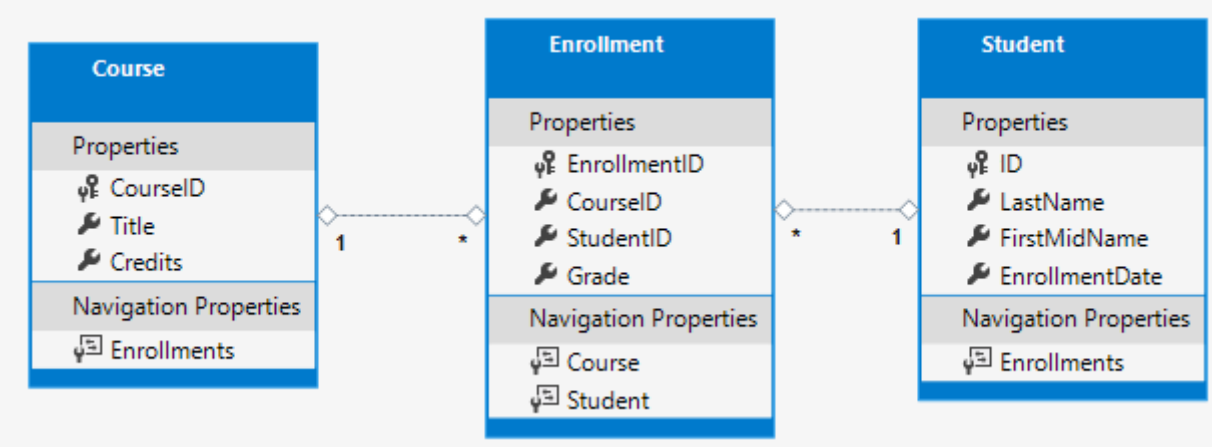
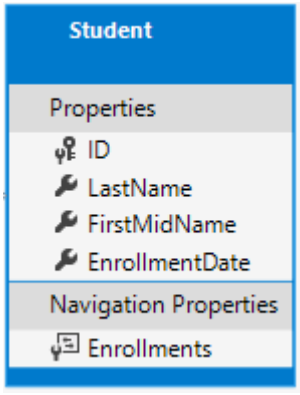
-rp/intro/samples" class="stretched-link">See project source code</a>
*@                  </p>
            </div>
        </div>
```



```
    </div>
</div>
```

The preceding code replaces the text about ASP.NET Core with text about this app.

Run the app to verify that the home page appears.



The data model

The following sections create a data model:

A student can enroll in any number of courses, and a course can have any number of students enrolled in it.

The Student entity

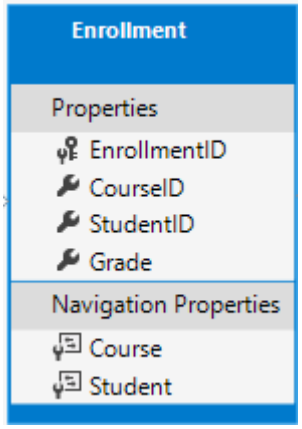
- Create a *Models* folder in the project folder.
- Create `Models/Student.cs` with the following code:

```
C#

namespace ContosoUniversity.Models
{
    public class Student
```

```
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```



The `ID` property becomes the primary key column of the database table that corresponds to this class. By default, EF Core interprets a property that's named `ID` or `classnameID` as the primary key. So the alternative automatically recognized name for the `Student` class primary key is `StudentID`. For more information, see EF Core - Keys.

The `Enrollments` property is a navigation property. Navigation properties hold other entities that are related to this entity. In this case, the `Enrollments` property of a `Student` entity holds all of the `Enrollment` entities that are related to that Student. For example, if a Student row in the database has two related Enrollment rows, the `Enrollments` navigation property contains those two Enrollment entities.

In the database, an Enrollment row is related to a Student row if its `StudentID` column contains the student's ID value. For example, suppose a Student row has ID=1. Related Enrollment rows will have `StudentID` = 1. `StudentID` is a *foreign key* in the Enrollment table.

The `Enrollments` property is defined as `ICollection<Enrollment>` because there may be multiple related Enrollment entities. Other collection types can be used, such as `List<Enrollment>` or `HashSet<Enrollment>`. When `ICollection<Enrollment>` is used, EF Core creates a `HashSet<Enrollment>` collection by default.

The Enrollment entity

Create `Models/Enrollment.cs` with the following code:

```
C#

using System.ComponentModel.DataAnnotations;

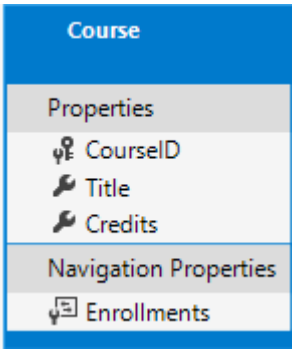
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property is the primary key; this entity uses the `classnameID` pattern instead of `ID` by itself. For a production data model, many developers choose one pattern and use it consistently. This tutorial uses both just to illustrate that both work. Using `ID` without `classname` makes it easier to implement some kinds of data model changes.

The `Grade` property is an `enum`. The question mark after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's null is different from a zero grade—null means a grade isn't known or hasn't been assigned yet.



The `StudentID` property is a foreign key, and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property contains a single `Student` entity.

The `CourseID` property is a foreign key, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

EF Core interprets a property as a foreign key if it's named `<navigation property name><primary key property name>`. For example, `StudentID` is the foreign key for the `Student` navigation property, since the `Student` entity's primary key is `ID`. Foreign key properties

can also be named `<primary key property name>`. For example, `CourseID` since the `Course` entity's primary key is `CourseID`.

The Course entity

Create `Models/Course.cs` with the following code:

C#

```
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

The `DatabaseGenerated` attribute allows the app to specify the primary key rather than having the database generate it.

Build the app. The compiler generates several warnings about how `null` values are handled. See this GitHub issue, Nullable reference types, and Tutorial: Express your design intent more clearly with nullable and non-nullable reference types for more information.

To eliminate the warnings from nullable reference types, remove the following line from the `ContosoUniversity.csproj` file:

XML

```
<Nullable>enable</Nullable>
```

The scaffolding engine currently does not support nullable reference types, therefore the models used in scaffold can't either.

Remove the `?` nullable reference type annotation from `public string? RequestId { get; set; }` in `Pages/Error.cshtml.cs` so the project builds without compiler warnings.

Scaffold Student pages

In this section, the ASP.NET Core scaffolding tool is used to generate:

- An EF Core `DbContext` class. The context is the main class that coordinates Entity Framework functionality for a given data model. It derives from the Microsoft.EntityFrameworkCore.DbContext class.
- Razor pages that handle Create, Read, Update, and Delete (CRUD) operations for the `Student` entity.

Visual Studio

- Create a *Pages/Students* folder.
- In **Solution Explorer**, right-click the *Pages/Students* folder and select **Add** > **New Scaffolded Item**.
- In the **Add New Scaffold Item** dialog:
  - In the left tab, select **Installed** > **Common** > **Razor Pages**
  - Select **Razor Pages using Entity Framework (CRUD)** > **ADD**.
- In the **Add Razor Pages using Entity Framework (CRUD)** dialog:
  - In the **Model class** drop-down, select **Student (ContosoUniversity.Models)**.
  - In the **Data context class** row, select the + (plus) sign.
    - Change the data context name to end in `SchoolContext` rather than `ContosoUniversityContext`. The updated context name: `ContosoUniversity.Data.SchoolContext`
    - Select **Add** to finish adding the data context class.
    - Select **Add** to finish the **Add Razor Pages** dialog.

The following packages are automatically installed:

- `Microsoft.EntityFrameworkCore.SqlServer`
- `Microsoft.EntityFrameworkCore.Tools`

- `Microsoft.VisualStudio.Web.CodeGeneration.Design`

If the preceding step fails, build the project and retry the scaffold step.

The scaffolding process:

- Creates Razor pages in the *Pages/Students* folder:
  - `Create.cshtml` and `Create.cshtml.cs`
  - `Delete.cshtml` and `Delete.cshtml.cs`
  - `Details.cshtml` and `Details.cshtml.cs`
  - `Edit.cshtml` and `Edit.cshtml.cs`
  - `Index.cshtml` and `Index.cshtml.cs`
- Creates `Data/SchoolContext.cs`.
- Adds the context to dependency injection in `Program.cs`.
- Adds a database connection string to `appsettings.json`.

Database connection string

The scaffolding tool generates a connection string in the `appsettings.json` file.

Visual Studio

The connection string specifies SQL Server LocalDB:

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "SchoolContext": "Server=
(localdb)\\mssqllocaldb;Database=SchoolContext-
0e9;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for app development, not production use. By default, LocalDB creates *.mdf*

files in the `C:/Users/<user>` directory.

Update the database context class

The main class that coordinates EF Core functionality for a given data model is the database context class. The context is derived from Microsoft.EntityFrameworkCore.DbContext. The context specifies which entities are included in the data model. In this project, the class is named `SchoolContext`.

Update `Data/SchoolContext.cs` with the following code:

C#

```
using Microsoft.EntityFrameworkCore;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext (DbContextOptions<SchoolContext> options)
            : base(options)
        {
        }

        public DbSet<Student> Students { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Course> Courses { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
        }
    }
}
```

The preceding code changes from the singular `DbSet<Student> Student` to the plural `DbSet<Student> Students`. To make the Razor Pages code match the new `DBSet` name, make a global change from: `_context.Student.` to: `_context.Students.`

There are 8 occurrences.

Because an entity set contains multiple entities, many developers prefer the `DBSet` property names should be plural.

The highlighted code:

- Creates a DbSet<TEntity> property for each entity set. In EF Core terminology:
  - An entity set typically corresponds to a database table.
  - An entity corresponds to a row in the table.
- Calls OnModelCreating. `OnModelCreating`:
  - Is called when `SchoolContext` has been initialized but before the model has been secured and used to initialize the context.
  - Is required because later in the tutorial the `Student` entity will have references to the other entities.

We hope to fix this issue in a future release.

Program.cs

ASP.NET Core is built with dependency injection. Services such as the `SchoolContext` are registered with dependency injection during app startup. Components that require these services, such as Razor Pages, are provided these services via constructor parameters. The constructor code that gets a database context instance is shown later in the tutorial.

The scaffolding tool automatically registered the context class with the dependency injection container.

Visual Studio

The following highlighted lines were added by the scaffolder:

C#

```
using ContosoUniversity.Data;
using Microsoft.EntityFrameworkCore;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddDbContext<SchoolContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("SchoolCo
ntext")));
```

The name of the connection string is passed in to the context by calling a method on a DbContextOptions object. For local development, the ASP.NET Core configuration

system reads the connection string from the `appsettings.json` or the `appsettings.Development.json` file.

Add the database exception filter

Add AddDatabaseDeveloperPageExceptionFilter and UseMigrationsEndPoint as shown in the following code:

Visual Studio

C#

```
using ContosoUniversity.Data;
using Microsoft.EntityFrameworkCore;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddDbContext<SchoolContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("SchoolCo
ntext")));

builder.Services.AddDatabaseDeveloperPageExceptionFilter();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
else
{
    app.UseDeveloperExceptionPage();
    app.UseMigrationsEndPoint();
}
```

Add the Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore NuGet package.

In the Package Manager Console, enter the following to add the NuGet package:

PowerShell

```
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
```

The `Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore` NuGet package provides ASP.NET Core middleware for Entity Framework Core error pages. This middleware helps to detect and diagnose errors with Entity Framework Core migrations.

The `AddDatabaseDeveloperPageExceptionFilter` provides helpful error information in the development environment for EF migrations errors.

Create the database

Update `Program.cs` to create the database if it doesn't exist:

Visual Studio

C#

```
using ContosoUniversity.Data;
using Microsoft.EntityFrameworkCore;
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddDbContext<SchoolContext>(options =>

options.UseSqlServer(builder.Configuration.GetConnectionString("SchoolCo
ntext")));

builder.Services.AddDatabaseDeveloperPageExceptionFilter();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}
else
{
    app.UseDeveloperExceptionPage();
    app.UseMigrationsEndPoint();
}

using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;

    var context = services.GetRequiredService<SchoolContext>();
    context.Database.EnsureCreated();
    // DbInitializer.Initialize(context);
}
```

```
app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

The EnsureCreated method takes no action if a database for the context exists. If no database exists, it creates the database and schema. `EnsureCreated` enables the following workflow for handling data model changes:

- Delete the database. Any existing data is lost.
- Change the data model. For example, add an `EmailAddress` field.
- Run the app.
- `EnsureCreated` creates a database with the new schema.

This workflow works early in development when the schema is rapidly evolving, as long as data doesn't need to be preserved. The situation is different when data that has been entered into the database needs to be preserved. When that is the case, use migrations.

Later in the tutorial series, the database is deleted that was created by `EnsureCreated` and migrations is used. A database that is created by `EnsureCreated` can't be updated by using migrations.

Test the app

- Run the app.
- Select the **Students** link and then **Create New**.
- Test the Edit, Details, and Delete links.

Seed the database

The `EnsureCreated` method creates an empty database. This section adds code that populates the database with test data.

Create `Data/DbInitializer.cs` with the following code:

```
C#
```

```
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new
Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.P
arse("2019-09-01")},
                new
Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Pa
rse("2017-09-01")},
                new
Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse
("2018-09-01")},
                new
Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Pa
rse("2017-09-01")},
                new
Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2017
-09-01")},
                new
Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Pars
e("2016-09-01")},
                new
Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse
("2018-09-01")},
                new
Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Pars
e("2019-09-01")}
            };

            context.Students.AddRange(students);
            context.SaveChanges();

            var courses = new Course[]
            {
                new Course{CourseID=1050,Title="Chemistry",Credits=3},
                new Course{CourseID=4022,Title="Microeconomics",Credits=3},
                new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
                new Course{CourseID=1045,Title="Calculus",Credits=4},
                new Course{CourseID=3141,Title="Trigonometry",Credits=4},
                new Course{CourseID=2021,Title="Composition",Credits=3},
                new Course{CourseID=2042,Title="Literature",Credits=4}
```

```
            };

            context.Courses.AddRange(courses);
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
                new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
                new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
                new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
                new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
                new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
                new Enrollment{StudentID=3,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=1050},
                new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
                new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
                new Enrollment{StudentID=6,CourseID=1045},
                new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };

            context.Enrollments.AddRange(enrollments);
            context.SaveChanges();
        }
    }
}
```

The code checks if there are any students in the database. If there are no students, it adds test data to the database. It creates the test data in arrays rather than `List<T>` collections to optimize performance.

- In `Program.cs`, remove `//` from the `DbInitializer.Initialize` line:

C#

```
using (var scope = app.Services.CreateScope())
{
    var services = scope.ServiceProvider;

    var context = services.GetRequiredService<SchoolContext>();
    context.Database.EnsureCreated();
    DbInitializer.Initialize(context);
}
```

Visual Studio

- Stop the app if it's running, and run the following command in the **Package Manager Console** (PMC):

PowerShell

```
Drop-Database -Confirm
```

- Respond with `Y` to delete the database.

- Restart the app.
- Select the Students page to see the seeded data.

View the database

Visual Studio

- Open **SQL Server Object Explorer** (SSOX) from the **View** menu in Visual Studio.
- In SSOX, select **(localdb)\MSSQLLocalDB** > **Databases** > **SchoolContext-{GUID}**. The database name is generated from the context name provided earlier plus a dash and a GUID.
- Expand the **Tables** node.
- Right-click the **Student** table and click **View Data** to see the columns created and the rows inserted into the table.
- Right-click the **Student** table and click **View Code** to see how the `Student` model maps to the `Student` table schema.

Asynchronous EF methods in ASP.NET Core web apps

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't doing work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server can handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time. For low traffic situations, the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, the async keyword, `Task` return value, `await` keyword, and `ToListAsync` method make the code execute asynchronously.

```
C#

public async Task OnGetAsync()
{
    Students = await _context.Students.ToListAsync();
}
```

- The `async` keyword tells the compiler to:
  - Generate callbacks for parts of the method body.
  - Create the Task object that's returned.
- The `Task` return type represents ongoing work.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when writing asynchronous code that uses EF Core:

- Only statements that cause queries or commands to be sent to the database are executed asynchronously. That includes `ToListAsync`, `SingleOrDefaultAsync`, `FirstOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF Core context isn't thread safe: don't try to do multiple operations in parallel.
- To take advantage of the performance benefits of async code, verify that library packages (such as for paging) use async if they call EF Core methods that send queries to the database.

For more information about asynchronous programming in .NET, see Async Overview and Asynchronous programming with async and await.

> ⚠ **Warning**
>
> The async implementation of Microsoft.Data.SqlClient has some known issues (#593, #601, and others). If you're seeing unexpected performance problems,

try using sync command execution instead, especially when dealing with large text or binary values.

Performance considerations

In general, a web page shouldn't be loading an arbitrary number of rows. A query should use paging or a limiting approach. For example, the preceding query could use `Take` to limit the rows returned:

C#

```
public async Task OnGetAsync()
{
    Student = await _context.Students.Take(10).ToListAsync();
}
```

Enumerating a large table in a view could return a partially constructed HTTP 200 response if a database exception occurs part way through the enumeration.

Paging is covered later in the tutorial.

For more information, see Performance considerations (EF).

By Tom Dykstra, Jeremy Likness, and Jon P Smith

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

In this tutorial, the scaffolded CRUD (create, read, update, delete) code is reviewed and customized.

No repository

Some developers use a service layer or repository pattern to create an abstraction layer between the UI (Razor Pages) and the data access layer. This tutorial doesn't do that. To minimize complexity and keep the tutorial focused on EF Core, EF Core code is added directly to the page model classes.

Update the Details page

The scaffolded code for the Students pages doesn't include enrollment data. In this section, enrollments are added to the `Details` page.

Read enrollments

To display a student's enrollment data on the page, the enrollment data must be read. The scaffolded code in `Pages/Students/Details.cshtml.cs` reads only the `Student` data, without the `Enrollment` data:

C#

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Students.FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}
```

Replace the `OnGetAsync` method with the following code to read enrollment data for the selected student. The changes are highlighted.

C#

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    Student = await _context.Students
        .Include(s => s.Enrollments)
        .ThenInclude(e => e.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}
```

The Include and ThenInclude methods cause the context to load the `Student.Enrollments` navigation property, and within each enrollment the

`Enrollment.Course` navigation property. These methods are examined in detail in the Read related data tutorial.

The AsNoTracking method improves performance in scenarios where the entities returned are not updated in the current context. `AsNoTracking` is discussed later in this tutorial.

Display enrollments

Replace the code in `Pages/Students/Details.cshtml` with the following code to display a list of enrollments. The changes are highlighted.

CSHTML

```
@page
@model ContosoUniversity.Pages.Students.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Student</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.LastName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.LastName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.FirstMidName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.FirstMidName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.EnrollmentDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.EnrollmentDate)
        </dd>
```

```
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.Enrollments)
        </dt>
        <dd class="col-sm-10">
            <table class="table">
                <tr>
                    <th>Course Title</th>
                    <th>Grade</th>
                </tr>
                @foreach (var item in Model.Student.Enrollments)
                {
                    <tr>
                        <td>
                            @Html.DisplayFor(modelItem => item.Course.Title)
                        </td>
                        <td>
                            @Html.DisplayFor(modelItem => item.Grade)
                        </td>
                    </tr>
                }
            </table>
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Student.ID">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

The preceding code loops through the entities in the `Enrollments` navigation property. For each enrollment, it displays the course title and the grade. The course title is retrieved from the `Course` entity that's stored in the `Course` navigation property of the Enrollments entity.

Run the app, select the **Students** tab, and click the **Details** link for a student. The list of courses and grades for the selected student is displayed.

Ways to read one entity

The generated code uses FirstOrDefaultAsync to read one entity. This method returns null if nothing is found; otherwise, it returns the first row found that satisfies the query filter criteria. `FirstOrDefaultAsync` is generally a better choice than the following alternatives:

- SingleOrDefaultAsync - Throws an exception if there's more than one entity that satisfies the query filter. To determine if more than one row could be returned by the query, `SingleOrDefaultAsync` tries to fetch multiple rows. This extra work is

unnecessary if the query can only return one entity, as when it searches on a unique key.

- FindAsync - Finds an entity with the primary key (PK). If an entity with the PK is being tracked by the context, it's returned without a request to the database. This method is optimized to look up a single entity, but you can't call `Include` with `FindAsync`. So if related data is needed, `FirstOrDefaultAsync` is the better choice.

Route data vs. query string

The URL for the Details page is `https://localhost:<port>/Students/Details?id=1`. The entity's primary key value is in the query string. Some developers prefer to pass the key value in route data: `https://localhost:<port>/Students/Details/1`. For more information, see Update the generated code.

Update the Create page

The scaffolded `OnPostAsync` code for the Create page is vulnerable to overposting. Replace the `OnPostAsync` method in `Pages/Students/Create.cshtml.cs` with the following code.

C#

```
public async Task<IActionResult> OnPostAsync()
{
    var emptyStudent = new Student();

    if (await TryUpdateModelAsync<Student>(
        emptyStudent,
        "student",   // Prefix for form value.
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        _context.Students.Add(emptyStudent);
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }

    return Page();
}
```

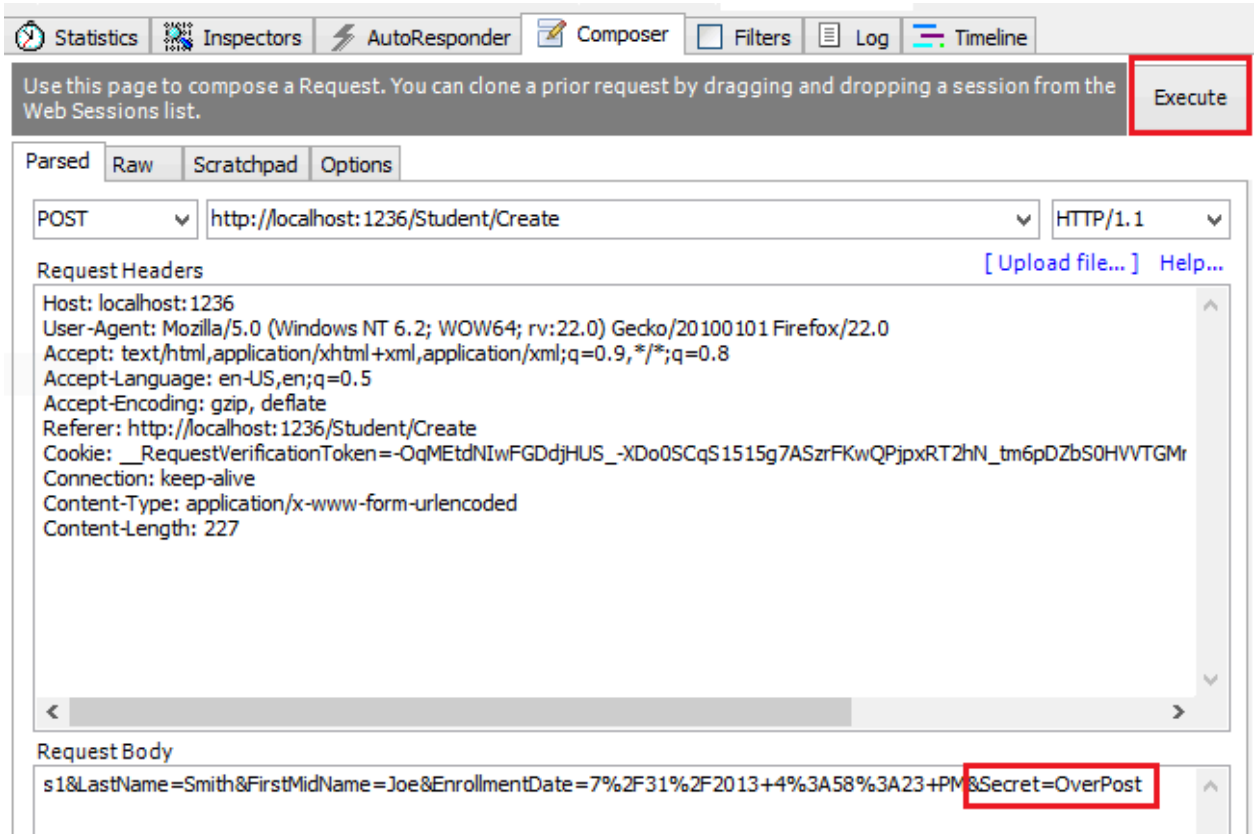
TryUpdateModelAsync

The preceding code creates a Student object and then uses posted form fields to update the Student object's properties. The TryUpdateModelAsync method:

- Uses the posted form values from the PageContext property in the PageModel.
- Updates only the properties listed (`s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate`).
- Looks for form fields with a "student" prefix. For example, `Student.FirstMidName`. It's not case sensitive.
- Uses the model binding system to convert form values from strings to the types in the `Student` model. For example, `EnrollmentDate` is converted to `DateTime`.

Run the app, and create a student entity to test the Create page.

Overposting



Using `TryUpdateModel` to update fields with posted values is a security best practice because it prevents overposting. For example, suppose the Student entity includes a `Secret` property that this web page shouldn't update or add:

C#

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }
}
```

Even if the app doesn't have a `Secret` field on the create or update Razor Page, a hacker could set the `Secret` value by overposting. A hacker could use a tool such as Fiddler, or write some JavaScript, to post a `Secret` form value. The original code doesn't limit the fields that the model binder uses when it creates a Student instance.

Whatever value the hacker specified for the `Secret` form field is updated in the database. The following image shows the Fiddler tool adding the `Secret` field, with the value "OverPost", to the posted form values.

The value "OverPost" is successfully added to the `Secret` property of the inserted row. That happens even though the app designer never intended the `Secret` property to be set with the Create page.

View model

View models provide an alternative way to prevent overposting.

The application model is often called the domain model. The domain model typically contains all the properties required by the corresponding entity in the database. The view model contains only the properties needed for the UI page, for example, the Create page.

In addition to the view model, some apps use a binding model or input model to pass data between the Razor Pages page model class and the browser.

Consider the following `StudentVM` view model:

C#

```
public class StudentVM
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
```

```
    public DateTime EnrollmentDate { get; set; }
}
```

The following code uses the `StudentVM` view model to create a new student:

C#

```
[BindProperty]
public StudentVM StudentVM { get; set; }

public async Task<IActionResult> OnPostAsync()
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    var entry = _context.Add(new Student());
    entry.CurrentValues.SetValues(StudentVM);
    await _context.SaveChangesAsync();
    return RedirectToPage("./Index");
}
```

The SetValues method sets the values of this object by reading values from another PropertyValues object. `SetValues` uses property name matching. The view model type:

- Doesn't need to be related to the model type.
- Needs to have properties that match.

Using `StudentVM` requires the Create page use `StudentVM` rather than `Student`:

CSHTML

```
@page
@model CreateVMModel

@{
    ViewData["Title"] = "Create";
}

<h1>Create</h1>

<h4>Student</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
```

```
                <label asp-for="StudentVM.LastName" class="control-label">
</label>
                <input asp-for="StudentVM.LastName" class="form-control" />
                <span asp-validation-for="StudentVM.LastName" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="StudentVM.FirstMidName" class="control-
label"></label>
                <input asp-for="StudentVM.FirstMidName" class="form-control"
/>
                <span asp-validation-for="StudentVM.FirstMidName"
class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="StudentVM.EnrollmentDate" class="control-
label"></label>
                <input asp-for="StudentVM.EnrollmentDate" class="form-
control" />
                <span asp-validation-for="StudentVM.EnrollmentDate"
class="text-danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary"
/>
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Update the Edit page

In `Pages/Students/Edit.cshtml.cs`, replace the `OnGetAsync` and `OnPostAsync` methods with the following code.

C#

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
    {
        return NotFound();
    }
```

```
    Student = await _context.Students.FindAsync(id);

    if (Student == null)
    {
        return NotFound();
    }
    return Page();
}

public async Task<IActionResult> OnPostAsync(int id)
{
    var studentToUpdate = await _context.Students.FindAsync(id);

    if (studentToUpdate == null)
    {
        return NotFound();
    }

    if (await TryUpdateModelAsync<Student>(
        studentToUpdate,
        "student",
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }

    return Page();
}
```

The code changes are similar to the Create page with a few exceptions:

- `FirstOrDefaultAsync` has been replaced with FindAsync. When you don't have to include related data, `FindAsync` is more efficient.
- `OnPostAsync` has an `id` parameter.
- The current student is fetched from the database, rather than creating an empty student.

Run the app, and test it by creating and editing a student.

Entity States

The database context keeps track of whether entities in memory are in sync with their corresponding rows in the database. This tracking information determines what happens when SaveChangesAsync is called. For example, when a new entity is passed to the AddAsync method, that entity's state is set to Added. When `SaveChangesAsync` is called, the database context issues a SQL `INSERT` command.

An entity may be in one of the following states:

- `Added`: The entity doesn't yet exist in the database. The `SaveChanges` method issues an `INSERT` statement.
- `Unchanged`: No changes need to be saved with this entity. An entity has this status when it's read from the database.
- `Modified`: Some or all of the entity's property values have been modified. The `SaveChanges` method issues an `UPDATE` statement.
- `Deleted`: The entity has been marked for deletion. The `SaveChanges` method issues a `DELETE` statement.
- `Detached`: The entity isn't being tracked by the database context.

In a desktop app, state changes are typically set automatically. An entity is read, changes are made, and the entity state is automatically changed to `Modified`. Calling `SaveChanges` generates a SQL `UPDATE` statement that updates only the changed properties.

In a web app, the `DbContext` that reads an entity and displays the data is disposed after a page is rendered. When a page's `OnPostAsync` method is called, a new web request is made and with a new instance of the `DbContext`. Rereading the entity in that new context simulates desktop processing.

Update the Delete page

In this section, a custom error message is implemented when the call to `SaveChanges` fails.

Replace the code in `Pages/Students/Delete.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.Logging;
using System;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
```

```
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;
        private readonly ILogger<DeleteModel> _logger;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context,
                           ILogger<DeleteModel> logger)
        {
            _context = context;
            _logger = logger;
        }

        [BindProperty]
        public Student Student { get; set; }
        public string ErrorMessage { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id, bool?
saveChangesError = false)
        {
            if (id == null)
            {
                return NotFound();
            }

            Student = await _context.Students
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.ID == id);

            if (Student == null)
            {
                return NotFound();
            }

            if (saveChangesError.GetValueOrDefault())
            {
                ErrorMessage = String.Format("Delete {ID} failed. Try
again", id);
            }

            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            var student = await _context.Students.FindAsync(id);

            if (student == null)
            {
                return NotFound();
            }
```

```
            try
            {
                _context.Students.Remove(student);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            catch (DbUpdateException ex)
            {
                _logger.LogError(ex, ErrorMessage);

                return RedirectToAction("./Delete",
                                        new { id, saveChangesError = true });
            }
        }
    }
}
```

The preceding code:

- Adds Logging.
- Adds the optional parameter `saveChangesError` to the `OnGetAsync` method signature. `saveChangesError` indicates whether the method was called after a failure to delete the student object.

The delete operation might fail because of transient network problems. Transient network errors are more likely when the database is in the cloud. The `saveChangesError` parameter is `false` when the Delete page `OnGetAsync` is called from the UI. When `OnGetAsync` is called by `OnPostAsync` because the delete operation failed, the `saveChangesError` parameter is `true`.

The `OnPostAsync` method retrieves the selected entity, then calls the Remove method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL `DELETE` command is generated. If `Remove` fails:

- The database exception is caught.
- The Delete pages `OnGetAsync` method is called with `saveChangesError=true`.

Add an error message to `Pages/Students/Delete.cshtml`:

CSHTML

```
@page
@model ContosoUniversity.Pages.Students.DeleteModel

@{
    ViewData["Title"] = "Delete";
}
```

```
<h1>Delete</h1>

<p class="text-danger">@Model.ErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Student</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.LastName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.LastName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.FirstMidName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.FirstMidName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Student.EnrollmentDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Student.EnrollmentDate)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Student.ID" />
        <input type="submit" value="Delete" class="btn btn-danger" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

Run the app and delete a student to test the Delete page.

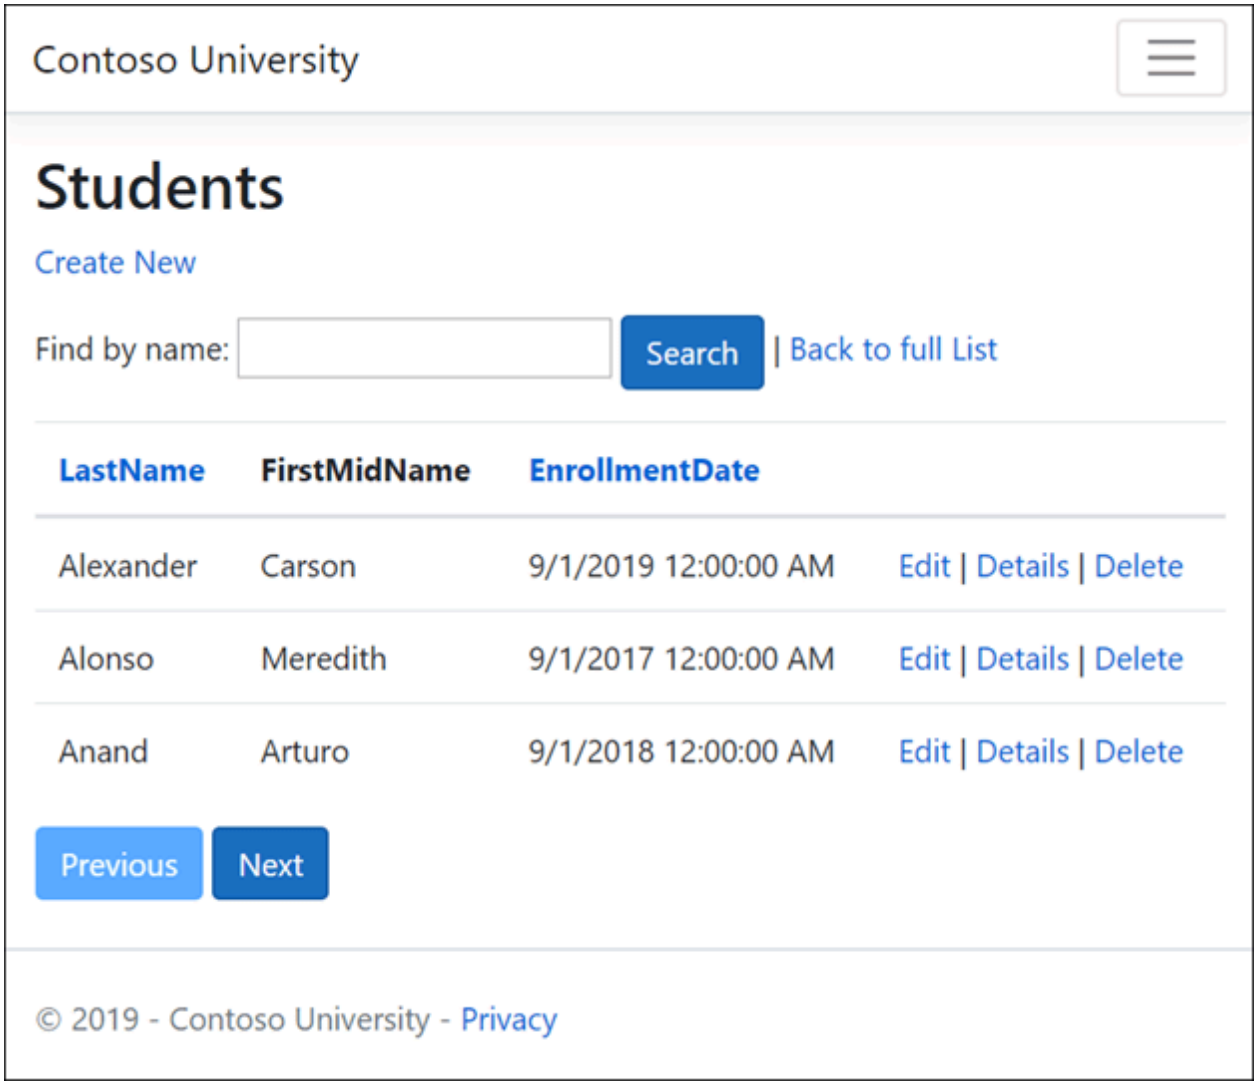
Part 3, Razor Pages with EF Core in ASP.NET Core - Sort, Filter, Paging

Article • 04/10/2024



By Tom Dykstra, Jeremy Likness, and Jon P Smith

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial adds sorting, filtering, and paging functionality to the Students pages.

The following illustration shows a completed page. The column headings are clickable links to sort the column. Click a column heading repeatedly to switch between ascending and descending sort order.

Add sorting

Replace the code in `Pages/Students/Index.cshtml.cs` with the following code to add sorting.

C#

```
public class IndexModel : PageModel
{
    private readonly SchoolContext _context;
    public IndexModel(SchoolContext context)
    {
        _context = context;
    }

    public string NameSort { get; set; }
    public string DateSort { get; set; }
    public string CurrentFilter { get; set; }
    public string CurrentSort { get; set; }

    public IList<Student> Students { get; set; }

    public async Task OnGetAsync(string sortOrder)
    {
        // using System;
        NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
        DateSort = sortOrder == "Date" ? "date_desc" : "Date";

        IQueryable<Student> studentsIQ = from s in _context.Students
                                         select s;

        switch (sortOrder)
        {
            case "name_desc":
                studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
                break;
            case "Date":
                studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                break;
            case "date_desc":
                studentsIQ = studentsIQ.OrderByDescending(s =>
s.EnrollmentDate);
                break;
            default:
                studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                break;
        }

        Students = await studentsIQ.AsNoTracking().ToListAsync();
    }
}
```

The preceding code:

- Requires adding `using System;`.
- Adds properties to contain the sorting parameters.
- Changes the name of the `Student` property to `Students`.
- Replaces the code in the `OnGetAsync` method.

The `OnGetAsync` method receives a `sortOrder` parameter from the query string in the URL. The URL and query string is generated by the Anchor Tag Helper.

The `sortOrder` parameter is either `Name` or `Date`. The `sortOrder` parameter is optionally followed by `_desc` to specify descending order. The default sort order is ascending.

When the Index page is requested from the **Students** link, there's no query string. The students are displayed in ascending order by last name. Ascending order by last name is the `default` in the `switch` statement. When the user clicks a column heading link, the appropriate `sortOrder` value is provided in the query string value.

`NameSort` and `DateSort` are used by the Razor Page to configure the column heading hyperlinks with the appropriate query string values:

```
C#
```

```
NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
DateSort = sortOrder == "Date" ? "date_desc" : "Date";
```

The code uses the C# conditional operator ?:. The `?:` operator is a ternary operator, it takes three operands. The first line specifies that when `sortOrder` is null or empty, `NameSort` is set to `name_desc`. If `sortOrder` is ***not*** null or empty, `NameSort` is set to an empty string.

These two statements enable the page to set the column heading hyperlinks as follows:

Expand table

Current sort order	Last Name Hyperlink	Date Hyperlink
Last Name ascending	descending	ascending
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code initializes an `IQueryable<Student>` before the switch statement, and modifies it in the switch statement:

C#

```
IQueryable<Student> studentsIQ = from s in _context.Students
                                 select s;

switch (sortOrder)
{
    case "name_desc":
        studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
        break;
    case "Date":
        studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
        break;
    case "date_desc":
        studentsIQ = studentsIQ.OrderByDescending(s => s.EnrollmentDate);
        break;
    default:
        studentsIQ = studentsIQ.OrderBy(s => s.LastName);
        break;
}

Students = await studentsIQ.AsNoTracking().ToListAsync();
```

When an `IQueryable` is created or modified, no query is sent to the database. The query isn't executed until the `IQueryable` object is converted into a collection. `IQueryable` are converted to a collection by calling a method such as `ToListAsync`. Therefore, the `IQueryable` code results in a single query that's not executed until the following statement:

C#

```
Students = await studentsIQ.AsNoTracking().ToListAsync();
```

`OnGetAsync` could get verbose with a large number of sortable columns. For information about an alternative way to code this functionality, see Use dynamic LINQ to simplify code in the MVC version of this tutorial series.

Add column heading hyperlinks to the Student Index page

Replace the code in `Students/Index.cshtml`, with the following code. The changes are highlighted.

CSHTML

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>
<p>
    <a asp-page="Create">Create New</a>
</p>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort">
                    @Html.DisplayNameFor(model =>
model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model =>
model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort">
                    @Html.DisplayNameFor(model =>
model.Students[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
```

```
                    <a asp-page="./Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

The preceding code:

- Adds hyperlinks to the `LastName` and `EnrollmentDate` column headings.
- Uses the information in `NameSort` and `DateSort` to set up hyperlinks with the current sort order values.
- Changes the page heading from Index to Students.
- Changes `Model.Student` to `Model.Students`.

To verify that sorting works:

- Run the app and select the **Students** tab.
- Click the column headings.

Add filtering

To add filtering to the Students Index page:

- A text box and a submit button is added to the Razor Page. The text box supplies a search string on the first or last name.
- The page model is updated to use the text box value.

Update the OnGetAsync method

Replace the code in `Students/Index.cshtml.cs` with the following code to add filtering:

C#

```
public class IndexModel : PageModel
{
    private readonly SchoolContext _context;

    public IndexModel(SchoolContext context)
    {
        _context = context;
    }
```

```
    public string NameSort { get; set; }
    public string DateSort { get; set; }
    public string CurrentFilter { get; set; }
    public string CurrentSort { get; set; }

    public IList<Student> Students { get; set; }

    public async Task OnGetAsync(string sortOrder, string searchString)
    {
        NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
        DateSort = sortOrder == "Date" ? "date_desc" : "Date";

        CurrentFilter = searchString;

        IQueryable<Student> studentsIQ = from s in _context.Students
                                         select s;
        if (!String.IsNullOrEmpty(searchString))
        {
            studentsIQ = studentsIQ.Where(s =>
s.LastName.Contains(searchString)
                                   ||
s.FirstMidName.Contains(searchString));
        }

        switch (sortOrder)
        {
            case "name_desc":
                studentsIQ = studentsIQ.OrderByDescending(s => s.LastName);
                break;
            case "Date":
                studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                break;
            case "date_desc":
                studentsIQ = studentsIQ.OrderByDescending(s =>
s.EnrollmentDate);
                break;
            default:
                studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                break;
        }

        Students = await studentsIQ.AsNoTracking().ToListAsync();
    }
}
```

The preceding code:

- Adds the `searchString` parameter to the `OnGetAsync` method, and saves the parameter value in the `CurrentFilter` property. The search string value is received from a text box that's added in the next section.
- Adds to the LINQ statement a `Where` clause. The `Where` clause selects only students whose first name or last name contains the search string. The LINQ statement is

executed only if there's a value to search for.

IQueryable vs. IEnumerable

The code calls the Where method on an `IQueryable` object, and the filter is processed on the server. In some scenarios, the app might be calling the `Where` method as an extension method on an in-memory collection. For example, suppose `_context.Students` changes from EF Core `DbSet` to a repository method that returns an `IEnumerable` collection. The result would normally be the same but in some cases may be different.

For example, the .NET Framework implementation of `Contains` performs a case-sensitive comparison by default. In SQL Server, `Contains` case-sensitivity is determined by the collation setting of the SQL Server instance. SQL Server defaults to case-insensitive. SQLite defaults to case-sensitive. `ToUpper` could be called to make the test explicitly case-insensitive:

```
C#

Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())`
```

The preceding code would ensure that the filter is case-insensitive even if the `Where` method is called on an `IEnumerable` or runs on SQLite.

When `Contains` is called on an `IEnumerable` collection, the .NET Core implementation is used. When `Contains` is called on an `IQueryable` object, the database implementation is used.

Calling `Contains` on an `IQueryable` is usually preferable for performance reasons. With `IQueryable`, the filtering is done by the database server. If an `IEnumerable` is created first, all the rows have to be returned from the database server.

There's a performance penalty for calling `ToUpper`. The `ToUpper` code adds a function in the WHERE clause of the TSQL SELECT statement. The added function prevents the optimizer from using an index. Given that SQL is installed as case-insensitive, it's best to avoid the `ToUpper` call when it's not needed.

For more information, see How to use case-insensitive query with Sqlite provider.

Update the Razor page

Replace the code in `Pages/Students/Index.cshtml` to add a **Search** button.

CSHTML

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name:
            <input type="text" name="SearchString"
value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-primary" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort">
                    @Html.DisplayNameFor(model =>
model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model =>
model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort">
                    @Html.DisplayNameFor(model =>
model.Students[0].EnrollmentDate)
                </a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
```

```
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

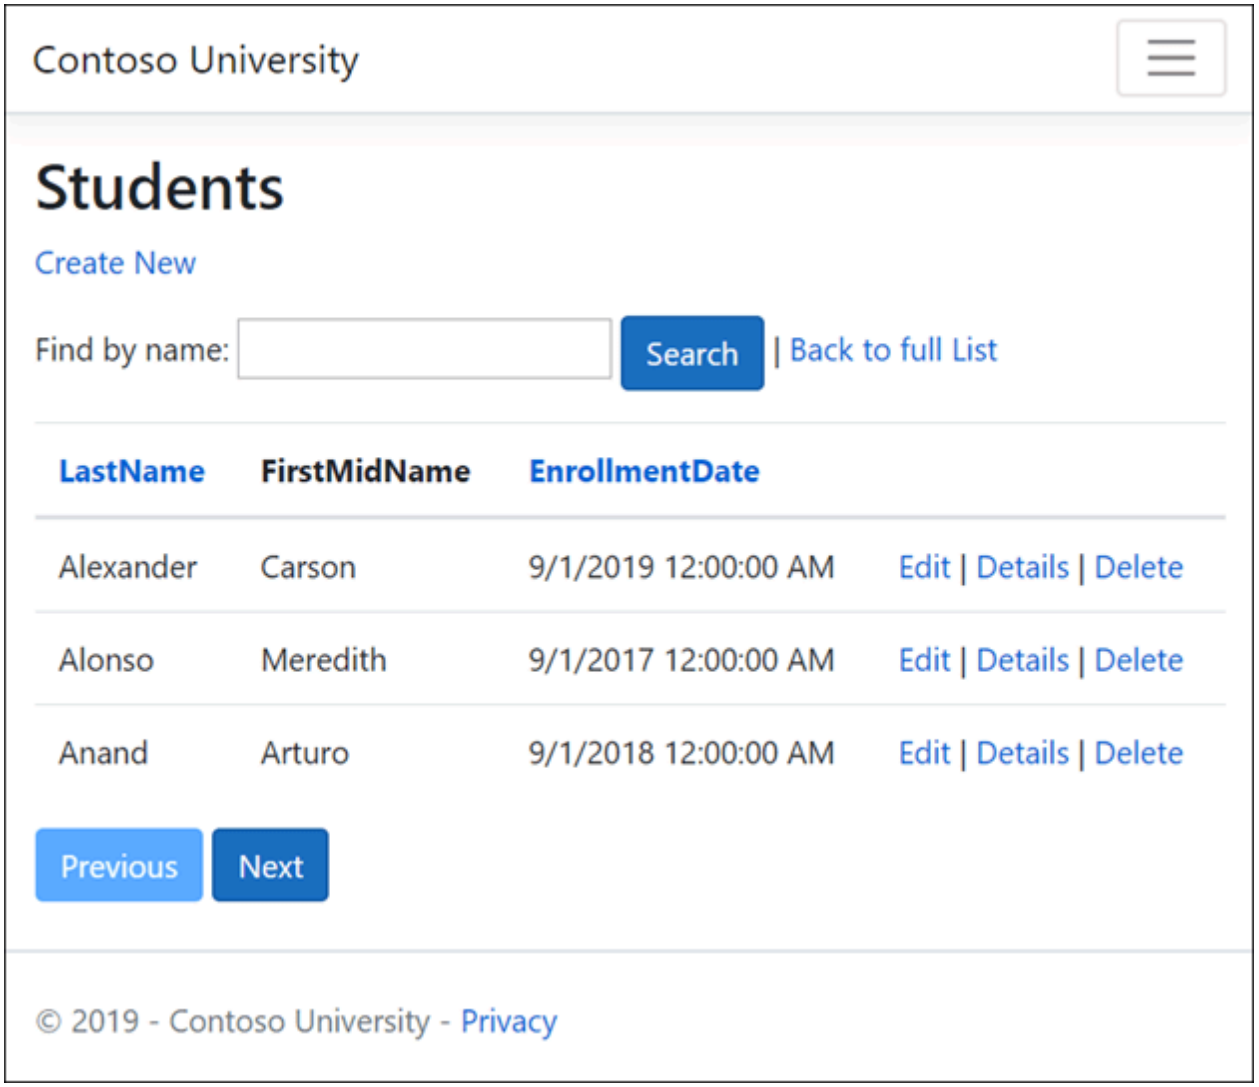
The preceding code uses the `<form>` tag helper to add the search text box and button. By default, the `<form>` tag helper submits form data with a POST. With POST, the parameters are passed in the HTTP message body and not in the URL. When HTTP GET is used, the form data is passed in the URL as query strings. Passing the data with query strings enables users to bookmark the URL. The W3C guidelines recommend that GET should be used when the action doesn't result in an update.

Test the app:

- Select the **Students** tab and enter a search string. If you're using SQLite, the filter is case-insensitive only if you implemented the optional `ToUpper` code shown earlier.
- Select **Search**.

Notice that the URL contains the search string. For example:

```
browser-address-bar
```



```
https://localhost:5001/Students?SearchString=an
```

If the page is bookmarked, the bookmark contains the URL to the page and the `SearchString` query string. The `method="get"` in the `form` tag is what caused the query string to be generated.

Currently, when a column heading sort link is selected, the filter value from the **Search** box is lost. The lost filter value is fixed in the next section.

Add paging

In this section, a `PaginatedList` class is created to support paging. The `PaginatedList` class uses `Skip` and `Take` statements to filter data on the server instead of retrieving all rows of the table. The following illustration shows the paging buttons.

Create the PaginatedList class

In the project folder, create `PaginatedList.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity
{
    public class PaginatedList<T> : List<T>
```

```
    {
        public int PageIndex { get; private set; }
        public int TotalPages { get; private set; }

        public PaginatedList(List<T> items, int count, int pageIndex, int
pageSize)
        {
            PageIndex = pageIndex;
            TotalPages = (int)Math.Ceiling(count / (double)pageSize);

            this.AddRange(items);
        }

        public bool HasPreviousPage => PageIndex > 1;

        public bool HasNextPage => PageIndex < TotalPages;

        public static async Task<PaginatedList<T>> CreateAsync(
            IQueryable<T> source, int pageIndex, int pageSize)
        {
            var count = await source.CountAsync();
            var items = await source.Skip(
                (pageIndex - 1) * pageSize)
                .Take(pageSize).ToListAsync();
            return new PaginatedList<T>(items, count, pageIndex, pageSize);
        }
    }
}
```

The `CreateAsync` method in the preceding code takes page size and page number and applies the appropriate `Skip` and `Take` statements to the `IQueryable`. When `ToListAsync` is called on the `IQueryable`, it returns a List containing only the requested page. The properties `HasPreviousPage` and `HasNextPage` are used to enable or disable **Previous** and **Next** paging buttons.

The `CreateAsync` method is used to create the `PaginatedList<T>`. A constructor can't create the `PaginatedList<T>` object; constructors can't run asynchronous code.

Add page size to configuration

Add `PageSize` to the `appsettings.json` Configuration file:

JSON

```
{
  "PageSize": 3,
  "Logging": {
    "LogLevel": {
      "Default": "Information",
```

```
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*",
  "ConnectionStrings": {
    "SchoolContext": "Server=(localdb)\\mssqllocaldb;Database=CU-
1;Trusted_Connection=True;MultipleActiveResultSets=true"
  }
}
```

Add paging to IndexModel

Replace the code in `Students/Index.cshtml.cs` to add paging.

C#

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.Configuration;
using System;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Students
{
    public class IndexModel : PageModel
    {
        private readonly SchoolContext _context;
        private readonly IConfiguration Configuration;

        public IndexModel(SchoolContext context, IConfiguration
configuration)
        {
            _context = context;
            Configuration = configuration;
        }

        public string NameSort { get; set; }
        public string DateSort { get; set; }
        public string CurrentFilter { get; set; }
        public string CurrentSort { get; set; }
```

```
        public PaginatedList<Student> Students { get; set; }

        public async Task OnGetAsync(string sortOrder,
            string currentFilter, string searchString, int? pageIndex)
        {
            CurrentSort = sortOrder;
            NameSort = String.IsNullOrEmpty(sortOrder) ? "name_desc" : "";
            DateSort = sortOrder == "Date" ? "date_desc" : "Date";
            if (searchString != null)
            {
                pageIndex = 1;
            }
            else
            {
                searchString = currentFilter;
            }

            CurrentFilter = searchString;

            IQueryable<Student> studentsIQ = from s in _context.Students
                                             select s;
            if (!String.IsNullOrEmpty(searchString))
            {
                studentsIQ = studentsIQ.Where(s =>
s.LastName.Contains(searchString)
                                       ||
s.FirstMidName.Contains(searchString));
            }
            switch (sortOrder)
            {
                case "name_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s =>
s.LastName);
                    break;
                case "Date":
                    studentsIQ = studentsIQ.OrderBy(s => s.EnrollmentDate);
                    break;
                case "date_desc":
                    studentsIQ = studentsIQ.OrderByDescending(s =>
s.EnrollmentDate);
                    break;
                default:
                    studentsIQ = studentsIQ.OrderBy(s => s.LastName);
                    break;
            }

            var pageSize = Configuration.GetValue("PageSize", 4);
            Students = await PaginatedList<Student>.CreateAsync(
                studentsIQ.AsNoTracking(), pageIndex ?? 1, pageSize);
        }
    }
}
```

The preceding code:

- Changes the type of the `Students` property from `IList<Student>` to `PaginatedList<Student>`.
- Adds the page index, the current `sortOrder`, and the `currentFilter` to the `OnGetAsync` method signature.
- Saves the sort order in the `CurrentSort` property.
- Resets page index to 1 when there's a new search string.
- Uses the `PaginatedList` class to get Student entities.
- Sets `pageSize` to 3 from Configuration, 4 if configuration fails.

All the parameters that `OnGetAsync` receives are null when:

- The page is called from the **Students** link.
- The user hasn't clicked a paging or sorting link.

When a paging link is clicked, the page index variable contains the page number to display.

The `CurrentSort` property provides the Razor Page with the current sort order. The current sort order must be included in the paging links to keep the sort order while paging.

The `CurrentFilter` property provides the Razor Page with the current filter string. The `CurrentFilter` value:

- Must be included in the paging links in order to maintain the filter settings during paging.
- Must be restored to the text box when the page is redisplayed.

If the search string is changed while paging, the page is reset to 1. The page has to be reset to 1 because the new filter can result in different data to display. When a search value is entered and **Submit** is selected:

- The search string is changed.
- The `searchString` parameter isn't null.

The `PaginatedList.CreateAsync` method converts the student query to a single page of students in a collection type that supports paging. That single page of students is passed to the Razor Page.

The two question marks after `pageIndex` in the `PaginatedList.CreateAsync` call represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type. The expression `pageIndex ?? 1` returns the value of `pageIndex` if it has a value, otherwise, it returns 1.

Add paging links

Replace the code in `Students/Index.cshtml` with the following code. The changes are highlighted:

CSHTML

```
@page
@model ContosoUniversity.Pages.Students.IndexModel

@{
    ViewData["Title"] = "Students";
}

<h2>Students</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>

<form asp-page="./Index" method="get">
    <div class="form-actions no-color">
        <p>
            Find by name:
            <input type="text" name="SearchString"
value="@Model.CurrentFilter" />
            <input type="submit" value="Search" class="btn btn-primary" /> |
            <a asp-page="./Index">Back to full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
                   asp-route-currentFilter="@Model.CurrentFilter">
                    @Html.DisplayNameFor(model =>
model.Students[0].LastName)
                </a>
            </th>
            <th>
                @Html.DisplayNameFor(model =>
model.Students[0].FirstMidName)
            </th>
            <th>
                <a asp-page="./Index" asp-route-sortOrder="@Model.DateSort"
                   asp-route-currentFilter="@Model.CurrentFilter">
                    @Html.DisplayNameFor(model =>
model.Students[0].EnrollmentDate)
                </a>
            </th>
```

```
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Students)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

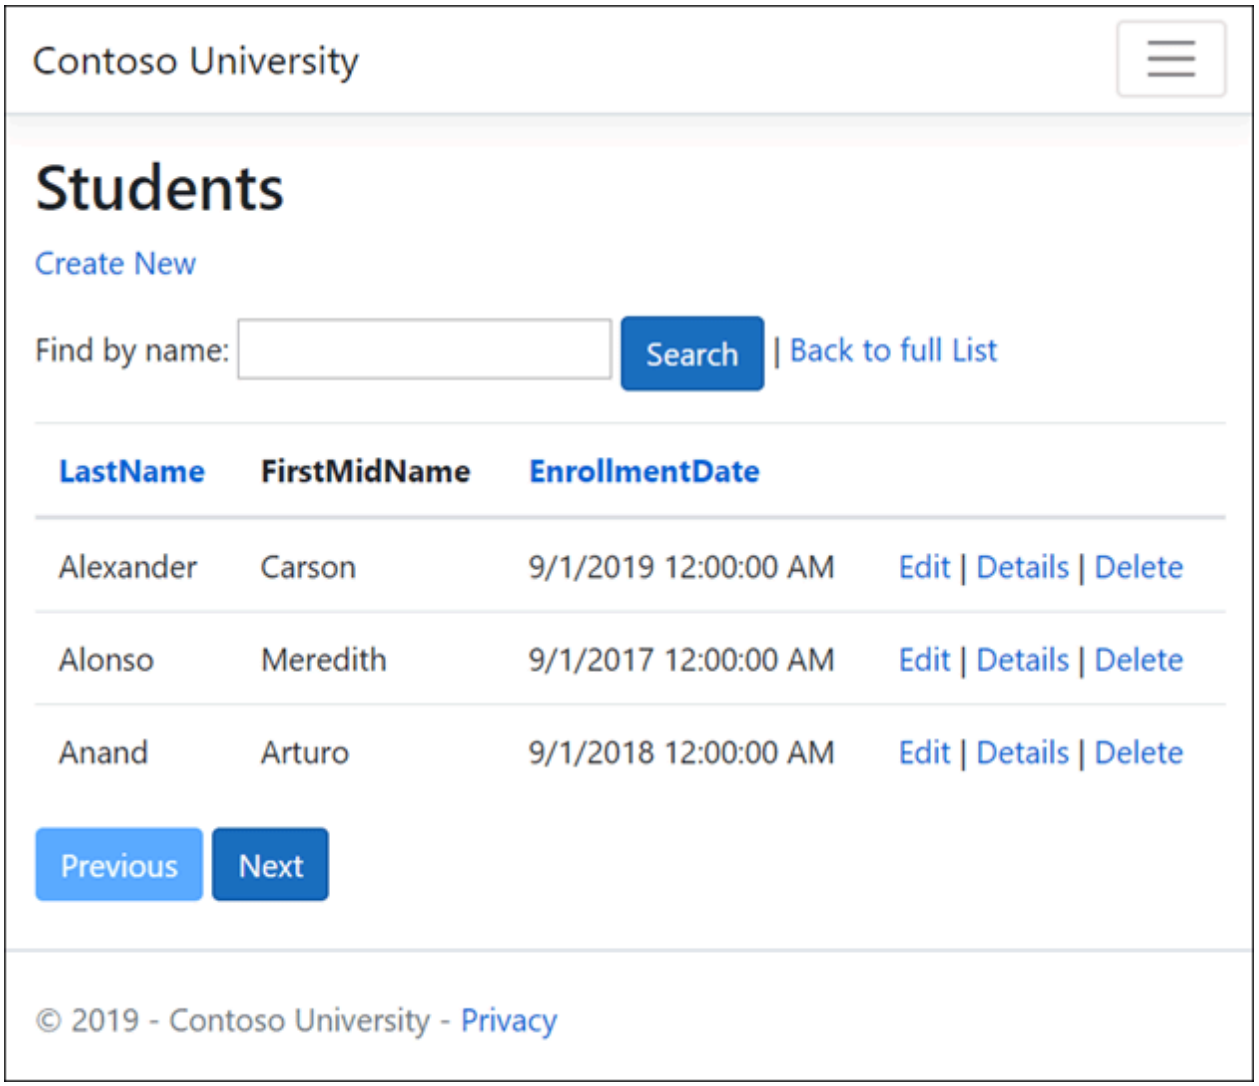
```
@{
    var prevDisabled = !Model.Students.HasPreviousPage ? "disabled" : "";
    var nextDisabled = !Model.Students.HasNextPage ? "disabled" : "";
}

<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @nextDisabled">
    Next
</a>
```

The column header links use the query string to pass the current search string to the `OnGetAsync` method:

CSHTML

```
<a asp-page="./Index" asp-route-sortOrder="@Model.NameSort"
   asp-route-currentFilter="@Model.CurrentFilter">
    @Html.DisplayNameFor(model => model.Students[0].LastName)
</a>
```



The paging buttons are displayed by tag helpers:

CSHTML

```
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex - 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @prevDisabled">
    Previous
</a>
<a asp-page="./Index"
   asp-route-sortOrder="@Model.CurrentSort"
   asp-route-pageIndex="@(Model.Students.PageIndex + 1)"
   asp-route-currentFilter="@Model.CurrentFilter"
   class="btn btn-primary @nextDisabled">
    Next
</a>
```

Run the app and navigate to the students page.

- To make sure paging works, click the paging links in different sort orders.
- To verify that paging works correctly with sorting and filtering, enter a search string and try paging.

Grouping

This section creates an `About` page that displays how many students have enrolled for each enrollment date. The update uses grouping and includes the following steps:

- Create a view model for the data used by the `About` page.
- Update the `About` page to use the view model.

Create the view model

Create a *Models/SchoolViewModels* folder.

Create `SchoolViewModels/EnrollmentDateGroup.cs` with the following code:

C#

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models.SchoolViewModels
```

```
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Create the Razor Page

Create a `Pages/About.cshtml` file with the following code:

CSHTML

```
@page
@model ContosoUniversity.Pages.AboutModel

@{
    ViewData["Title"] = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>

<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

    @foreach (var item in Model.Students)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                @item.StudentCount
            </td>
        </tr>
    }
</table>
```

Create the page model

Update the `Pages/About.cshtml.cs` file with the following code:

C#

```
using ContosoUniversity.Models.SchoolViewModels;
using ContosoUniversity.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using ContosoUniversity.Models;

namespace ContosoUniversity.Pages
{
    public class AboutModel : PageModel
    {
        private readonly SchoolContext _context;

        public AboutModel(SchoolContext context)
        {
            _context = context;
        }

        public IList<EnrollmentDateGroup> Students { get; set; }

        public async Task OnGetAsync()
        {
            IQueryable<EnrollmentDateGroup> data =
                from student in _context.Students
                group student by student.EnrollmentDate into dateGroup
                select new EnrollmentDateGroup()
                {
                    EnrollmentDate = dateGroup.Key,
                    StudentCount = dateGroup.Count()
                };

            Students = await data.AsNoTracking().ToListAsync();
        }
    }
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Run the app and navigate to the About page. The count of students for each enrollment date is displayed in a table.

Next steps

In the next tutorial, the app uses migrations to update the data model.

Previous tutorial | Next tutorial

Part 4, Razor Pages with EF Core migrations in ASP.NET Core

Article • 05/31/2024

By Tom Dykstra, Jon P Smith, and Rick Anderson

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial introduces the EF Core migrations feature for managing data model changes.

When a new app is developed, the data model changes frequently. Each time the model changes, the model gets out of sync with the database. This tutorial series started by configuring the Entity Framework to create the database if it doesn't exist. Each time the data model changes, the database needs to be dropped. The next time the app runs, the call to `EnsureCreated` re-creates the database to match the new data model. The `DbInitializer` class then runs to seed the new database.

This approach to keeping the DB in sync with the data model works well until the app needs to be deployed to production. When the app is running in production, it's usually storing data that needs to be maintained. The app can't start with a test DB each time a change is made (such as adding a new column). The EF Core Migrations feature solves this problem by enabling EF Core to update the DB schema instead of creating a new database.

Rather than dropping and recreating the database when the data model changes, migrations updates the schema and retains existing data.

> **Note**
>
> **SQLite limitations**
>
> This tutorial uses the Entity Framework Core migrations feature where possible. Migrations updates the database schema to match changes in the data model. However, migrations only does the kinds of changes that the database engine supports, and SQLite's schema change capabilities are limited. For example, adding

a column is supported, but removing a column is not supported. If a migration is created to remove a column, the `ef migrations add` command succeeds but the `ef database update` command fails.

The workaround for the SQLite limitations is to manually write migrations code to perform a table rebuild when something in the table changes. The code goes in the `Up` and `Down` methods for a migration and involves:

- Creating a new table.
- Copying data from the old table to the new table.
- Dropping the old table.
- Renaming the new table.

Writing database-specific code of this type is outside the scope of this tutorial. Instead, this tutorial drops and re-creates the database whenever an attempt to apply a migration would fail. For more information, see the following resources:

- SQLite EF Core Database Provider Limitations
- Customize migration code
- Data seeding
- SQLite ALTER TABLE statement

Drop the database

Visual Studio

Use **SQL Server Object Explorer** (SSOX) to delete the database, or run the following command in the **Package Manager Console** (PMC):

PowerShell

```
Drop-Database
```

Create an initial migration

Visual Studio

Run the following commands in the PMC:

PowerShell

```
Add-Migration InitialCreate
Update-Database
```

Remove EnsureCreated

This tutorial series started by using EnsureCreated. `EnsureCreated` doesn't create a migrations history table and so can't be used with migrations. It's designed for testing or rapid prototyping where the database is dropped and re-created frequently.

From this point forward, the tutorials will use migrations.

In `Program.cs`, delete the following line:

C#

```
context.Database.EnsureCreated();
```

Run the app and verify that the database is seeded.

Up and Down methods

The EF Core `migrations add` command generated code to create the database. This migrations code is in the `Migrations\<timestamp>_InitialCreate.cs` file. The `Up` method of the `InitialCreate` class creates the database tables that correspond to the data model entity sets. The `Down` method deletes them, as shown in the following example:

C#

```
using System;
using Microsoft.EntityFrameworkCore.Metadata;
using Microsoft.EntityFrameworkCore.Migrations;

namespace ContosoUniversity.Migrations
{
    public partial class InitialCreate : Migration
    {
        protected override void Up(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.CreateTable(
                name: "Course",
                columns: table => new
                {
```

```
                    CourseID = table.Column<int>(nullable: false),
                    Title = table.Column<string>(nullable: true),
                    Credits = table.Column<int>(nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Course", x => x.CourseID);
                });

            migrationBuilder.CreateTable(
                name: "Student",
                columns: table => new
                {
                    ID = table.Column<int>(nullable: false)
                        .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
                    LastName = table.Column<string>(nullable: true),
                    FirstMidName = table.Column<string>(nullable: true),
                    EnrollmentDate = table.Column<DateTime>(nullable: false)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Student", x => x.ID);
                });

            migrationBuilder.CreateTable(
                name: "Enrollment",
                columns: table => new
                {
                    EnrollmentID = table.Column<int>(nullable: false)
                        .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
                    CourseID = table.Column<int>(nullable: false),
                    StudentID = table.Column<int>(nullable: false),
                    Grade = table.Column<int>(nullable: true)
                },
                constraints: table =>
                {
                    table.PrimaryKey("PK_Enrollment", x => x.EnrollmentID);
                    table.ForeignKey(
                        name: "FK_Enrollment_Course_CourseID",
                        column: x => x.CourseID,
                        principalTable: "Course",
                        principalColumn: "CourseID",
                        onDelete: ReferentialAction.Cascade);
                    table.ForeignKey(
                        name: "FK_Enrollment_Student_StudentID",
                        column: x => x.StudentID,
                        principalTable: "Student",
                        principalColumn: "ID",
                        onDelete: ReferentialAction.Cascade);
                });

            migrationBuilder.CreateIndex(
                name: "IX_Enrollment_CourseID",
```

```
                table: "Enrollment",
                column: "CourseID");

            migrationBuilder.CreateIndex(
                name: "IX_Enrollment_StudentID",
                table: "Enrollment",
                column: "StudentID");
        }

        protected override void Down(MigrationBuilder migrationBuilder)
        {
            migrationBuilder.DropTable(
                name: "Enrollment");

            migrationBuilder.DropTable(
                name: "Course");

            migrationBuilder.DropTable(
                name: "Student");
        }
    }
}
```

The preceding code is for the initial migration. The code:

- Was generated by the `migrations add InitialCreate` command.
- Is executed by the `database update` command.
- Creates a database for the data model specified by the database context class.

The migration name parameter (`InitialCreate` in the example) is used for the file name. The migration name can be any valid file name. It's best to choose a word or phrase that summarizes what is being done in the migration. For example, a migration that added a department table might be called "AddDepartmentTable."

The migrations history table

- Use SSOX or SQLite tool to inspect the database.
- Notice the addition of an `__EFMigrationsHistory` table. The `__EFMigrationsHistory` table keeps track of which migrations have been applied to the database.
- View the data in the `__EFMigrationsHistory` table. It shows one row for the first migration.

The data model snapshot

Migrations creates a *snapshot* of the current data model in `Migrations/SchoolContextModelSnapshot.cs`. When add a migration is added, EF determines what changed by comparing the current data model to the snapshot file.

Because the snapshot file tracks the state of the data model, a migration cannot be deleted by deleting the `<timestamp>_<migrationname>.cs` file. To back out the most recent migration, use the migrations remove command. `migrations remove` deletes the migration and ensures the snapshot is correctly reset. For more information, see dotnet ef migrations remove.

See Resetting all migrations to remove all migrations.

Applying migrations in production

We recommend that production apps **not** call Database.Migrate at application startup. `Migrate` shouldn't be called from an app that is deployed to a server farm. If the app is scaled out to multiple server instances, it's hard to ensure database schema updates don't happen from multiple servers or conflict with read/write access.

Database migration should be done as part of deployment, and in a controlled way. Production database migration approaches include:

- Using migrations to create SQL scripts and using the SQL scripts in deployment.
- Running `dotnet ef database update` from a controlled environment.

Troubleshooting

If the app uses SQL Server LocalDB and displays the following exception:

```text
SqlException: Cannot open database "ContosoUniversity" requested by the
login.
The login failed.
Login failed for user 'user name'.
```

The solution may be to run `dotnet ef database update` at a command prompt.

Additional resources

- EF Core CLI.
- dotnet ef migrations CLI commands

- Package Manager Console (Visual Studio)

Next steps

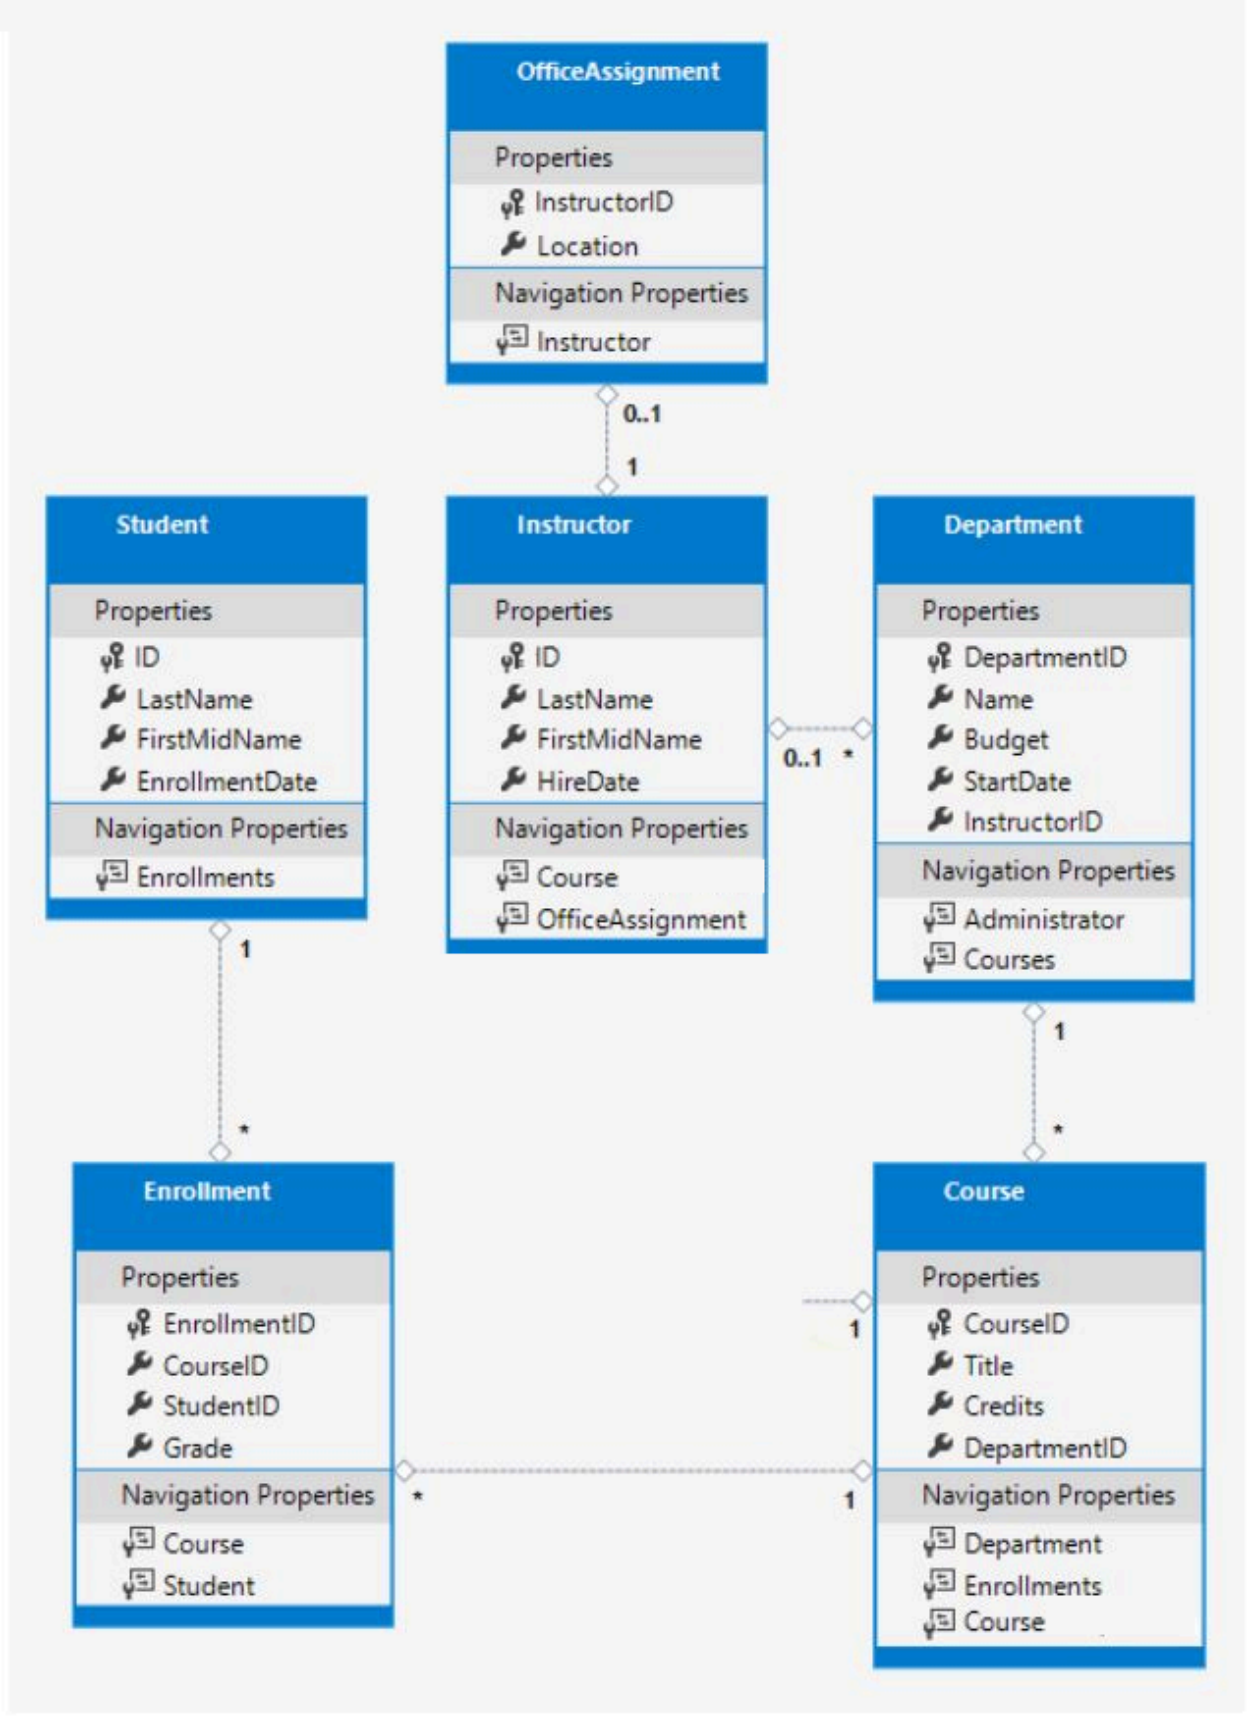
The next tutorial builds out the data model, adding entity properties and new entities.

Previous tutorial | Next tutorial

Part 5, Razor Pages with EF Core in ASP.NET Core - Data Model

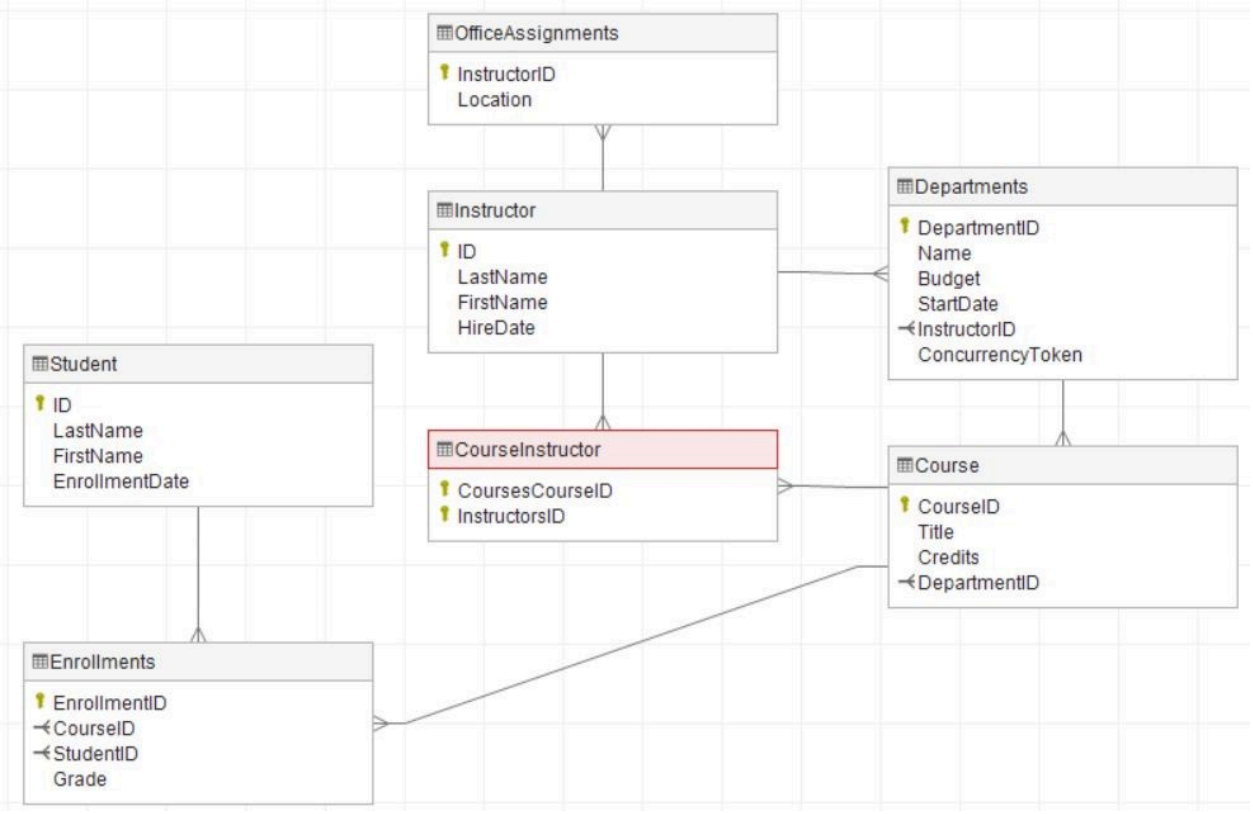
Article • 04/10/2024

By Tom Dykstra, Jeremy Likness, and Jon P Smith



The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.



The previous tutorials worked with a basic data model that was composed of three entities. In this tutorial:

- More entities and relationships are added.
- The data model is customized by specifying formatting, validation, and database mapping rules.

The completed data model is shown in the following illustration:

The following database diagram was made with Dataedo:

To create a database diagram with Dataedo:

- Deploy the app to Azure
- Download and install Dataedo on your computer.
- Follow the instructions Generate documentation for Azure SQL Database in 5 minutes

In the preceding Dataedo diagram, the `CourseInstructor` is a join table created by Entity Framework. For more information, see Many-to-many

The Student entity

Replace the code in `Models/Student.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
```

```
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than
50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The preceding code adds a `FullName` property and adds the following attributes to existing properties:

- [DataType]
- [DisplayFormat]
- [StringLength]
- [Column]
- [Required]
- [Display]

The FullName calculated property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties. `FullName` can't be set, so it has only a get accessor. No `FullName` column is created in the database.

The DataType attribute

```
C#
```

```
[DataType(DataType.Date)]
```

For student enrollment dates, all of the pages currently display the time of day along with the date, although only the date is relevant. By using data annotation attributes, you can make one code change that will fix the display format in every page that shows the data.

The DataType attribute specifies a data type that's more specific than the database intrinsic type. In this case only the date should be displayed, not the date and time. The DataType Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, etc. The `DataType` attribute can also enable the app to automatically provide type-specific features. For example:

- The `mailto:` link is automatically created for `DataType.EmailAddress`.
- The date selector is provided for `DataType.Date` in most browsers.

The `DataType` attribute emits HTML 5 `data-` (pronounced data dash) attributes. The `DataType` attributes don't provide validation.

The DisplayFormat attribute

C#

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode =
true)]
```

`DataType.Date` doesn't specify the format of the date that's displayed. By default, the date field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format. The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied to the edit UI. Some fields shouldn't use `ApplyFormatInEditMode`. For example, the currency symbol should generally not be displayed in an edit text box.

The `DisplayFormat` attribute can be used by itself. It's generally a good idea to use the `DataType` attribute with the `DisplayFormat` attribute. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen. The `DataType` attribute provides the following benefits that are not available in `DisplayFormat`:

- The browser can enable HTML5 features. For example, show a calendar control, the locale-appropriate currency symbol, email links, and client-side input validation.
- By default, the browser renders data using the correct format based on the locale.

For more information, see the <input> Tag Helper documentation.

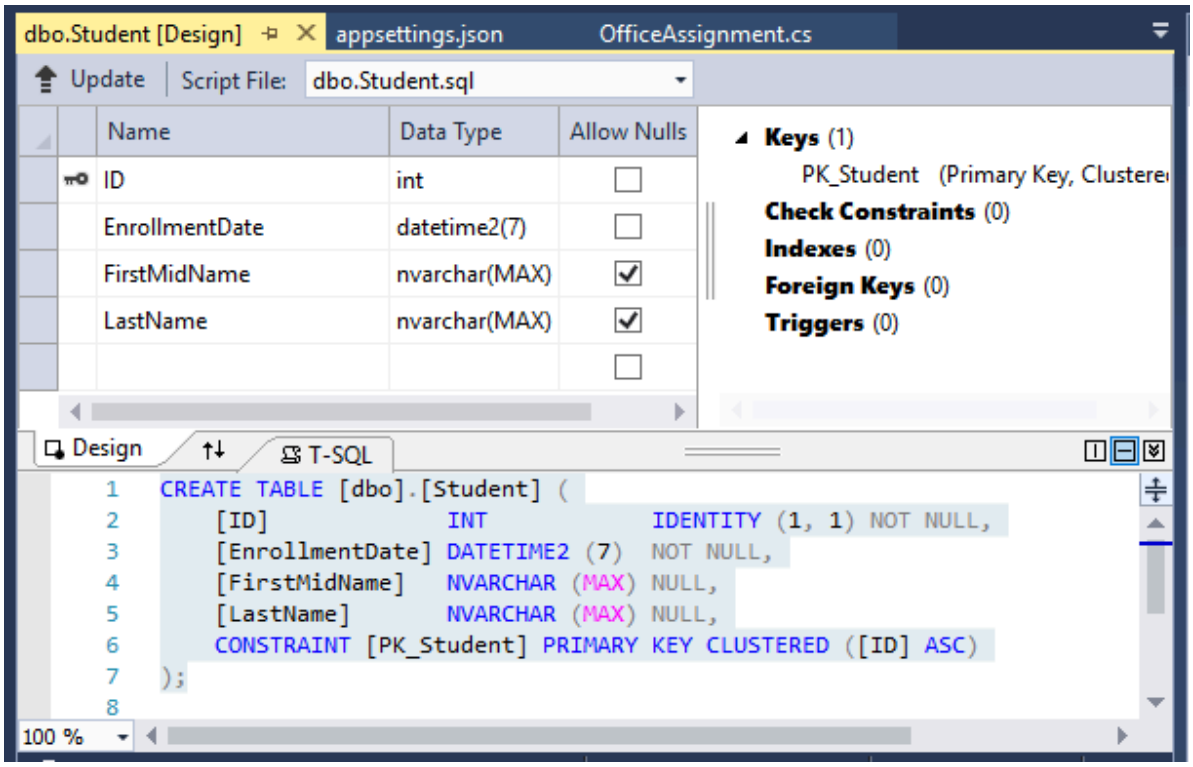
The StringLength attribute

C#

```
[StringLength(50, ErrorMessage = "First name cannot be longer than 50
characters.")]
```

Data validation rules and validation error messages can be specified with attributes. The StringLength attribute specifies the minimum and maximum length of characters that are allowed in a data field. The code shown limits names to no more than 50 characters. An example that sets the minimum string length is shown later.

The `StringLength` attribute also provides client-side and server-side validation. The minimum value has no impact on the database schema.



The `StringLength` attribute doesn't prevent a user from entering white space for a name. The RegularExpression attribute can be used to apply restrictions to the input. For example, the following code requires the first character to be upper case and the remaining characters to be alphabetical:

C#

```
[RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
```

Visual Studio

In **SQL Server Object Explorer** (SSOX), open the Student table designer by double-clicking the **Student** table.

The preceding image shows the schema for the `Student` table. The name fields have type `nvarchar(MAX)`. When a migration is created and applied later in this tutorial, the name fields become `nvarchar(50)` as a result of the string length attributes.

The Column attribute

C#

```
[Column("FirstName")]
public string FirstMidName { get; set; }
```

Attributes can control how classes and properties are mapped to the database. In the `Student` model, the `Column` attribute is used to map the name of the `FirstMidName` property to "FirstName" in the database.

When the database is created, property names on the model are used for column names (except when the `Column` attribute is used). The `Student` model uses `FirstMidName` for the first-name field because the field might also contain a middle name.

With the `[Column]` attribute, `Student.FirstMidName` in the data model maps to the `FirstName` column of the `Student` table. The addition of the `Column` attribute changes the model backing the `SchoolContext`. The model backing the `SchoolContext` no longer matches the database. That discrepancy will be resolved by adding a migration later in this tutorial.

The Required attribute

```
C#

[Required]
```

The `Required` attribute makes the name properties required fields. The `Required` attribute isn't needed for non-nullable types such as value types (for example, `DateTime`, `int`, and `double`). Types that can't be null are automatically treated as required fields.

The `Required` attribute must be used with `MinimumLength` for the `MinimumLength` to be enforced.

```
C#

[Display(Name = "Last Name")]
[Required]
[StringLength(50, MinimumLength=2)]
public string LastName { get; set; }
```

`MinimumLength` and `Required` allow whitespace to satisfy the validation. Use the `RegularExpression` attribute for full control over the string.

The Display attribute

```
C#

[Display(Name = "Last Name")]
```

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date." The default captions had no space dividing the words, for example "Lastname."

Create a migration

Run the app and go to the Students page. An exception is thrown. The `[Column]` attribute causes EF to expect to find a column named `FirstName`, but the column name in the database is still `FirstMidName`.

Visual Studio

The error message is similar to the following example:

```
SqlException: Invalid column name 'FirstName'.
There are pending model changes
Pending model changes are detected in the following:

SchoolContext
```

- In the PMC, enter the following commands to create a new migration and update the database:

  ```PowerShell
  Add-Migration ColumnFirstName
  Update-Database
  ```

  The first of these commands generates the following warning message:

  ```text
  An operation was scaffolded that may result in the loss of data.
  Please review the migration for accuracy.
  ```

  The warning is generated because the name fields are now limited to 50 characters. If a name in the database had more than 50 characters, the 51 to last character would be lost.

- Open the Student table in SSOX:

Before the migration was applied, the name columns were of type nvarchar(MAX). The name columns are now `nvarchar(50)`. The column name has changed from `FirstMidName` to `FirstName`.

- Run the app and go to the Students page.
- Notice that times are not input or displayed along with dates.
- Select **Create New**, and try to enter a name longer than 50 characters.

> ⓘ Note
>
> In the following sections, building the app at some stages generates compiler errors. The instructions specify when to build the app.

The Instructor Entity

Create `Models/Instructor.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
```

```
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public ICollection<Course> Courses { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Multiple attributes can be on one line. The `HireDate` attributes could be written as follows:

C#

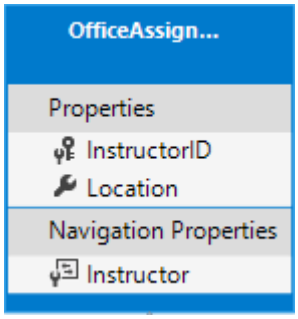
```
[DataType(DataType.Date),Display(Name = "Hire
Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
```

Navigation properties

The `Courses` and `OfficeAssignment` properties are navigation properties.

An instructor can teach any number of courses, so `Courses` is defined as a collection.

C#



```
public ICollection<Course> Courses { get; set; }
```

An instructor can have at most one office, so the `OfficeAssignment` property holds a single `OfficeAssignment` entity. `OfficeAssignment` is null if no office is assigned.

C#

```
public OfficeAssignment OfficeAssignment { get; set; }
```

The OfficeAssignment entity

Create `Models/OfficeAssignment.cs` with the following code:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }

        public Instructor Instructor { get; set; }
    }
}
```

The Key attribute

The [Key] attribute is used to identify a property as the primary key (PK) when the property name is something other than `classnameID` or `ID`.

There's a one-to-zero-or-one relationship between the `Instructor` and `OfficeAssignment` entities. An office assignment only exists in relation to the instructor it's assigned to. The `OfficeAssignment` PK is also its foreign key (FK) to the `Instructor` entity. A one-to-zero-or-one relationship occurs when a PK in one table is both a PK and a FK in another table.

EF Core can't automatically recognize `InstructorID` as the PK of `OfficeAssignment` because `InstructorID` doesn't follow the ID or classnameID naming convention. Therefore, the `Key` attribute is used to identify `InstructorID` as the PK:

C#

```
[Key]
public int InstructorID { get; set; }
```

By default, EF Core treats the key as non-database-generated because the column is for an identifying relationship. For more information, see EF Keys.

The Instructor navigation property

The `Instructor.OfficeAssignment` navigation property can be null because there might not be an `OfficeAssignment` row for a given instructor. An instructor might not have an office assignment.

The `OfficeAssignment.Instructor` navigation property will always have an instructor entity because the foreign key `InstructorID` type is `int`, a non-nullable value type. An office assignment can't exist without an instructor.

When an `Instructor` entity has a related `OfficeAssignment` entity, each entity has a reference to the other one in its navigation property.

The Course Entity

Update `Models/Course.cs` with the following code:

C#

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
```

```
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        [Display(Name = "Number")]
        public int CourseID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Title { get; set; }

        [Range(0, 5)]
        public int Credits { get; set; }

        public int DepartmentID { get; set; }

        public Department Department { get; set; }
        public ICollection<Enrollment> Enrollments { get; set; }
        public ICollection<Instructor> Instructors { get; set; }
    }
}
```

The `Course` entity has a foreign key (FK) property `DepartmentID`. `DepartmentID` points to the related `Department` entity. The `Course` entity has a `Department` navigation property.

EF Core doesn't require a foreign key property for a data model when the model has a navigation property for a related entity. EF Core automatically creates FKs in the database wherever they're needed. EF Core creates shadow properties for automatically created FKs. However, explicitly including the FK in the data model can make updates simpler and more efficient. For example, consider a model where the FK property `DepartmentID` is ***not*** included. When a course entity is fetched to edit:

- The `Department` property is `null` if it's not explicitly loaded.
- To update the course entity, the `Department` entity must first be fetched.

When the FK property `DepartmentID` is included in the data model, there's no need to fetch the `Department` entity before an update.

The DatabaseGenerated attribute

The `[DatabaseGenerated(DatabaseGeneratedOption.None)]` attribute specifies that the PK is provided by the application rather than generated by the database.

C#

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, EF Core assumes that PK values are generated by the database. Database-generated is generally the best approach. For `Course` entities, the user specifies the PK. For example, a course number such as a 1000 series for the math department, a 2000 series for the English department.

The `DatabaseGenerated` attribute can also be used to generate default values. For example, the database can automatically generate a date field to record the date a row was created or updated. For more information, see Generated Properties.

Foreign key and navigation properties

The foreign key (FK) properties and navigation properties in the `Course` entity reflect the following relationships:

A course is assigned to one department, so there's a `DepartmentID` FK and a `Department` navigation property.

C#

```
public int DepartmentID { get; set; }
public Department Department { get; set; }
```

A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

C#

```
public ICollection<Enrollment> Enrollments { get; set; }
```

A course may be taught by multiple instructors, so the `Instructors` navigation property is a collection:

C#

```
public ICollection<Instructor> Instructors { get; set; }
```

The Department entity

Create `Models/Department.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
                       ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Column attribute

Previously the `Column` attribute was used to change column name mapping. In the code for the `Department` entity, the `Column` attribute is used to change SQL data type mapping. The `Budget` column is defined using the SQL Server money type in the database:

C#

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required. EF Core chooses the appropriate SQL Server data type based on the CLR type for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. `Budget` is for currency, and the money data type is more appropriate for currency.

Foreign key and navigation properties

The FK and navigation properties reflect the following relationships:

- A department may or may not have an administrator.
- An administrator is always an instructor. Therefore the `InstructorID` property is included as the FK to the `Instructor` entity.

The navigation property is named `Administrator` but holds an `Instructor` entity:

C#

```
public int? InstructorID { get; set; }
public Instructor Administrator { get; set; }
```

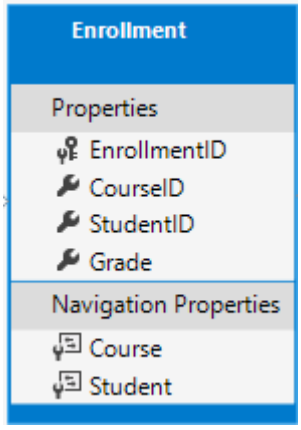
The `?` in the preceding code specifies the property is nullable.

A department may have many courses, so there's a Courses navigation property:

C#

```
public ICollection<Course> Courses { get; set; }
```

By convention, EF Core enables cascade delete for non-nullable FKs and for many-to-many relationships. This default behavior can result in circular cascade delete rules. Circular cascade delete rules cause an exception when a migration is added.



For example, if the `Department.InstructorID` property was defined as non-nullable, EF Core would configure a cascade delete rule. In that case, the department would be deleted when the instructor assigned as its administrator is deleted. In this scenario, a restrict rule would make more sense. The following fluent API would set a restrict rule and disable cascade delete.

C#

```
modelBuilder.Entity<Department>()
    .HasOne(d => d.Administrator)
    .WithMany()
    .OnDelete(DeleteBehavior.Restrict)
```

The Enrollment foreign key and navigation properties

An enrollment record is for one course taken by one student.

Update `Models/Enrollment.cs` with the following code:

C#

```
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

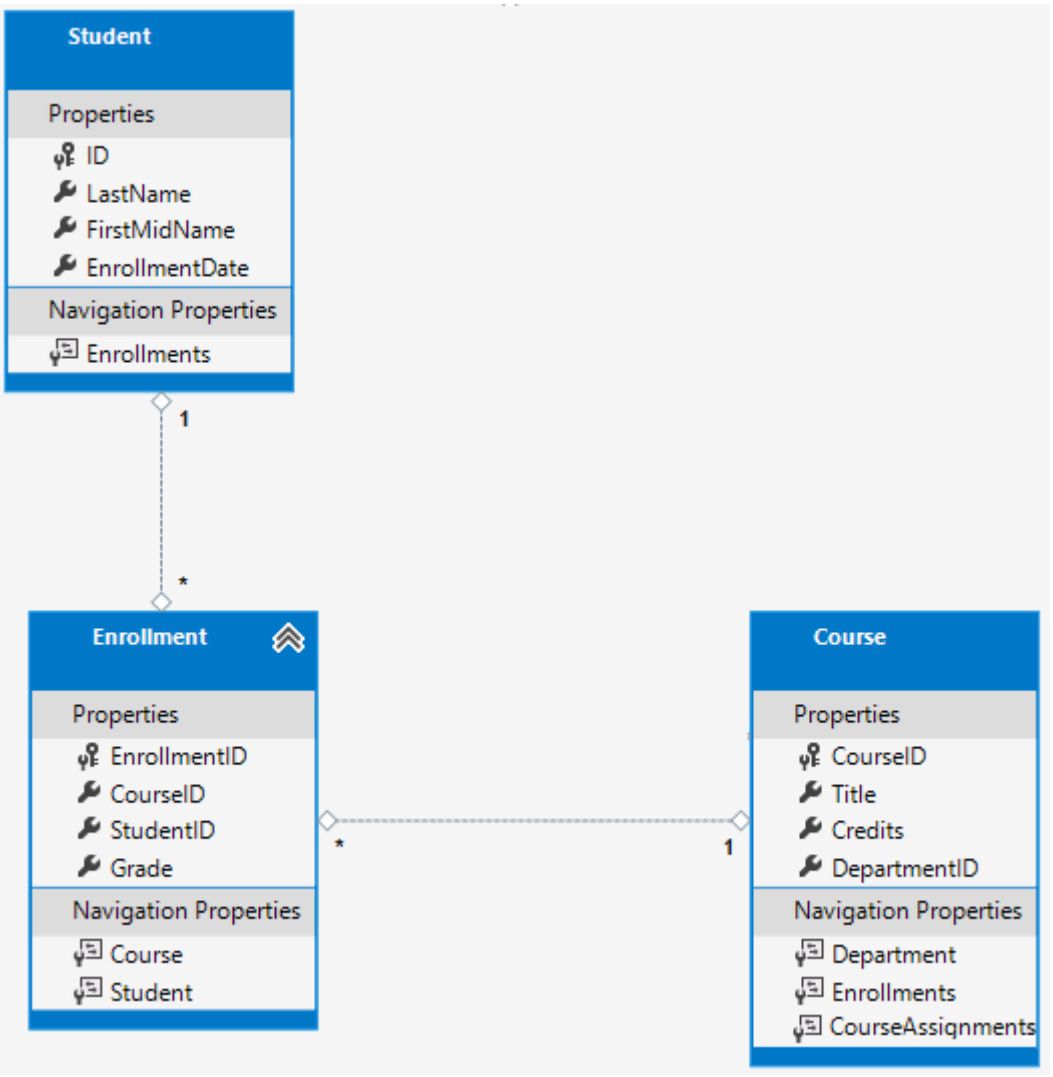
The FK properties and navigation properties reflect the following relationships:

An enrollment record is for one course, so there's a `CourseID` FK property and a `Course` navigation property:

C#

```
public int CourseID { get; set; }
public Course Course { get; set; }
```

An enrollment record is for one student, so there's a `StudentID` FK property and a `Student` navigation property:



C#

```
public int StudentID { get; set; }
public Student Student { get; set; }
```

Many-to-Many Relationships

There's a many-to-many relationship between the `Student` and `Course` entities. The `Enrollment` entity functions as a many-to-many join table ***with payload*** in the database. ***With payload*** means that the `Enrollment` table contains additional data besides FKs for the joined tables. In the `Enrollment` entity, the additional data besides FKs are the PK and `Grade`.

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using EF Power Tools for EF 6.x. Creating the diagram isn't part of the tutorial.)

Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the `Enrollment` table didn't include grade information, it would only need to contain the two FKs, `CourseID` and `StudentID`. A many-to-many join table without payload is sometimes called a pure join table (PJT).

The `Instructor` and `Course` entities have a many-to-many relationship using a PJT.

Update the database context

Update `Data/SchoolContext.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) :
base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable(nameof(Course))
                .HasMany(c => c.Instructors)
                .WithMany(i => i.Courses);
            modelBuilder.Entity<Student>().ToTable(nameof(Student));
            modelBuilder.Entity<Instructor>().ToTable(nameof(Instructor));
        }
    }
}
```

The preceding code adds the new entities and configures the many-to-many relationship between the `Instructor` and `Course` entities.

Fluent API alternative to attributes

The `OnModelCreating` method in the preceding code uses the *fluent API* to configure EF Core behavior. The API is called "fluent" because it's often used by stringing a series of method calls together into a single statement. The following code is an example of the fluent API:

```
C#
```

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    modelBuilder.Entity<Blog>()
        .Property(b => b.Url)
        .IsRequired();
}
```

In this tutorial, the fluent API is used only for database mapping that can't be done with attributes. However, the fluent API can specify most of the formatting, validation, and mapping rules that can be done with attributes.

Some attributes such as `MinimumLength` can't be applied with the fluent API. `MinimumLength` doesn't change the schema, it only applies a minimum length validation rule.

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes *clean*. Attributes and the fluent API can be mixed. There are some configurations that can only be done with the fluent API, for example, specifying a composite PK. There are some configurations that can only be done with attributes (`MinimumLength`). The recommended practice for using fluent API or attributes:

- Choose one of these two approaches.
- Use the chosen approach consistently as much as possible.

Some of the attributes used in this tutorial are used for:

- Validation only (for example, `MinimumLength`).
- EF Core configuration only (for example, `HasKey`).
- Validation and EF Core configuration (for example, `[StringLength(50)]`).

For more information about attributes vs. fluent API, see Methods of configuration.

Seed the database

Update the code in `Data/DbInitializer.cs`:

```
C#
```

```
using ContosoUniversity.Models;
using System;
using System.Collections.Generic;
using System.Linq;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var alexander = new Student
            {
                FirstMidName = "Carson",
                LastName = "Alexander",
                EnrollmentDate = DateTime.Parse("2016-09-01")
            };

            var alonso = new Student
            {
                FirstMidName = "Meredith",
                LastName = "Alonso",
                EnrollmentDate = DateTime.Parse("2018-09-01")
            };

            var anand = new Student
            {
                FirstMidName = "Arturo",
                LastName = "Anand",
                EnrollmentDate = DateTime.Parse("2019-09-01")
            };

            var barzdukas = new Student
            {
                FirstMidName = "Gytis",
                LastName = "Barzdukas",
                EnrollmentDate = DateTime.Parse("2018-09-01")
            };

            var li = new Student
            {
                FirstMidName = "Yan",
                LastName = "Li",
                EnrollmentDate = DateTime.Parse("2018-09-01")
            };

            var justice = new Student
            {
```

```
            FirstMidName = "Peggy",
            LastName = "Justice",
            EnrollmentDate = DateTime.Parse("2017-09-01")
        };

        var norman = new Student
        {
            FirstMidName = "Laura",
            LastName = "Norman",
            EnrollmentDate = DateTime.Parse("2019-09-01")
        };

        var olivetto = new Student
        {
            FirstMidName = "Nino",
            LastName = "Olivetto",
            EnrollmentDate = DateTime.Parse("2011-09-01")
        };

        var students = new Student[]
        {
            alexander,
            alonso,
            anand,
            barzdukas,
            li,
            justice,
            norman,
            olivetto
        };

        context.AddRange(students);

        var abercrombie = new Instructor
        {
            FirstMidName = "Kim",
            LastName = "Abercrombie",
            HireDate = DateTime.Parse("1995-03-11")
        };

        var fakhouri = new Instructor
        {
            FirstMidName = "Fadi",
            LastName = "Fakhouri",
            HireDate = DateTime.Parse("2002-07-06")
        };

        var harui = new Instructor
        {
            FirstMidName = "Roger",
            LastName = "Harui",
            HireDate = DateTime.Parse("1998-07-01")
        };

        var kapoor = new Instructor
```

```
            {
                FirstMidName = "Candace",
                LastName = "Kapoor",
                HireDate = DateTime.Parse("2001-01-15")
            };

            var zheng = new Instructor
            {
                FirstMidName = "Roger",
                LastName = "Zheng",
                HireDate = DateTime.Parse("2004-02-12")
            };

            var instructors = new Instructor[]
            {
                abercrombie,
                fakhouri,
                harui,
                kapoor,
                zheng
            };

            context.AddRange(instructors);

            var officeAssignments = new OfficeAssignment[]
            {
                new OfficeAssignment {
                    Instructor = fakhouri,
                    Location = "Smith 17" },
                new OfficeAssignment {
                    Instructor = harui,
                    Location = "Gowan 27" },
                new OfficeAssignment {
                    Instructor = kapoor,
                    Location = "Thompson 304" }
            };

            context.AddRange(officeAssignments);

            var english = new Department
            {
                Name = "English",
                Budget = 350000,
                StartDate = DateTime.Parse("2007-09-01"),
                Administrator = abercrombie
            };

            var mathematics = new Department
            {
                Name = "Mathematics",
                Budget = 100000,
                StartDate = DateTime.Parse("2007-09-01"),
                Administrator = fakhouri
            };
```

```
            var engineering = new Department
            {
                Name = "Engineering",
                Budget = 350000,
                StartDate = DateTime.Parse("2007-09-01"),
                Administrator = harui
            };

            var economics = new Department
            {
                Name = "Economics",
                Budget = 100000,
                StartDate = DateTime.Parse("2007-09-01"),
                Administrator = kapoor
            };

            var departments = new Department[]
            {
                english,
                mathematics,
                engineering,
                economics
            };

            context.AddRange(departments);

            var chemistry = new Course
            {
                CourseID = 1050,
                Title = "Chemistry",
                Credits = 3,
                Department = engineering,
                Instructors = new List<Instructor> { kapoor, harui }
            };

            var microeconomics = new Course
            {
                CourseID = 4022,
                Title = "Microeconomics",
                Credits = 3,
                Department = economics,
                Instructors = new List<Instructor> { zheng }
            };

            var macroeconmics = new Course
            {
                CourseID = 4041,
                Title = "Macroeconomics",
                Credits = 3,
                Department = economics,
                Instructors = new List<Instructor> { zheng }
            };

            var calculus = new Course
            {
```

```
            CourseID = 1045,
            Title = "Calculus",
            Credits = 4,
            Department = mathematics,
            Instructors = new List<Instructor> { fakhouri }
        };

        var trigonometry = new Course
        {
            CourseID = 3141,
            Title = "Trigonometry",
            Credits = 4,
            Department = mathematics,
            Instructors = new List<Instructor> { harui }
        };

        var composition = new Course
        {
            CourseID = 2021,
            Title = "Composition",
            Credits = 3,
            Department = english,
            Instructors = new List<Instructor> { abercrombie }
        };

        var literature = new Course
        {
            CourseID = 2042,
            Title = "Literature",
            Credits = 4,
            Department = english,
            Instructors = new List<Instructor> { abercrombie }
        };

        var courses = new Course[]
        {
            chemistry,
            microeconomics,
            macroeconmics,
            calculus,
            trigonometry,
            composition,
            literature
        };

        context.AddRange(courses);

        var enrollments = new Enrollment[]
        {
            new Enrollment {
                Student = alexander,
                Course = chemistry,
                Grade = Grade.A
            },
            new Enrollment {
```

```
                    Student = alexander,
                    Course = microeconomics,
                    Grade = Grade.C
                },
                new Enrollment {
                    Student = alexander,
                    Course = macroeconmics,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = alonso,
                    Course = calculus,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = alonso,
                    Course = trigonometry,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = alonso,
                    Course = composition,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = anand,
                    Course = chemistry
                },
                new Enrollment {
                    Student = anand,
                    Course = microeconomics,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = barzdukas,
                    Course = chemistry,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = li,
                    Course = composition,
                    Grade = Grade.B
                },
                new Enrollment {
                    Student = justice,
                    Course = literature,
                    Grade = Grade.B
                }
            };

            context.AddRange(enrollments);
            context.SaveChanges();
        }
    }
}
```

The preceding code provides seed data for the new entities. Most of this code creates new entity objects and loads sample data. The sample data is used for testing.

Apply the migration or drop and re-create

With the existing database, there are two approaches to changing the database:

- Drop and re-create the database. Choose this section when using SQLite.
- Apply the migration to the existing database. The instructions in this section work for SQL Server only, ***not for SQLite***.

Either choice works for SQL Server. While the apply-migration method is more complex and time-consuming, it's the preferred approach for real-world, production environments.

Drop and re-create the database

To force EF Core to create a new database, drop and update the database:

Visual Studio

- Delete the *Migrations* folder.
- In the **Package Manager Console** (PMC), run the following commands:

PowerShell

```
Drop-Database
Add-Migration InitialCreate
Update-Database
```

Run the app. Running the app runs the `DbInitializer.Initialize` method. The `DbInitializer.Initialize` populates the new database.

Visual Studio

Open the database in SSOX:

- If SSOX was opened previously, click the **Refresh** button.
- Expand the **Tables** node. The created tables are displayed.

Next steps

The next two tutorials show how to read and update related data.

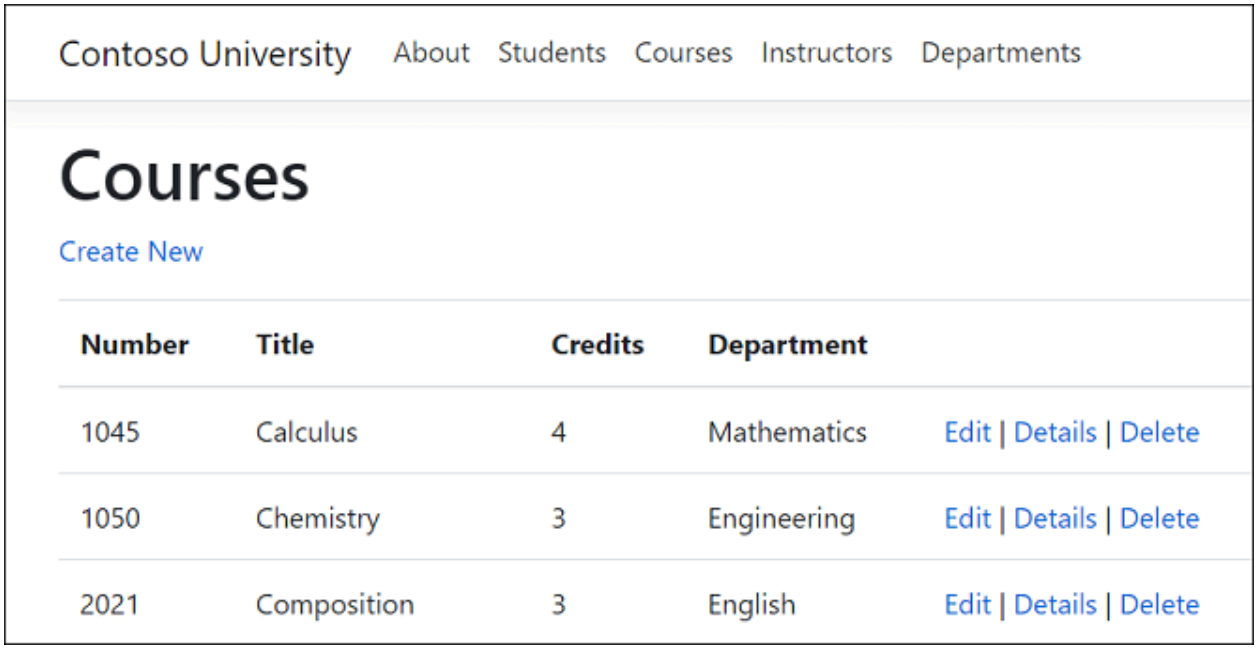
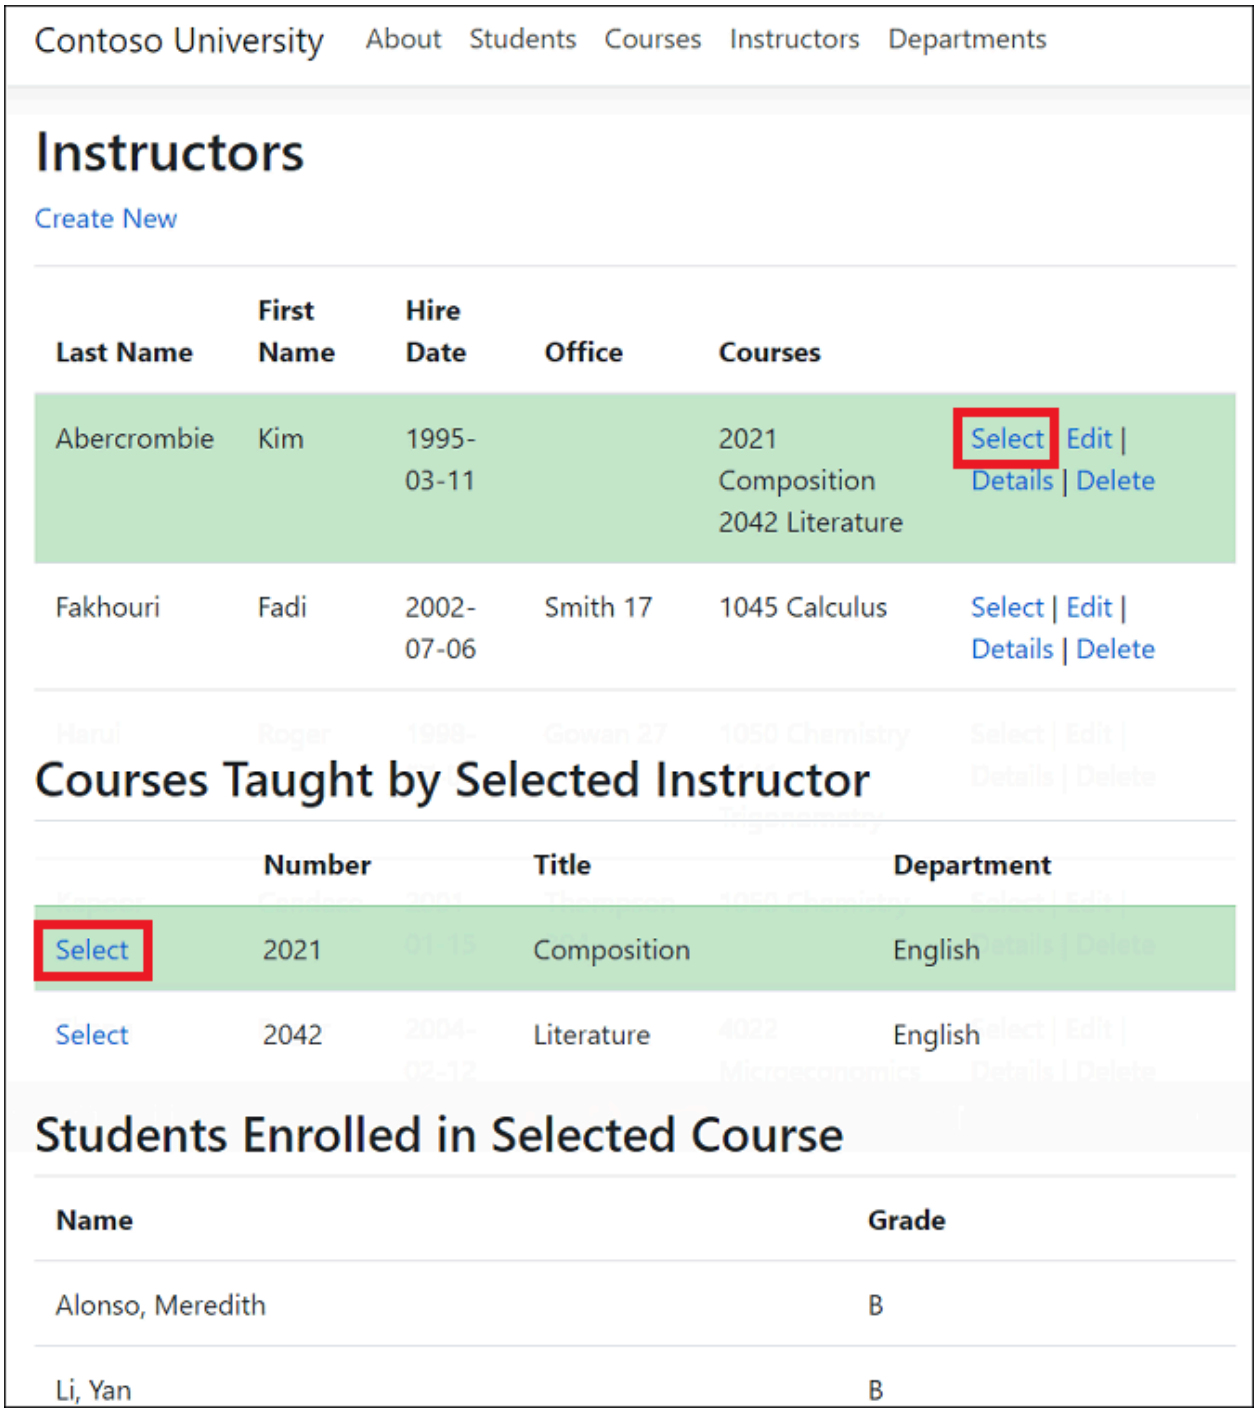
Part 6, Razor Pages with EF Core in ASP.NET Core - Read Related Data

Article • 04/10/2024



By Tom Dykstra, Jon P Smith, and Rick Anderson



The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial shows how to read and display related data. Related data is data that EF Core loads into navigation properties.

The following illustrations show the completed pages for this tutorial:

Eager, explicit, and lazy loading

There are several ways that EF Core can load related data into the navigation properties of an entity:

- Eager loading. Eager loading is when a query for one type of entity also loads related entities. When an entity is read, its related data is retrieved. This typically results in a single join query that retrieves all of the data that's needed. EF Core will issue multiple queries for some types of eager loading. Issuing multiple queries can be more efficient than a large single query. Eager loading is specified with the Include and ThenInclude methods.

```
var departments = _context.Departments.Include(d => d.Courses);
foreach (Department d in departments)
{
    foreach(Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department entities and related Course entities

Eager loading sends multiple queries when a collection navigation is included:

- One query for the main query
- One query for each collection "edge" in the load tree.

- Separate queries with `Load`: The data can be retrieved in separate queries, and EF Core "fixes up" the navigation properties. "Fixes up" means that EF Core automatically populates the navigation properties. Separate queries with `Load` is more like explicit loading than eager loading.

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Courses.Where(c => c.DepartmentID == d.DepartmentID).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows

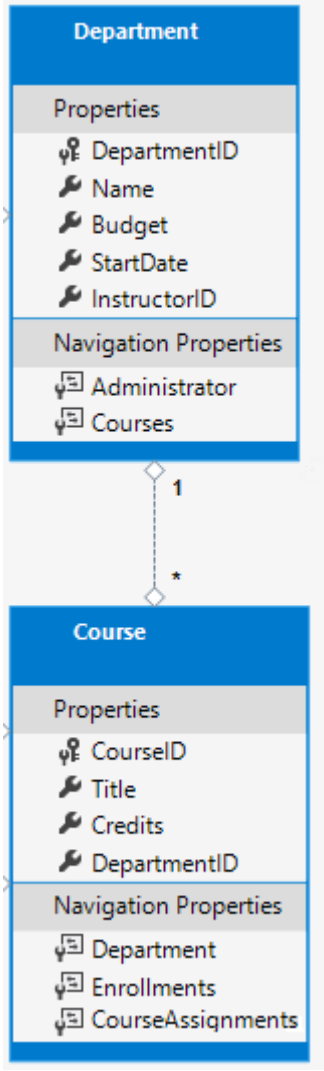
Query: Course rows related to Department d

Note: EF Core automatically fixes up navigation properties to any other entities that were previously loaded into the context instance. Even if the data for a navigation property is *not* explicitly included, the property may still be populated if some or all of the related entities were previously loaded.

- Explicit loading. When the entity is first read, related data isn't retrieved. Code must be written to retrieve the related data when it's needed. Explicit loading with separate queries results in multiple queries sent to the database. With explicit loading, the code specifies the navigation properties to be loaded. Use the `Load` method to do explicit loading. For example:

```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Entry(d).Collection(p => p.Courses).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

Query: all Department rows



Query: Course rows related to Department d

- Lazy loading. When the entity is first read, related data isn't retrieved. The first time a navigation property is accessed, the data required for that navigation property is automatically retrieved. A query is sent to the database each time a navigation property is accessed for the first time. Lazy loading can hurt performance, for

example when developers use N+1 queries. N+1 queries load a parent and enumerate through children.

Create Course pages

The `Course` entity includes a navigation property that contains the related `Department` entity.

To display the name of the assigned department for a course:

- Load the related `Department` entity into the `Course.Department` navigation property.
- Get the name from the `Department` entity's `Name` property.

Scaffold Course pages

Visual Studio

- Follow the instructions in Scaffold Student pages with the following exceptions:
  - Create a *Pages/Courses* folder.
  - Use `Course` for the model class.
  - Use the existing context class instead of creating a new one.

- Open `Pages/Courses/Index.cshtml.cs` and examine the `OnGetAsync` method. The scaffolding engine specified eager loading for the `Department` navigation property. The `Include` method specifies eager loading.

- Run the app and select the **Courses** link. The department column displays the `DepartmentID`, which isn't useful.

Display the department name

Update Pages/Courses/Index.cshtml.cs with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IList<Course> Courses { get; set; }

        public async Task OnGetAsync()
        {
            Courses = await _context.Courses
                .Include(c => c.Department)
                .AsNoTracking()
                .ToListAsync();
        }
```

```
    }
}
```

The preceding code changes the `Course` property to `Courses` and adds `AsNoTracking`.

No-tracking queries are useful when the results are used in a read-only scenario. They're generally quicker to execute because there's no need to set up the change tracking information. If the entities retrieved from the database don't need to be updated, then a no-tracking query is likely to perform better than a tracking query.

In some cases a tracking query is more efficient than a no-tracking query. For more information, see Tracking vs. No-Tracking Queries. In the preceding code, `AsNoTracking` is called because the entities aren't updated in the current context.

Update `Pages/Courses/Index.cshtml` with the following code.

CSHTML

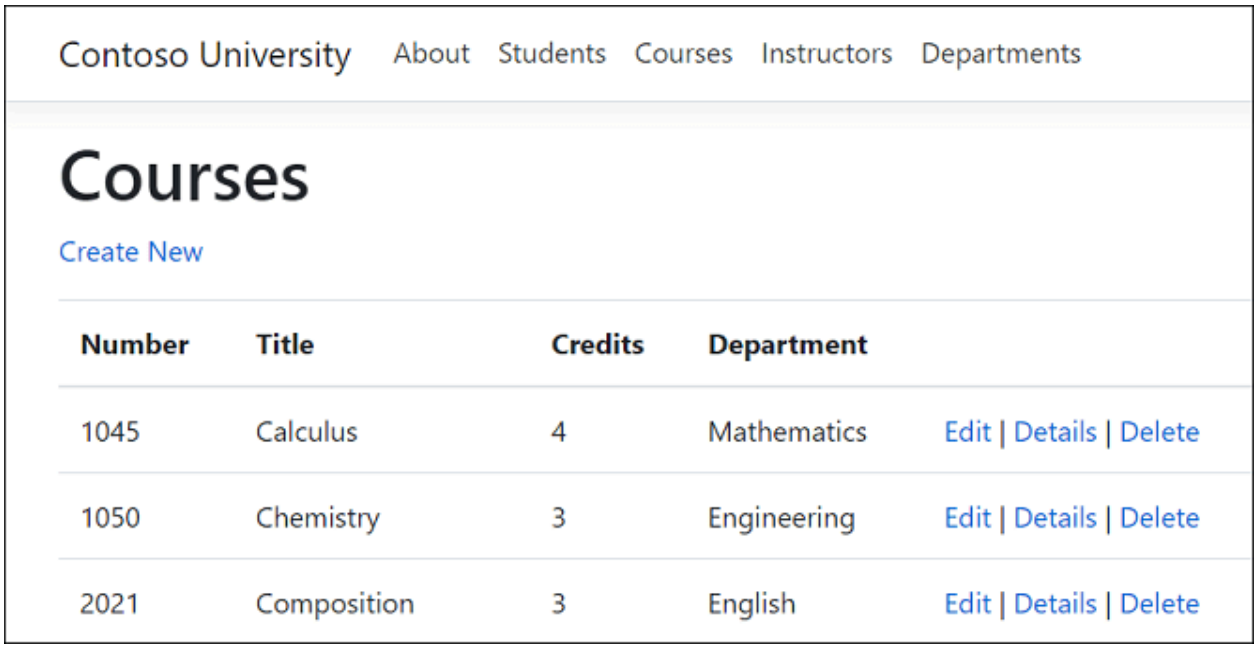
```
@page
@model ContosoUniversity.Pages.Courses.IndexModel

@{
    ViewData["Title"] = "Courses";
}

<h1>Courses</h1>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].CourseID)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Credits)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Courses[0].Department)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model.Courses)
{
```

```
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.CourseID)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Title)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Credits)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.Department.Name)
            </td>
            <td>
                <a asp-page="./Edit" asp-route-id="@item.CourseID">Edit</a>
|
                <a asp-page="./Details" asp-route-
id="@item.CourseID">Details</a> |
                <a asp-page="./Delete" asp-route-
id="@item.CourseID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```



The following changes have been made to the scaffolded code:

- Changed the `Course` property name to `Courses`.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they're meaningless to end users. However, in this case the primary key is meaningful.
- Changed the **Department** column to display the department name. The code displays the `Name` property of the `Department` entity that's loaded into the `Department` navigation property:

  HTML

  ```
  @Html.DisplayFor(modelItem => item.Department.Name)
  ```

Run the app and select the **Courses** tab to see the list with department names.

Loading related data with Select

The `OnGetAsync` method loads related data with the `Include` method. The `Select` method is an alternative that loads only the related data needed. For single items, like the `Department.Name` it uses a `SQL INNER JOIN`. For collections, it uses another database access, but so does the `Include` operator on collections.

The following code loads related data with the `Select` method:

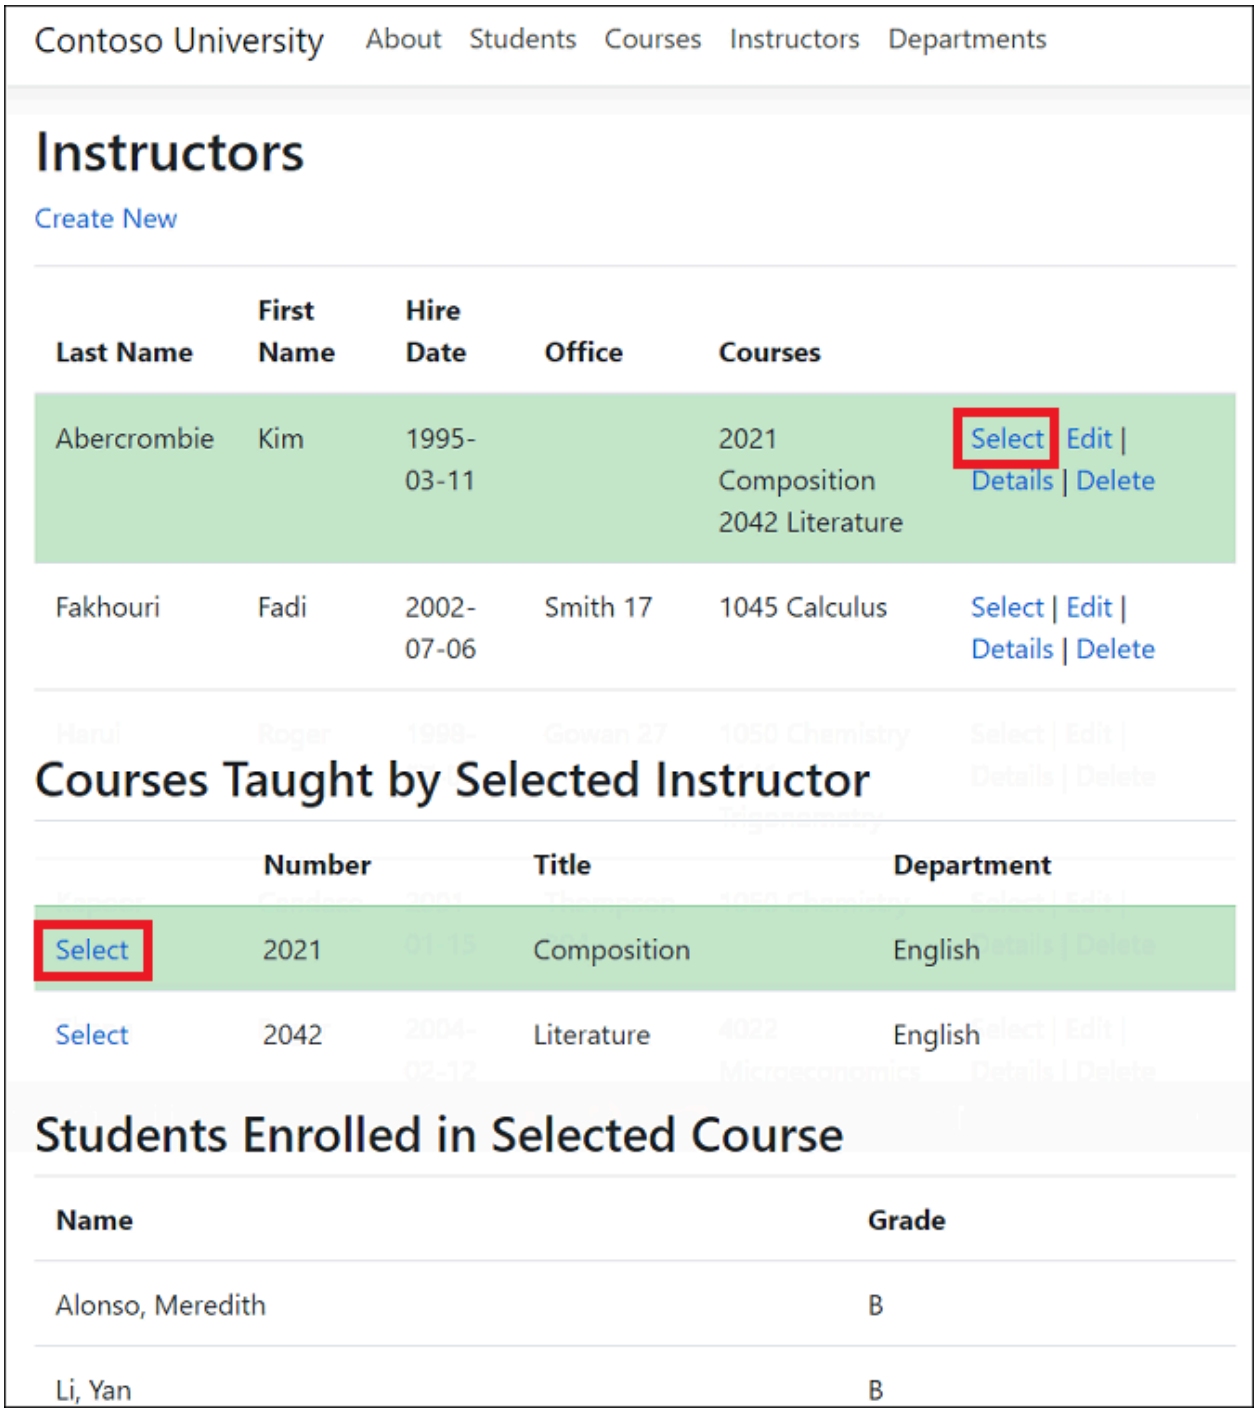
C#

```
public IList<CourseViewModel> CourseVM { get; set; }

public async Task OnGetAsync()
{
    CourseVM = await _context.Courses
    .Select(p => new CourseViewModel
    {
        CourseID = p.CourseID,
        Title = p.Title,
        Credits = p.Credits,
        DepartmentName = p.Department.Name
    }).ToListAsync();
}
```

The preceding code doesn't return any entity types, therefore no tracking is done. For more information about the EF tracking, see Tracking vs. No-Tracking Queries.

The `CourseViewModel`:



C#

```
public class CourseViewModel
{
    public int CourseID { get; set; }
    public string Title { get; set; }
    public int Credits { get; set; }
    public string DepartmentName { get; set; }
}
```

See IndexSelectModel for the complete Razor Pages.

Create Instructor pages

This section scaffolds Instructor pages and adds related Courses and Enrollments to the Instructors Index page.

This page reads and displays related data in the following ways:

- The list of instructors displays related data from the `OfficeAssignment` entity (Office in the preceding image). The `Instructor` and `OfficeAssignment` entities are in a one-to-zero-or-one relationship. Eager loading is used for the `OfficeAssignment` entities. Eager loading is typically more efficient when the related data needs to be displayed. In this case, office assignments for the instructors are displayed.
- When the user selects an instructor, related `Course` entities are displayed. The `Instructor` and `Course` entities are in a many-to-many relationship. Eager loading is used for the `Course` entities and their related `Department` entities. In this case, separate queries might be more efficient because only courses for the selected

instructor are needed. This example shows how to use eager loading for navigation properties in entities that are in navigation properties.

- When the user selects a course, related data from the `Enrollments` entity is displayed. In the preceding image, student name and grade are displayed. The `Course` and `Enrollment` entities are in a one-to-many relationship.

Create a view model

The instructors page shows data from three different tables. A view model is needed that includes three properties representing the three tables.

Create `Models/SchoolViewModels/InstructorIndexData.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Scaffold Instructor pages

Visual Studio

- Follow the instructions in Scaffold the student pages with the following exceptions:
  - Create a *Pages/Instructors* folder.
  - Use `Instructor` for the model class.
  - Use the existing context class instead of creating a new one.

Run the app and navigate to the Instructors page.

Update `Pages/Instructors/Index.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;  // Add VM
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class IndexModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public IndexModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public InstructorIndexData InstructorData { get; set; }
        public int InstructorID { get; set; }
        public int CourseID { get; set; }

        public async Task OnGetAsync(int? id, int? courseID)
        {
            InstructorData = new InstructorIndexData();
            InstructorData.Instructors = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.Courses)
                    .ThenInclude(c => c.Department)
                .OrderBy(i => i.LastName)
                .ToListAsync();

            if (id != null)
            {
                InstructorID = id.Value;
                Instructor instructor = InstructorData.Instructors
                    .Where(i => i.ID == id.Value).Single();
                InstructorData.Courses = instructor.Courses;
            }

            if (courseID != null)
            {
                CourseID = courseID.Value;
                IEnumerable<Enrollment> Enrollments = await
_context.Enrollments
                    .Where(x => x.CourseID == CourseID)
                    .Include(i=>i.Student)
                    .ToListAsync();
                InstructorData.Enrollments = Enrollments;
```

```
            }
        }
    }
}
```

The `OnGetAsync` method accepts optional route data for the ID of the selected instructor.

Examine the query in the `Pages/Instructors/Index.cshtml.cs` file:

C#

```
InstructorData = new InstructorIndexData();
InstructorData.Instructors = await _context.Instructors
    .Include(i => i.OfficeAssignment)
    .Include(i => i.Courses)
        .ThenInclude(c => c.Department)
    .OrderBy(i => i.LastName)
    .ToListAsync();
```

The code specifies eager loading for the following navigation properties:

- `Instructor.OfficeAssignment`
- `Instructor.Courses`
  - `Course.Department`

The following code executes when an instructor is selected, that is, `id != null`.

C#

```
if (id != null)
{
    InstructorID = id.Value;
    Instructor instructor = InstructorData.Instructors
        .Where(i => i.ID == id.Value).Single();
    InstructorData.Courses = instructor.Courses;
}
```

The selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is loaded with the `Course` entities from the selected instructor's `Courses` navigation property.

The `Where` method returns a collection. In this case, the filter select a single entity, so the `Single` method is called to convert the collection into a single `Instructor` entity. The `Instructor` entity provides access to the `Course` navigation property.

The Single method is used on a collection when the collection has only one item. The `Single` method throws an exception if the collection is empty or if there's more than one item. An alternative is SingleOrDefault, which returns a default value if the collection is empty. For this query, `null` in the default returned.

The following code populates the view model's `Enrollments` property when a course is selected:

C#

```
if (courseID != null)
{
    CourseID = courseID.Value;
    IEnumerable<Enrollment> Enrollments = await _context.Enrollments
        .Where(x => x.CourseID == CourseID)
        .Include(i=>i.Student)
        .ToListAsync();
    InstructorData.Enrollments = Enrollments;
}
```

Update the instructors Index page

Update `Pages/Instructors/Index.cshtml` with the following code.

CSHTML

```
@page "{id:int?}"
@model ContosoUniversity.Pages.Instructors.IndexModel

@{
    ViewData["Title"] = "Instructors";
}

<h2>Instructors</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>Last Name</th>
            <th>First Name</th>
            <th>Hire Date</th>
            <th>Office</th>
            <th>Courses</th>
            <th></th>
        </tr>
    </thead>
```

```
    <tbody>
        @foreach (var item in Model.InstructorData.Instructors)
        {
            string selectedRow = "";
            if (item.ID == Model.InstructorID)
            {
                selectedRow = "table-success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.HireDate)
                </td>
                <td>
                    @if (item.OfficeAssignment != null)
                    {
                        @item.OfficeAssignment.Location
                    }
                </td>
                <td>
                    @{
                        foreach (var course in item.Courses)
                        {
                            @course.CourseID @:  @course.Title <br />
                        }
                    }
                </td>
                <td>
                    <a asp-page="./Index" asp-route-id="@item.ID">Select</a>
|
                    <a asp-page="./Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-page="./Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-page="./Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>

@if (Model.InstructorData.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
```

```
        </tr>

        @foreach (var item in Model.InstructorData.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == Model.CourseID)
            {
                selectedRow = "table-success";
            }
            <tr class="@selectedRow">
                <td>
                    <a asp-page="./Index" asp-route-
courseID="@item.CourseID">Select</a>
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}

@if (Model.InstructorData.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.InstructorData.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

The preceding code makes the following changes:

- Updates the `page` directive to `@page "{id:int?}"`. `"{id:int?}"` is a route template. The route template changes integer query strings in the URL to route data. For example, clicking on the **Select** link for an instructor with only the `@page` directive produces a URL like the following:

  `https://localhost:5001/Instructors?id=2`

  When the page directive is `@page "{id:int?}"`, the URL is: `https://localhost:5001/Instructors/2`

- Adds an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` isn't null. Because this is a one-to-zero-or-one relationship, there might not be a related OfficeAssignment entity.

  HTML

  ```
  @if (item.OfficeAssignment != null)
  {
      @item.OfficeAssignment.Location
  }
  ```

- Adds a **Courses** column that displays courses taught by each instructor. See Explicit line transition for more about this razor syntax.

- Adds code that dynamically adds `class="table-success"` to the `tr` element of the selected instructor and course. This sets a background color for the selected row using a Bootstrap class.

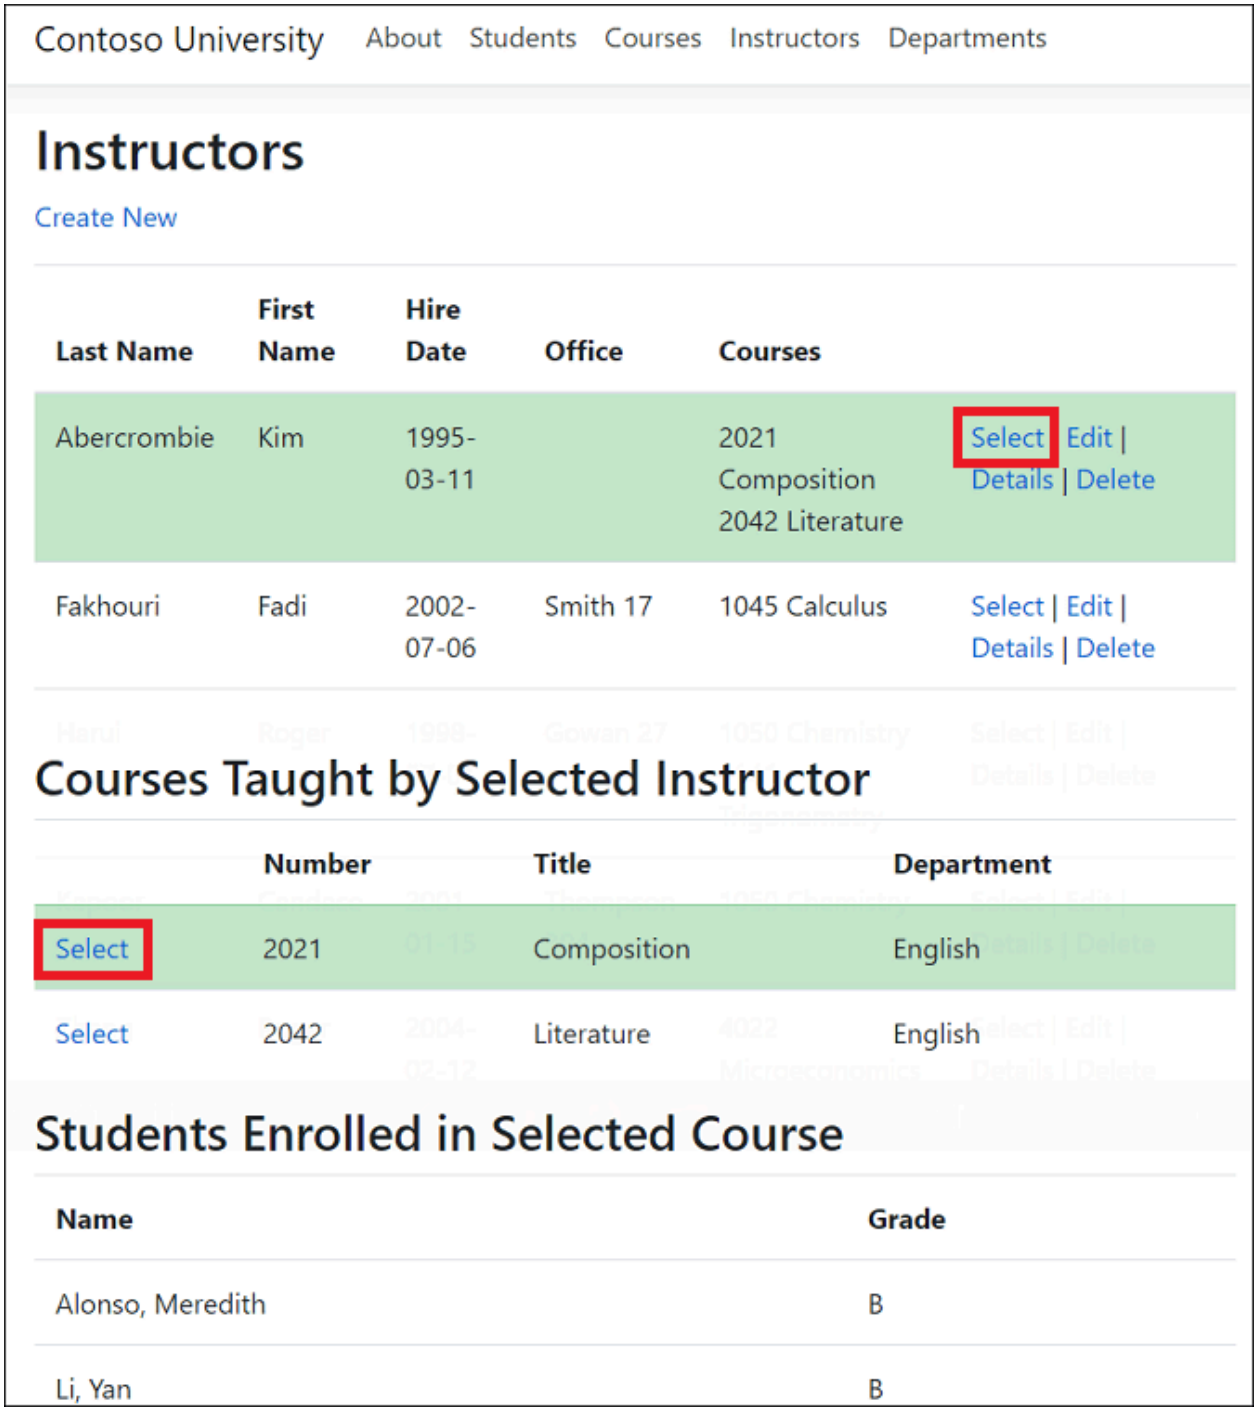
  HTML

  ```
  string selectedRow = "";
  if (item.CourseID == Model.CourseID)
  {
      selectedRow = "table-success";
  }
  <tr class="@selectedRow">
  ```

- Adds a new hyperlink labeled **Select**. This link sends the selected instructor's ID to the `Index` method and sets a background color.

  HTML

  ```
  <a asp-action="Index" asp-route-id="@item.ID">Select</a> |
  ```



- Adds a table of courses for the selected Instructor.

- Adds a table of student enrollments for the selected course.

Run the app and select the **Instructors** tab. The page displays the `Location` (office) from the related `OfficeAssignment` entity. If `OfficeAssignment` is null, an empty table cell is displayed.

Click on the **Select** link for an instructor. The row style changes and courses assigned to that instructor are displayed.

Select a course to see the list of enrolled students and their grades.

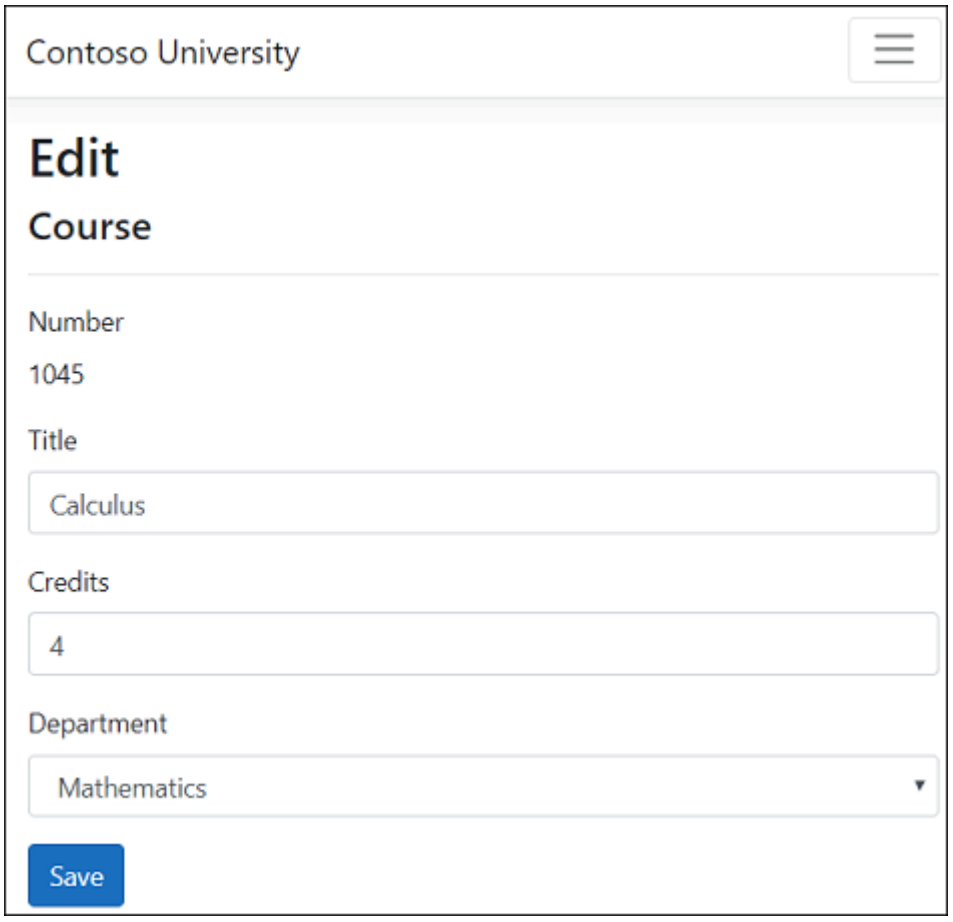
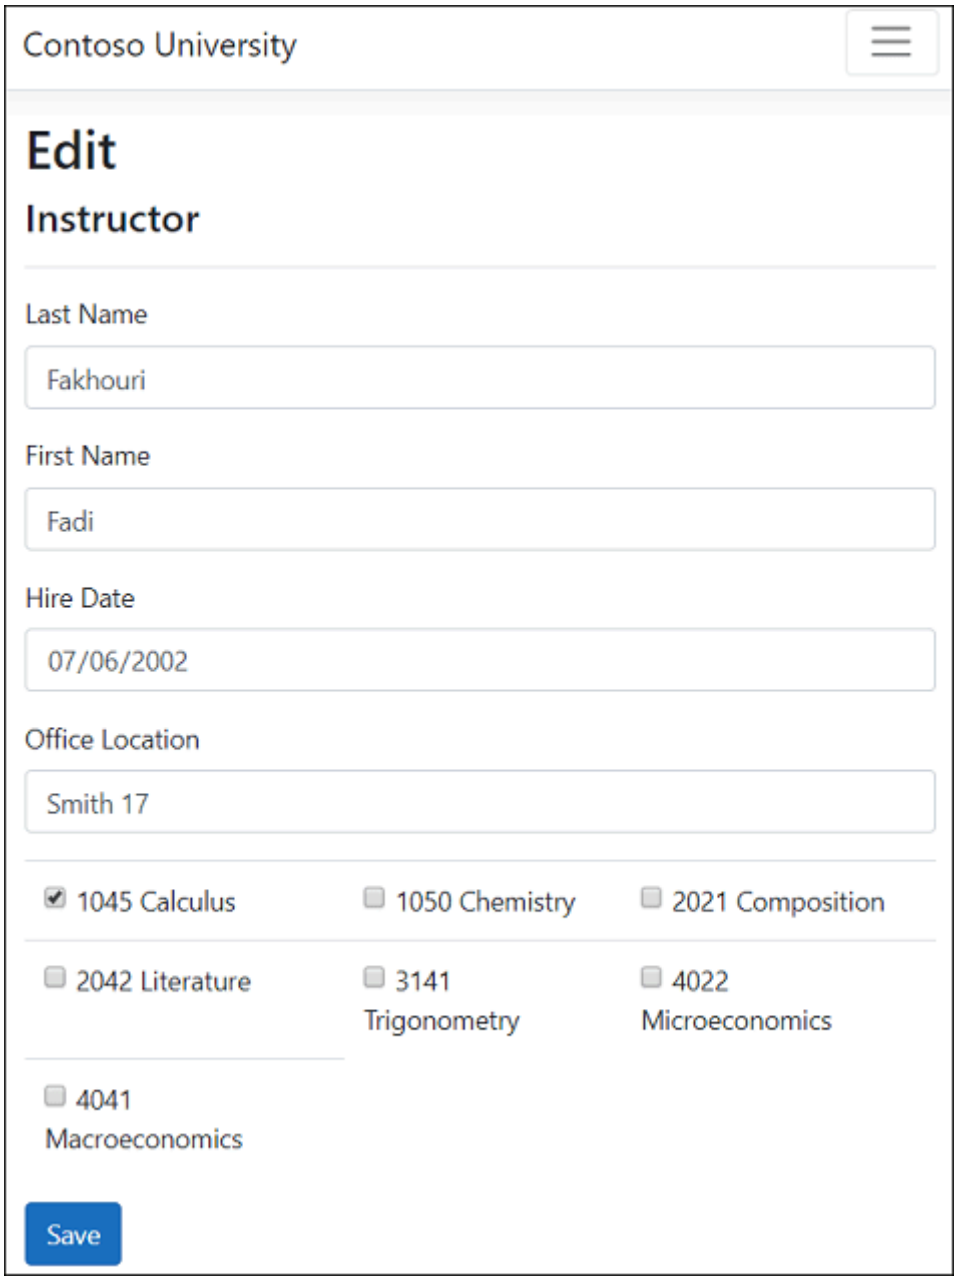
Part 7, Razor Pages with EF Core in ASP.NET Core - Update Related Data



Article • 04/10/2024



By Tom Dykstra, Jon P Smith, and Rick Anderson

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

This tutorial shows how to update related data. The following illustrations show some of the completed pages.

Update the Course Create and Edit pages

The scaffolded code for the Course Create and Edit pages has a Department drop-down list that shows `DepartmentID`, an `int`. The drop-down should show the Department name, so both of these pages need a list of department names. To provide that list, use a base class for the Create and Edit pages.

Create a base class for Course Create and Edit

Create a `Pages/Courses/DepartmentNamePageModel.cs` file with the following code:

```
C#

using ContosoUniversity.Data;
using ContosoUniversity.Models;
```

```
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;

namespace ContosoUniversity.Pages.Courses
{
    public class DepartmentNamePageModel : PageModel
    {
        public SelectList DepartmentNameSL { get; set; }

        public void PopulateDepartmentsDropDownList(SchoolContext _context,
            object selectedDepartment = null)
        {
            var departmentsQuery = from d in _context.Departments
                                   orderby d.Name // Sort by name.
                                   select d;

            DepartmentNameSL = new
SelectList(departmentsQuery.AsNoTracking(),
                nameof(Department.DepartmentID),
                nameof(Department.Name),
                selectedDepartment);
        }
    }
}
```

The preceding code creates a SelectList to contain the list of department names. If `selectedDepartment` is specified, that department is selected in the `SelectList`.

The Create and Edit page model classes will derive from `DepartmentNamePageModel`.

Update the Course Create page model

A Course is assigned to a Department. The base class for the Create and Edit pages provides a `SelectList` for selecting the department. The drop-down list that uses the `SelectList` sets the `Course.DepartmentID` foreign key (FK) property. EF Core uses the `Course.DepartmentID` FK to load the `Department` navigation property.

Update `Pages/Courses/Create.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class CreateModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public CreateModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        public IActionResult OnGet()
```

```
        {
            PopulateDepartmentsDropDownList(_context);
            return Page();
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnPostAsync()
        {
            var emptyCourse = new Course();

            if (await TryUpdateModelAsync<Course>(
                 emptyCourse,
                 "course",   // Prefix for form value.
                 s => s.CourseID, s => s.DepartmentID, s => s.Title, s =>
s.Credits))
            {
                _context.Courses.Add(emptyCourse);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context,
emptyCourse.DepartmentID);
            return Page();
        }
    }
}
```

If you would like to see code comments translated to languages other than English, let us know in this GitHub discussion issue.

The preceding code:

- Derives from `DepartmentNamePageModel`.
- Uses TryUpdateModelAsync to prevent overposting.
- Removes `ViewData["DepartmentID"]`. The `DepartmentNameSL` `SelectList` is a strongly typed model and will be used by the Razor page. Strongly typed models are preferred over weakly typed. For more information, see Weakly typed data (ViewData and ViewBag).

Update the Course Create Razor page

Update `Pages/Courses/Create.cshtml` with the following code:

CSHTML

```
@page
@model ContosoUniversity.Pages.Courses.CreateModel
@{
    ViewData["Title"] = "Create Course";
}
<h2>Create</h2>
<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label">
</label>
                <input asp-for="Course.CourseID" class="form-control" />
                <span asp-validation-for="Course.CourseID" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label">
</label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Department" class="control-label">
</label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL">
                    <option value="">-- Select Department --</option>
                </select>
                <span asp-validation-for="Course.DepartmentID" class="text-
danger" />
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary"
/>
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="Index">Back to List</a>
</div>
@section Scripts {
```

```
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code makes the following changes:

- Changes the caption from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL` (from the base class).
- Adds the "Select Department" option. This change renders "Select Department" in the drop-down when no department has been selected yet, rather than the first department.
- Adds a validation message when the department isn't selected.

The Razor Page uses the Select Tag Helper:

CSHTML

```
<div class="form-group">
    <label asp-for="Course.Department" class="control-label"></label>
    <select asp-for="Course.DepartmentID" class="form-control"
            asp-items="@Model.DepartmentNameSL">
        <option value="">-- Select Department --</option>
    </select>
    <span asp-validation-for="Course.DepartmentID" class="text-danger" />
</div>
```

Test the Create page. The Create page displays the department name rather than the department ID.

Update the Course Edit page model

Update `Pages/Courses/Edit.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Courses
{
    public class EditModel : DepartmentNamePageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
```

```
            _context = context;
        }

        [BindProperty]
        public Course Course { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Course = await _context.Courses
                .Include(c => c.Department).FirstOrDefaultAsync(m =>
m.CourseID == id);

            if (Course == null)
            {
                return NotFound();
            }

            // Select current DepartmentID.
            PopulateDepartmentsDropDownList(_context, Course.DepartmentID);
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            var courseToUpdate = await _context.Courses.FindAsync(id);

            if (courseToUpdate == null)
            {
                return NotFound();
            }

            if (await TryUpdateModelAsync<Course>(
                 courseToUpdate,
                 "course",   // Prefix for form value.
                   c => c.Credits, c => c.DepartmentID, c => c.Title))
            {
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }

            // Select DepartmentID if TryUpdateModelAsync fails.
            PopulateDepartmentsDropDownList(_context,
courseToUpdate.DepartmentID);
            return Page();
        }
```

```
    }
}
```

The changes are similar to those made in the Create page model. In the preceding code, `PopulateDepartmentsDropDownList` passes in the department ID, which selects that department in the drop-down list.

Update the Course Edit Razor page

Update `Pages/Courses/Edit.cshtml` with the following code:

CSHTML

```
@page
@model ContosoUniversity.Pages.Courses.EditModel

@{
    ViewData["Title"] = "Edit";
}

<h2>Edit</h2>

<h4>Course</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="Course.CourseID" />
            <div class="form-group">
                <label asp-for="Course.CourseID" class="control-label">
</label>
                <div>@Html.DisplayFor(model => model.Course.CourseID)</div>
            </div>
            <div class="form-group">
                <label asp-for="Course.Title" class="control-label"></label>
                <input asp-for="Course.Title" class="form-control" />
                <span asp-validation-for="Course.Title" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="Course.Credits" class="control-label">
</label>
                <input asp-for="Course.Credits" class="form-control" />
                <span asp-validation-for="Course.Credits" class="text-
danger"></span>
            </div>
            <div class="form-group">
```

```
                <label asp-for="Course.Department" class="control-label">
</label>
                <select asp-for="Course.DepartmentID" class="form-control"
                        asp-items="@Model.DepartmentNameSL"></select>
                <span asp-validation-for="Course.DepartmentID" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code makes the following changes:

- Displays the course ID. Generally the Primary Key (PK) of an entity isn't displayed. PKs are usually meaningless to users. In this case, the PK is the course number.
- Changes the caption for the Department drop-down from **DepartmentID** to **Department**.
- Replaces `"ViewBag.DepartmentID"` with `DepartmentNameSL`, which is in the base class.

The page contains a hidden field (`<input type="hidden">`) for the course number. Adding a `<label>` tag helper with `asp-for="Course.CourseID"` doesn't eliminate the need for the hidden field. `<input type="hidden">` is required for the course number to be included in the posted data when the user selects **Save**.

Update the Course page models

AsNoTracking can improve performance when tracking isn't required.

Update `Pages/Courses/Delete.cshtml.cs` and `Pages/Courses/Details.cshtml.cs` by adding `AsNoTracking` to the `OnGetAsync` methods:

C#

```
public async Task<IActionResult> OnGetAsync(int? id)
{
    if (id == null)
```

```
    {
        return NotFound();
    }

    Course = await _context.Courses
        .AsNoTracking()
        .Include(c => c.Department)
        .FirstOrDefaultAsync(m => m.CourseID == id);

    if (Course == null)
    {
        return NotFound();
    }
    return Page();
}
```

Update the Course Razor pages

Update `Pages/Courses/Delete.cshtml` with the following code:

CSHTML

```
@page
@model ContosoUniversity.Pages.Courses.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Credits)
        </dt>
        <dd class="col-sm-10">
```

```
            @Html.DisplayFor(model => model.Course.Credits)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Department.Name)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Course.CourseID" />
        <input type="submit" value="Delete" class="btn btn-danger" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

Make the same changes to the Details page.

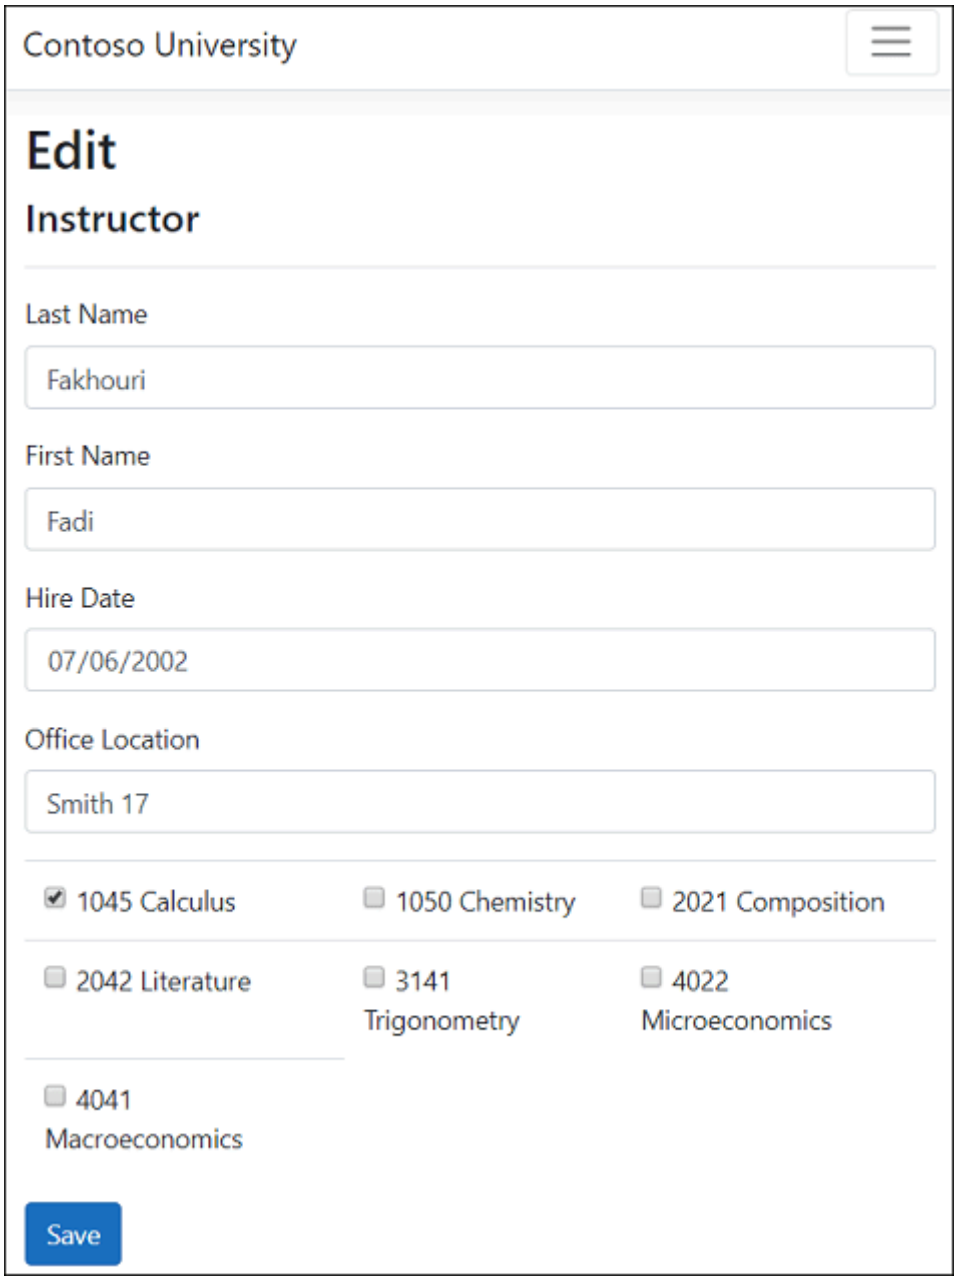
CSHTML

```
@page
@model ContosoUniversity.Pages.Courses.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h2>Details</h2>

<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Course.Credits)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Credits)
        </dd>
        <dt class="col-sm-2">
```



```
            @Html.DisplayNameFor(model => model.Course.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Course.Department.Name)
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Course.CourseID">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

Test the Course pages

Test the create, edit, details, and delete pages.

Update the instructor Create and Edit pages

Instructors may teach any number of courses. The following image shows the instructor Edit page with an array of course checkboxes.

The checkboxes enable changes to courses an instructor is assigned to. A checkbox is displayed for every course in the database. Courses that the instructor is assigned to are selected. The user can select or clear checkboxes to change course assignments. If the number of courses were much greater, a different UI might work better. But the method of managing a many-to-many relationship shown here wouldn't change. To create or delete relationships, you manipulate a join entity.

Create a class for assigned courses data

Create `Models/SchoolViewModels/AssignedCourseData.cs` with the following code:

C#

```
namespace ContosoUniversity.Models.SchoolViewModels
{
    public class AssignedCourseData
```

```
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

The `AssignedCourseData` class contains data to create the checkboxes for courses assigned to an instructor.

Create an Instructor page model base class

Create the `Pages/Instructors/InstructorCoursesPageModel.cs` base class:

C#

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using ContosoUniversity.Models.SchoolViewModels;
using Microsoft.AspNetCore.Mvc.RazorPages;
using System.Collections.Generic;
using System.Linq;

namespace ContosoUniversity.Pages.Instructors
{
    public class InstructorCoursesPageModel : PageModel
    {
        public List<AssignedCourseData> AssignedCourseDataList;

        public void PopulateAssignedCourseData(SchoolContext context,
                                               Instructor instructor)
        {
            var allCourses = context.Courses;
            var instructorCourses = new HashSet<int>(
                instructor.Courses.Select(c => c.CourseID));
            AssignedCourseDataList = new List<AssignedCourseData>();
            foreach (var course in allCourses)
            {
                AssignedCourseDataList.Add(new AssignedCourseData
                {
                    CourseID = course.CourseID,
                    Title = course.Title,
                    Assigned = instructorCourses.Contains(course.CourseID)
                });
            }
        }
    }
}
```

The `InstructorCoursesPageModel` is the base class for the Edit and Create page models. `PopulateAssignedCourseData` reads all `Course` entities to populate `AssignedCourseDataList`. For each course, the code sets the `CourseID`, title, and whether or not the instructor is assigned to the course. A HashSet is used for efficient lookups.

Handle office location

Another relationship the edit page has to handle is the one-to-zero-or-one relationship that the Instructor entity has with the `OfficeAssignment` entity. The instructor edit code must handle the following scenarios:

- If the user clears the office assignment, delete the `OfficeAssignment` entity.
- If the user enters an office assignment and it was empty, create a new `OfficeAssignment` entity.
- If the user changes the office assignment, update the `OfficeAssignment` entity.

Update the Instructor Edit page model

Update `Pages/Instructors/Edit.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class EditModel : InstructorCoursesPageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
```

```
            {
                return NotFound();
            }

            Instructor = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.Courses)
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.ID == id);

            if (Instructor == null)
            {
                return NotFound();
            }
            PopulateAssignedCourseData(_context, Instructor);
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id, string[]
selectedCourses)
        {
            if (id == null)
            {
                return NotFound();
            }

            var instructorToUpdate = await _context.Instructors
                .Include(i => i.OfficeAssignment)
                .Include(i => i.Courses)
                .FirstOrDefaultAsync(s => s.ID == id);

            if (instructorToUpdate == null)
            {
                return NotFound();
            }

            if (await TryUpdateModelAsync<Instructor>(
                instructorToUpdate,
                "Instructor",
                i => i.FirstMidName, i => i.LastName,
                i => i.HireDate, i => i.OfficeAssignment))
            {
                if (String.IsNullOrWhiteSpace(
                    instructorToUpdate.OfficeAssignment?.Location))
                {
                    instructorToUpdate.OfficeAssignment = null;
                }
                UpdateInstructorCourses(selectedCourses,
instructorToUpdate);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            UpdateInstructorCourses(selectedCourses, instructorToUpdate);
            PopulateAssignedCourseData(_context, instructorToUpdate);
            return Page();
```

```
        }

        public void UpdateInstructorCourses(string[] selectedCourses,
                                            Instructor instructorToUpdate)
        {
            if (selectedCourses == null)
            {
                instructorToUpdate.Courses = new List<Course>();
                return;
            }

            var selectedCoursesHS = new HashSet<string>(selectedCourses);
            var instructorCourses = new HashSet<int>
                (instructorToUpdate.Courses.Select(c => c.CourseID));
            foreach (var course in _context.Courses)
            {
                if (selectedCoursesHS.Contains(course.CourseID.ToString()))
                {
                    if (!instructorCourses.Contains(course.CourseID))
                    {
                        instructorToUpdate.Courses.Add(course);
                    }
                }
                else
                {
                    if (instructorCourses.Contains(course.CourseID))
                    {
                        var courseToRemove =
instructorToUpdate.Courses.Single(
                                                              c => c.CourseID ==
course.CourseID);
                        instructorToUpdate.Courses.Remove(courseToRemove);
                    }
                }
            }
        }
    }
}
```

The preceding code:

- Gets the current `Instructor` entity from the database using eager loading for the `OfficeAssignment` and `Courses` navigation properties.
- Updates the retrieved `Instructor` entity with values from the model binder. TryUpdateModelAsync prevents overposting.
- If the office location is blank, sets `Instructor.OfficeAssignment` to null. When `Instructor.OfficeAssignment` is null, the related row in the `OfficeAssignment` table is deleted.
- Calls `PopulateAssignedCourseData` in `OnGetAsync` to provide information for the checkboxes using the `AssignedCourseData` view model class.

- Calls `UpdateInstructorCourses` in `OnPostAsync` to apply information from the checkboxes to the Instructor entity being edited.
- Calls `PopulateAssignedCourseData` and `UpdateInstructorCourses` in `OnPostAsync` if TryUpdateModelAsync fails. These method calls restore the assigned course data entered on the page when it is redisplayed with an error message.

Since the Razor page doesn't have a collection of Course entities, the model binder can't automatically update the `Courses` navigation property. Instead of using the model binder to update the `Courses` navigation property, that's done in the new `UpdateInstructorCourses` method. Therefore you need to exclude the `Courses` property from model binding. This doesn't require any change to the code that calls TryUpdateModelAsync because you're using the overload with declared properties and `Courses` isn't in the include list.

If no checkboxes were selected, the code in `UpdateInstructorCourses` initializes the `instructorToUpdate.Courses` with an empty collection and returns:

C#

```
if (selectedCourses == null)
{
    instructorToUpdate.Courses = new List<Course>();
    return;
}
```

The code then loops through all courses in the database and checks each course against the ones currently assigned to the instructor versus the ones that were selected in the page. To facilitate efficient lookups, the latter two collections are stored in `HashSet` objects.

If the checkbox for a course is selected but the course is ***not*** in the `Instructor.Courses` navigation property, the course is added to the collection in the navigation property.

C#

```
if (selectedCoursesHS.Contains(course.CourseID.ToString()))
{
    if (!instructorCourses.Contains(course.CourseID))
    {
        instructorToUpdate.Courses.Add(course);
    }
}
```

If the checkbox for a course is ***not*** selected, but the course is in the `Instructor.Courses` navigation property, the course is removed from the navigation property.

C#

```
else
{
    if (instructorCourses.Contains(course.CourseID))
    {
        var courseToRemove = instructorToUpdate.Courses.Single(
                                        c => c.CourseID == course.CourseID);
        instructorToUpdate.Courses.Remove(courseToRemove);
    }
}
```

Update the Instructor Edit Razor page

Update `Pages/Instructors/Edit.cshtml` with the following code:

CSHTML

```
@page
@model ContosoUniversity.Pages.Instructors.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="Instructor.ID" />
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label">
</label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-
label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-
control" />
                <span asp-validation-for="Instructor.FirstMidName"
class="text-danger"></span>
            </div>
            <div class="form-group">
```

```
                <label asp-for="Instructor.HireDate" class="control-label">
</label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location"
class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location"
class="form-control" />
                <span asp-validation-
for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <div class="table">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in
Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ?
"checked=\"checked\"" : "")) />
                                               @course.CourseID @:
@course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>

@section Scripts {
```

```
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code creates an HTML table that has three columns. Each column has a checkbox and a caption containing the course number and title. The checkboxes all have the same name ("selectedCourses"). Using the same name informs the model binder to treat them as a group. The value attribute of each checkbox is set to `CourseID`. When the page is posted, the model binder passes an array that consists of the `CourseID` values for only the checkboxes that are selected.

When the checkboxes are initially rendered, courses assigned to the instructor are selected.

Note: The approach taken here to edit instructor course data works well when there's a limited number of courses. For collections that are much larger, a different UI and a different updating method would be more useable and efficient.

Run the app and test the updated Instructors Edit page. Change some course assignments. The changes are reflected on the Index page.

Update the Instructor Create page

Update the Instructor Create page model and with code similar to the Edit page:

C#

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.Logging;
using System;
using System.Collections.Generic;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class CreateModel : InstructorCoursesPageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;
        private readonly ILogger<InstructorCoursesPageModel> _logger;

        public CreateModel(SchoolContext context,
                           ILogger<InstructorCoursesPageModel> logger)
        {
            _context = context;
            _logger = logger;
        }
```

```
        public IActionResult OnGet()
        {
            var instructor = new Instructor();
            instructor.Courses = new List<Course>();

            // Provides an empty collection for the foreach loop
            // foreach (var course in Model.AssignedCourseDataList)
            // in the Create Razor page.
            PopulateAssignedCourseData(_context, instructor);
            return Page();
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnPostAsync(string[]
selectedCourses)
        {
            var newInstructor = new Instructor();

            if (selectedCourses.Length > 0)
            {
                newInstructor.Courses = new List<Course>();
                // Load collection with one DB call.
                _context.Courses.Load();
            }

            // Add selected Courses courses to the new instructor.
            foreach (var course in selectedCourses)
            {
                var foundCourse = await
_context.Courses.FindAsync(int.Parse(course));
                if (foundCourse != null)
                {
                    newInstructor.Courses.Add(foundCourse);
                }
                else
                {
                    _logger.LogWarning("Course {course} not found", course);
                }
            }

            try
            {
                if (await TryUpdateModelAsync<Instructor>(
                                newInstructor,
                                "Instructor",
                                i => i.FirstMidName, i => i.LastName,
                                i => i.HireDate, i => i.OfficeAssignment))
                {
                    _context.Instructors.Add(newInstructor);
                    await _context.SaveChangesAsync();
                    return RedirectToPage("./Index");
                }
```

```
                return RedirectToPage("./Index");
            }
            catch (Exception ex)
            {
                _logger.LogError(ex.Message);
            }

            PopulateAssignedCourseData(_context, newInstructor);
            return Page();
        }
    }
}
```

The preceding code:

- Adds logging for warning and error messages.
- Calls Load, which fetches all the Courses in one database call. For small collections this is an optimization when using FindAsync. `FindAsync` returns the tracked entity without a request to the database.

```
C#

public async Task<IActionResult> OnPostAsync(string[] selectedCourses)
{
    var newInstructor = new Instructor();

    if (selectedCourses.Length > 0)
    {
        newInstructor.Courses = new List<Course>();
        // Load collection with one DB call.
        _context.Courses.Load();
    }

    // Add selected Courses courses to the new instructor.
    foreach (var course in selectedCourses)
    {
        var foundCourse = await
_context.Courses.FindAsync(int.Parse(course));
        if (foundCourse != null)
        {
            newInstructor.Courses.Add(foundCourse);
        }
        else
        {
            _logger.LogWarning("Course {course} not found", course);
        }
    }

    try
    {
        if (await TryUpdateModelAsync<Instructor>(
```

```
                        newInstructor,
                        "Instructor",
                        i => i.FirstMidName, i => i.LastName,
                        i => i.HireDate, i => i.OfficeAssignment))
            {
                _context.Instructors.Add(newInstructor);
                await _context.SaveChangesAsync();
                return RedirectToPage("./Index");
            }
            return RedirectToPage("./Index");
        }
        catch (Exception ex)
        {
            _logger.LogError(ex.Message);
        }

        PopulateAssignedCourseData(_context, newInstructor);
        return Page();
    }
```

- `_context.Instructors.Add(newInstructor)` creates a new `Instructor` using many-to-many relationships without explicitly mapping the join table. Many-to-many was added in EF 5.0.

Test the instructor Create page.

Update the Instructor Create Razor page with code similar to the Edit page:

CSHTML

```
@page
@model ContosoUniversity.Pages.Instructors.CreateModel

@{
    ViewData["Title"] = "Create";
}

<h2>Create</h2>

<h4>Instructor</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
                <label asp-for="Instructor.LastName" class="control-label">
</label>
                <input asp-for="Instructor.LastName" class="form-control" />
                <span asp-validation-for="Instructor.LastName" class="text-
danger"></span>
```

```
            </div>
            <div class="form-group">
                <label asp-for="Instructor.FirstMidName" class="control-
label"></label>
                <input asp-for="Instructor.FirstMidName" class="form-
control" />
                <span asp-validation-for="Instructor.FirstMidName"
class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.HireDate" class="control-label">
</label>
                <input asp-for="Instructor.HireDate" class="form-control" />
                <span asp-validation-for="Instructor.HireDate" class="text-
danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Instructor.OfficeAssignment.Location"
class="control-label"></label>
                <input asp-for="Instructor.OfficeAssignment.Location"
class="form-control" />
                <span asp-validation-
for="Instructor.OfficeAssignment.Location" class="text-danger" />
            </div>
            <div class="form-group">
                <div class="table">
                    <table>
                        <tr>
                            @{
                                int cnt = 0;

                                foreach (var course in
Model.AssignedCourseDataList)
                                {
                                    if (cnt++ % 3 == 0)
                                    {
                                        @:</tr><tr>
                                    }
                                    @:<td>
                                        <input type="checkbox"
                                               name="selectedCourses"
                                               value="@course.CourseID"
                                               @(Html.Raw(course.Assigned ?
"checked=\"checked\"" : "")) />

                                               @course.CourseID @:
@course.Title
                                    @:</td>
                                }
                                @:</tr>
                            }
                    </table>
                </div>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-primary"
```

```
/>
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Update the Instructor Delete page

Update `Pages/Instructors/Delete.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Instructors
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Instructor Instructor { get; set; }

        public async Task<IActionResult> OnGetAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor = await _context.Instructors.FirstOrDefaultAsync(m =>
m.ID == id);
```

```
            if (Instructor == null)
            {
                return NotFound();
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int? id)
        {
            if (id == null)
            {
                return NotFound();
            }

            Instructor instructor = await _context.Instructors
                .Include(i => i.Courses)
                .SingleAsync(i => i.ID == id);

            if (instructor == null)
            {
                return RedirectToPage("./Index");
            }

            var departments = await _context.Departments
                .Where(d => d.InstructorID == id)
                .ToListAsync();
            departments.ForEach(d => d.InstructorID = null);

            _context.Instructors.Remove(instructor);

            await _context.SaveChangesAsync();
            return RedirectToPage("./Index");
        }
    }
}
```

The preceding code makes the following changes:

- Uses eager loading for the `Courses` navigation property. `Courses` must be included or they aren't deleted when the instructor is deleted. To avoid needing to read them, configure cascade delete in the database.
- If the instructor to be deleted is assigned as administrator of any departments, removes the instructor assignment from those departments.

Run the app and test the Delete page.

Part 8, Razor Pages with EF Core in ASP.NET Core - Concurrency

Article • 04/10/2024

Tom Dykstra, and Jon P Smith

The Contoso University web app demonstrates how to create Razor Pages web apps using EF Core and Visual Studio. For information about the tutorial series, see the first tutorial.

If you run into problems you can't solve, download the completed app and compare that code to what you created by following the tutorial.

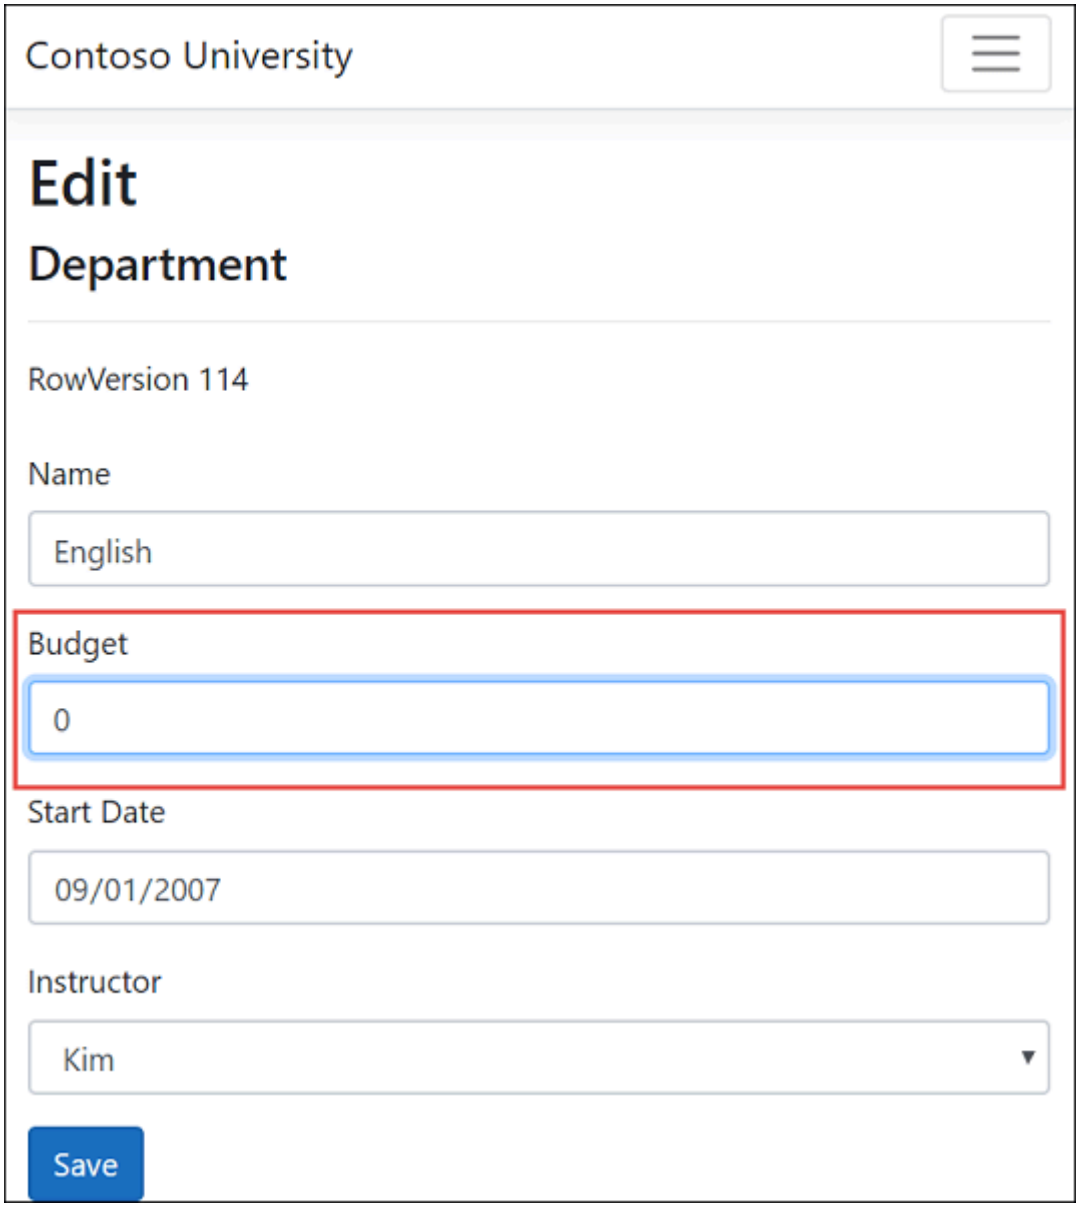
This tutorial shows how to handle conflicts when multiple users update an entity concurrently.

Concurrency conflicts

A concurrency conflict occurs when:

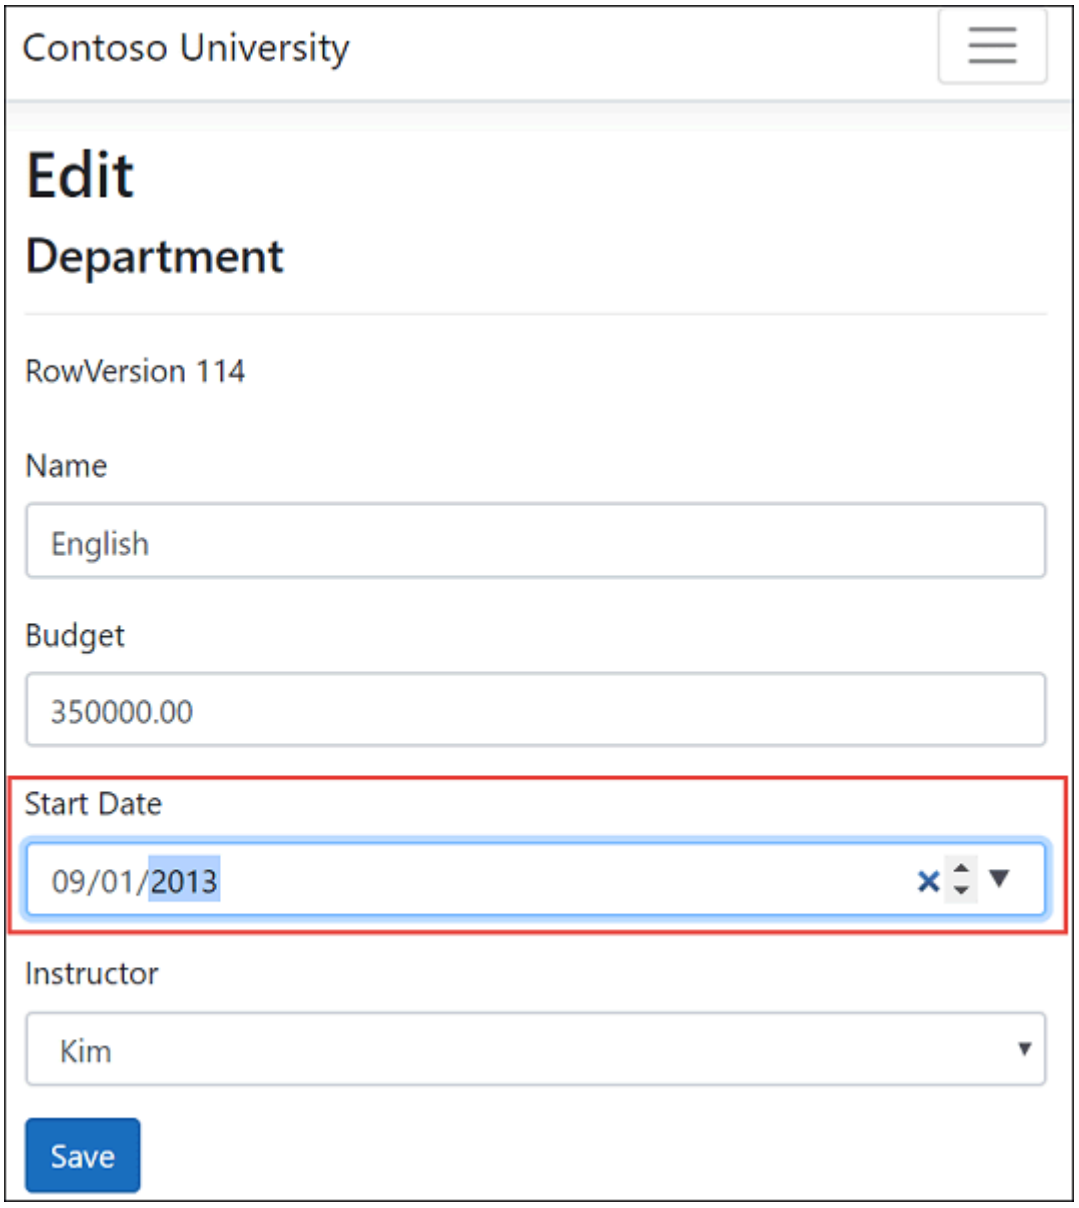
- A user navigates to the edit page for an entity.
- Another user updates the same entity before the first user's change is written to the database.

If concurrency detection isn't enabled, whoever updates the database last overwrites the other user's changes. If this risk is acceptable, the cost of programming for concurrency might outweigh the benefit.



Pessimistic concurrency

One way to prevent concurrency conflicts is to use database locks. This is called pessimistic concurrency. Before the app reads a database row that it intends to update, it requests a lock. Once a row is locked for update access, no other users are allowed to lock the row until the first lock is released.



Managing locks has disadvantages. It can be complex to program and can cause performance problems as the number of users increases. Entity Framework Core provides no built-in support for pessimistic concurrency.

Optimistic concurrency

Optimistic concurrency allows concurrency conflicts to happen, and then reacts appropriately when they do. For example, Jane visits the Department edit page and changes the budget for the English department from $350,000.00 to $0.00.

Before Jane clicks **Save**, John visits the same page and changes the Start Date field from 9/1/2007 to 9/1/2013.

Jane clicks **Save** first and sees her change take effect, since the browser displays the Index page with zero as the Budget amount.

John clicks **Save** on an Edit page that still shows a budget of $350,000.00. What happens next is determined by how you handle concurrency conflicts:

- Keep track of which property a user has modified and update only the corresponding columns in the database.

  In the scenario, no data would be lost. Different properties were updated by the two users. The next time someone browses the English department, they will see both Jane's and John's changes. This method of updating can reduce the number of conflicts that could result in data loss. This approach has some disadvantages:
  - Can't avoid data loss if competing changes are made to the same property.
  - Is generally not practical in a web app. It requires maintaining significant state in order to keep track of all fetched values and new values. Maintaining large amounts of state can affect app performance.

    - Can increase app complexity compared to concurrency detection on an entity.

- Let John's change overwrite Jane's change.

  The next time someone browses the English department, they will see 9/1/2013 and the fetched $350,000.00 value. This approach is called a *Client Wins* or *Last in Wins* scenario. All values from the client take precedence over what's in the data store. The scaffolded code does no concurrency handling, Client Wins happens automatically.

- Prevent John's change from being updated in the database. Typically, the app would:
    - Display an error message.
    - Show the current state of the data.
    - Allow the user to reapply the changes.

  This is called a *Store Wins* scenario. The data-store values take precedence over the values submitted by the client. The Store Wins scenario is used in this tutorial. This method ensures that no changes are overwritten without a user being alerted.

Conflict detection in EF Core

Properties configured as concurrency tokens are used to implement optimistic concurrency control. When an update or delete operation is triggered by SaveChanges or SaveChangesAsync, the value of the concurrency token in the database is compared against the original value read by EF Core:

- If the values match, the operation can complete.
- If the values do not match, EF Core assumes that another user has performed a conflicting operation, aborts the current transaction, and throws a DbUpdateConcurrencyException.

Another user or process performing an operation that conflicts with the current operation is known as *concurrency conflict*.

On relational databases EF Core checks for the value of the concurrency token in the `WHERE` clause of `UPDATE` and `DELETE` statements to detect a concurrency conflict.

The data model must be configured to enable conflict detection by including a tracking column that can be used to determine when a row has been changed. EF provides two approaches for concurrency tokens:

- Applying [ConcurrencyCheck] or IsConcurrencyToken to a property on the model. This approach is not recommended. For more information, see Concurrency Tokens in EF Core.
- Applying TimestampAttribute or IsRowVersion to a concurrency token in the model. This is the approach used in this tutorial.

The SQL Server approach and SQLite implementation details are slightly different. A difference file is shown later in the tutorial listing the differences. The Visual Studio tab shows the SQL Server approach. The Visual Studio Code tab shows the approach for non-SQL Server databases, such as SQLite.

Visual Studio

- In the model, include a tracking column that is used to determine when a row has been changed.
- Apply the TimestampAttribute to the concurrency property.

Update the `Models/Department.cs` file with the following highlighted code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
                       ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        [Timestamp]
```

```
        public byte[] ConcurrencyToken { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The TimestampAttribute is what identifies the column as a concurrency tracking column. The fluent API is an alternative way to specify the tracking property:

C#

```
modelBuilder.Entity<Department>()
  .Property<byte[]>("ConcurrencyToken")
  .IsRowVersion();
```

The [Timestamp] attribute on an entity property generates the following code in the ModelBuilder method:

C#

```
 b.Property<byte[]>("ConcurrencyToken")
     .IsConcurrencyToken()
     .ValueGeneratedOnAddOrUpdate()
     .HasColumnType("rowversion");
```

The preceding code:

- Sets the property type `ConcurrencyToken` to byte array. `byte[]` is the required type for SQL Server.
- Calls IsConcurrencyToken. `IsConcurrencyToken` configures the property as a concurrency token. On updates, the concurrency token value in the database is compared to the original value to ensure it has not changed since the instance was retrieved from the database. If it has changed, a DbUpdateConcurrencyException is thrown and changes are not applied.
- Calls ValueGeneratedOnAddOrUpdate, which configures the `ConcurrencyToken` property to have a value automatically generated when adding or updating an entity.
- `HasColumnType("rowversion")` sets the column type in the SQL Server database to rowversion.

The following code shows a portion of the T-SQL generated by EF Core when the `Department` name is updated:

```
```

SQL

```
SET NOCOUNT ON;
UPDATE [Departments] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [ConcurrencyToken] = @p2;
SELECT [ConcurrencyToken]
FROM [Departments]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

The preceding highlighted code shows the `WHERE` clause containing `ConcurrencyToken`. If the database `ConcurrencyToken` doesn't equal the `ConcurrencyToken` parameter `@p2`, no rows are updated.

The following highlighted code shows the T-SQL that verifies exactly one row was updated:

SQL

```
SET NOCOUNT ON;
UPDATE [Departments] SET [Name] = @p0
WHERE [DepartmentID] = @p1 AND [ConcurrencyToken] = @p2;
SELECT [ConcurrencyToken]
FROM [Departments]
WHERE @@ROWCOUNT = 1 AND [DepartmentID] = @p1;
```

@@ROWCOUNT returns the number of rows affected by the last statement. If no rows are updated, EF Core throws a `DbUpdateConcurrencyException`.

Add a migration

Adding the `ConcurrencyToken` property changes the data model, which requires a migration.

Build the project.

Visual Studio

Run the following commands in the PMC:

PowerShell

```
Add-Migration RowVersion
Update-Database
```

The preceding commands:

- Creates the `Migrations/{time stamp}_RowVersion.cs` migration file.
- Updates the `Migrations/SchoolContextModelSnapshot.cs` file. The update adds the following code to the `BuildModel` method:

C#

```
b.Property<byte[]>("ConcurrencyToken")
    .IsConcurrencyToken()
    .ValueGeneratedOnAddOrUpdate()
    .HasColumnType("rowversion");
```

Scaffold Department pages

Visual Studio

Follow the instructions in Scaffold Student pages with the following exceptions:

- Create a *Pages/Departments* folder.
- Use `Department` for the model class.
- Use the existing context class instead of creating a new one.

Add a utility class

In the project folder, create the `Utility` class with the following code:

Visual Studio

C#

```
namespace ContosoUniversity
{
    public static class Utility
    {
        public static string GetLastChars(byte[] token)
        {
            return token[7].ToString();
        }
    }
}
```

The `Utility` class provides the `GetLastChars` method used to display the last few characters of the concurrency token. The following code shows the code that works with both SQLite ad SQL Server:

C#

```
#if SQLiteVersion
using System;

namespace ContosoUniversity
{
    public static class Utility
    {
        public static string GetLastChars(Guid token)
        {
            return token.ToString().Substring(
                                    token.ToString().Length - 3);
        }
    }
}
#else
namespace ContosoUniversity
{
    public static class Utility
    {
        public static string GetLastChars(byte[] token)
        {
            return token[7].ToString();
        }
    }
}
#endif
```

The `#if SQLiteVersion` preprocessor directive isolates the differences in the SQLite and SQL Server versions and helps:

- The author maintain one code base for both versions.
- SQLite developers deploy the app to Azure and use SQL Azure.

Build the project.

Update the Index page

The scaffolding tool created a `ConcurrencyToken` column for the Index page, but that field wouldn't be displayed in a production app. In this tutorial, the last portion of the `ConcurrencyToken` is displayed to help show how concurrency handling works. The last portion isn't guaranteed to be unique by itself.

Update *Pages\Departments\Index.cshtml* page:

- Replace Index with Departments.
- Change the code containing `ConcurrencyToken` to show just the last few characters.
- Replace `FirstMidName` with `FullName`.

The following code shows the updated page:

CSHTML

```
@page
@model ContosoUniversity.Pages.Departments.IndexModel

@{
    ViewData["Title"] = "Departments";
}

<h2>Departments</h2>

<p>
    <a asp-page="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Department[0].Name)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Department[0].Budget)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Department[0].StartDate)
            </th>

        }
    </tbody>
</table>
```

Update the Edit page model

Update `Pages/Departments/Edit.cshtml.cs` with the following code:

Visual Studio

C#

```
using ContosoUniversity.Data;
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.EntityFrameworkCore;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class EditModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public EditModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
```

```
        }

        [BindProperty]
        public Department Department { get; set; }
        // Replace ViewData["InstructorID"]
        public SelectList InstructorNameSL { get; set; }

        public async Task<IActionResult> OnGetAsync(int id)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)  // eager loading
                .AsNoTracking()                 // tracking not required
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                return NotFound();
            }

            // Use strongly typed data rather than ViewData.
            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FirstMidName");

            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            if (!ModelState.IsValid)
            {
                return Page();
            }

            // Fetch current department from DB.
            // ConcurrencyToken may have changed.
            var departmentToUpdate = await _context.Departments
                .Include(i => i.Administrator)
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (departmentToUpdate == null)
            {
                return HandleDeletedDepartment();
            }

            // Set ConcurrencyToken to value read in OnGetAsync
            _context.Entry(departmentToUpdate).Property(
                 d => d.ConcurrencyToken).OriginalValue =
Department.ConcurrencyToken;

            if (await TryUpdateModelAsync<Department>(
                departmentToUpdate,
                "Department",
                s => s.Name, s => s.StartDate, s => s.Budget, s =>
s.InstructorID))
            {
```

```
                try
                {
                    await _context.SaveChangesAsync();
                    return RedirectToPage("./Index");
                }
                catch (DbUpdateConcurrencyException ex)
                {
                    var exceptionEntry = ex.Entries.Single();
                    var clientValues =
(Department)exceptionEntry.Entity;
                    var databaseEntry =
exceptionEntry.GetDatabaseValues();
                    if (databaseEntry == null)
                    {
                        ModelState.AddModelError(string.Empty, "Unable
to save. " +
                            "The department was deleted by another
user.");
                        return Page();
                    }

                    var dbValues = (Department)databaseEntry.ToObject();
                    await SetDbErrorMessage(dbValues, clientValues,
_context);

                    // Save the current ConcurrencyToken so next
postback
                    // matches unless an new concurrency issue happens.
                    Department.ConcurrencyToken =
(byte[])dbValues.ConcurrencyToken;
                    // Clear the model error for the next postback.
                    ModelState.Remove($"{nameof(Department)}.
{nameof(Department.ConcurrencyToken)}");
                }
            }

            InstructorNameSL = new SelectList(_context.Instructors,
                "ID", "FullName", departmentToUpdate.InstructorID);

            return Page();
        }

        private IActionResult HandleDeletedDepartment()
        {
            // ModelState contains the posted data because of the
deletion error
            // and overides the Department instance values when
displaying Page().
            ModelState.AddModelError(string.Empty,
                "Unable to save. The department was deleted by another
user.");
            InstructorNameSL = new SelectList(_context.Instructors,
"ID", "FullName", Department.InstructorID);
            return Page();
        }
```

```
        private async Task SetDbErrorMessage(Department dbValues,
                Department clientValues, SchoolContext context)
        {

            if (dbValues.Name != clientValues.Name)
            {
                ModelState.AddModelError("Department.Name",
                    $"Current value: {dbValues.Name}");
            }
            if (dbValues.Budget != clientValues.Budget)
            {
                ModelState.AddModelError("Department.Budget",
                    $"Current value: {dbValues.Budget:c}");
            }
            if (dbValues.StartDate != clientValues.StartDate)
            {
                ModelState.AddModelError("Department.StartDate",
                    $"Current value: {dbValues.StartDate:d}");
            }
            if (dbValues.InstructorID != clientValues.InstructorID)
            {
                Instructor dbInstructor = await _context.Instructors
                   .FindAsync(dbValues.InstructorID);
                ModelState.AddModelError("Department.InstructorID",
                    $"Current value: {dbInstructor?.FullName}");
            }

            ModelState.AddModelError(string.Empty,
                "The record you attempted to edit "
              + "was modified by another user after you. The "
              + "edit operation was canceled and the current values in
the database "
              + "have been displayed. If you still want to edit this
record, click "
              + "the Save button again.");
        }
    }
}
```

The concurrency updates

OriginalValue is updated with the `ConcurrencyToken` value from the entity when it was fetched in the `OnGetAsync` method. EF Core generates a `SQL UPDATE` command with a `WHERE` clause containing the original `ConcurrencyToken` value. If no rows are affected by the `UPDATE` command, a `DbUpdateConcurrencyException` exception is thrown. No rows are affected by the `UPDATE` command when no rows have the original `ConcurrencyToken` value.

Visual Studio

C#

```
public async Task<IActionResult> OnPostAsync(int id)
{
    if (!ModelState.IsValid)
    {
        return Page();
    }

    // Fetch current department from DB.
    // ConcurrencyToken may have changed.
    var departmentToUpdate = await _context.Departments
        .Include(i => i.Administrator)
        .FirstOrDefaultAsync(m => m.DepartmentID == id);

    if (departmentToUpdate == null)
    {
        return HandleDeletedDepartment();
    }

    // Set ConcurrencyToken to value read in OnGetAsync
    _context.Entry(departmentToUpdate).Property(
         d => d.ConcurrencyToken).OriginalValue =
Department.ConcurrencyToken;
```

In the preceding highlighted code:

- The value in `Department.ConcurrencyToken` is the value when the entity was fetched in the `Get` request for the `Edit` page. The value is provided to the `OnPost` method by a hidden field in the Razor page that displays the entity to be edited. The hidden field value is copied to `Department.ConcurrencyToken` by the model binder.
- `OriginalValue` is what EF Core uses in the `WHERE` clause. Before the highlighted line of code executes:
  - `OriginalValue` has the value that was in the database when `FirstOrDefaultAsync` was called in this method.
  - This value might be different from what was displayed on the Edit page.
- The highlighted code makes sure that EF Core uses the original `ConcurrencyToken` value from the displayed `Department` entity in the SQL `UPDATE` statement's `WHERE` clause.

The following code shows the `Department` model. `Department` is initialized in the:

- `OnGetAsync` method by the EF query.

- `OnPostAsync` method by the hidden field in the Razor page using model binding:

Visual Studio

C#

```
public class EditModel : PageModel
{
    private readonly ContosoUniversity.Data.SchoolContext _context;

    public EditModel(ContosoUniversity.Data.SchoolContext context)
    {
        _context = context;
    }

    [BindProperty]
    public Department Department { get; set; }
    // Replace ViewData["InstructorID"]
    public SelectList InstructorNameSL { get; set; }

    public async Task<IActionResult> OnGetAsync(int id)
    {
        Department = await _context.Departments
            .Include(d => d.Administrator)  // eager loading
            .AsNoTracking()                 // tracking not required
            .FirstOrDefaultAsync(m => m.DepartmentID == id);

        if (Department == null)
        {
            return NotFound();
        }

        // Use strongly typed data rather than ViewData.
        InstructorNameSL = new SelectList(_context.Instructors,
            "ID", "FirstMidName");

        return Page();
    }

    public async Task<IActionResult> OnPostAsync(int id)
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        // Fetch current department from DB.
        // ConcurrencyToken may have changed.
        var departmentToUpdate = await _context.Departments
            .Include(i => i.Administrator)
            .FirstOrDefaultAsync(m => m.DepartmentID == id);

        if (departmentToUpdate == null)
```

```
            {
                return HandleDeletedDepartment();
            }

            // Set ConcurrencyToken to value read in OnGetAsync
            _context.Entry(departmentToUpdate).Property(
                 d => d.ConcurrencyToken).OriginalValue =
    Department.ConcurrencyToken;
```

The preceding code shows the `ConcurrencyToken` value of the `Department` entity from the `HTTP POST` request is set to the `ConcurrencyToken` value from the `HTTP GET` request.

When a concurrency error happens, the following highlighted code gets the client values (the values posted to this method) and the database values.

C#

```
if (await TryUpdateModelAsync<Department>(
    departmentToUpdate,
    "Department",
    s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
{
    try
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }
    catch (DbUpdateConcurrencyException ex)
    {
        var exceptionEntry = ex.Entries.Single();
        var clientValues = (Department)exceptionEntry.Entity;
        var databaseEntry = exceptionEntry.GetDatabaseValues();
        if (databaseEntry == null)
        {
            ModelState.AddModelError(string.Empty, "Unable to save. " +
                "The department was deleted by another user.");
            return Page();
        }

        var dbValues = (Department)databaseEntry.ToObject();
        await SetDbErrorMessage(dbValues, clientValues, _context);

        // Save the current ConcurrencyToken so next postback
        // matches unless an new concurrency issue happens.
        Department.ConcurrencyToken = dbValues.ConcurrencyToken;
        // Clear the model error for the next postback.
        ModelState.Remove($"{nameof(Department)}.
{nameof(Department.ConcurrencyToken)}");
    }
```

The following code adds a custom error message for each column that has database values different from what was posted to `OnPostAsync`:

C#

```
private async Task SetDbErrorMessage(Department dbValues,
        Department clientValues, SchoolContext context)
{

    if (dbValues.Name != clientValues.Name)
    {
        ModelState.AddModelError("Department.Name",
            $"Current value: {dbValues.Name}");
    }
    if (dbValues.Budget != clientValues.Budget)
    {
        ModelState.AddModelError("Department.Budget",
            $"Current value: {dbValues.Budget:c}");
    }
    if (dbValues.StartDate != clientValues.StartDate)
    {
        ModelState.AddModelError("Department.StartDate",
            $"Current value: {dbValues.StartDate:d}");
    }
    if (dbValues.InstructorID != clientValues.InstructorID)
    {
        Instructor dbInstructor = await _context.Instructors
           .FindAsync(dbValues.InstructorID);
        ModelState.AddModelError("Department.InstructorID",
            $"Current value: {dbInstructor?.FullName}");
    }

    ModelState.AddModelError(string.Empty,
        "The record you attempted to edit "
      + "was modified by another user after you. The "
      + "edit operation was canceled and the current values in the database
"
      + "have been displayed. If you still want to edit this record, click "
      + "the Save button again.");
}
```

The following highlighted code sets the `ConcurrencyToken` value to the new value retrieved from the database. The next time the user clicks **Save**, only concurrency errors that happen since the last display of the Edit page will be caught.

C#

```
if (await TryUpdateModelAsync<Department>(
    departmentToUpdate,
    "Department",
    s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
```

```
{
    try
    {
        await _context.SaveChangesAsync();
        return RedirectToPage("./Index");
    }
    catch (DbUpdateConcurrencyException ex)
    {
        var exceptionEntry = ex.Entries.Single();
        var clientValues = (Department)exceptionEntry.Entity;
        var databaseEntry = exceptionEntry.GetDatabaseValues();
        if (databaseEntry == null)
        {
            ModelState.AddModelError(string.Empty, "Unable to save. " +
                "The department was deleted by another user.");
            return Page();
        }

        var dbValues = (Department)databaseEntry.ToObject();
        await SetDbErrorMessage(dbValues, clientValues, _context);

        // Save the current ConcurrencyToken so next postback
        // matches unless an new concurrency issue happens.
        Department.ConcurrencyToken = dbValues.ConcurrencyToken;
        // Clear the model error for the next postback.
        ModelState.Remove($"{nameof(Department)}.
{nameof(Department.ConcurrencyToken)}");
    }
```

The ModelState.Remove statement is required because `ModelState` has the previous `ConcurrencyToken` value. In the Razor Page, the `ModelState` value for a field takes precedence over the model property values when both are present.

SQL Server vs SQLite code differences

The following shows the differences between the SQL Server and SQLite versions:

diff

```
+ using System;    // For GUID on SQLite

+ departmentToUpdate.ConcurrencyToken = Guid.NewGuid();

 _context.Entry(departmentToUpdate)
    .Property(d => d.ConcurrencyToken).OriginalValue =
Department.ConcurrencyToken;

- Department.ConcurrencyToken = (byte[])dbValues.ConcurrencyToken;
+ Department.ConcurrencyToken = dbValues.ConcurrencyToken;
```

Update the Edit Razor page

Update `Pages/Departments/Edit.cshtml` with the following code:

CSHTML

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.EditModel
@{
    ViewData["Title"] = "Edit";
}
<h2>Edit</h2>
<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="Department.DepartmentID" />
            <input type="hidden" asp-for="Department.ConcurrencyToken" />
            <div class="form-group">
                <label>Version</label>
                @Utility.GetLastChars(Model.Department.ConcurrencyToken)
            </div>
            <div class="form-group">
                <label asp-for="Department.Name" class="control-label">
</label>
                <input asp-for="Department.Name" class="form-control" />

            </div>
            <div class="form-group">
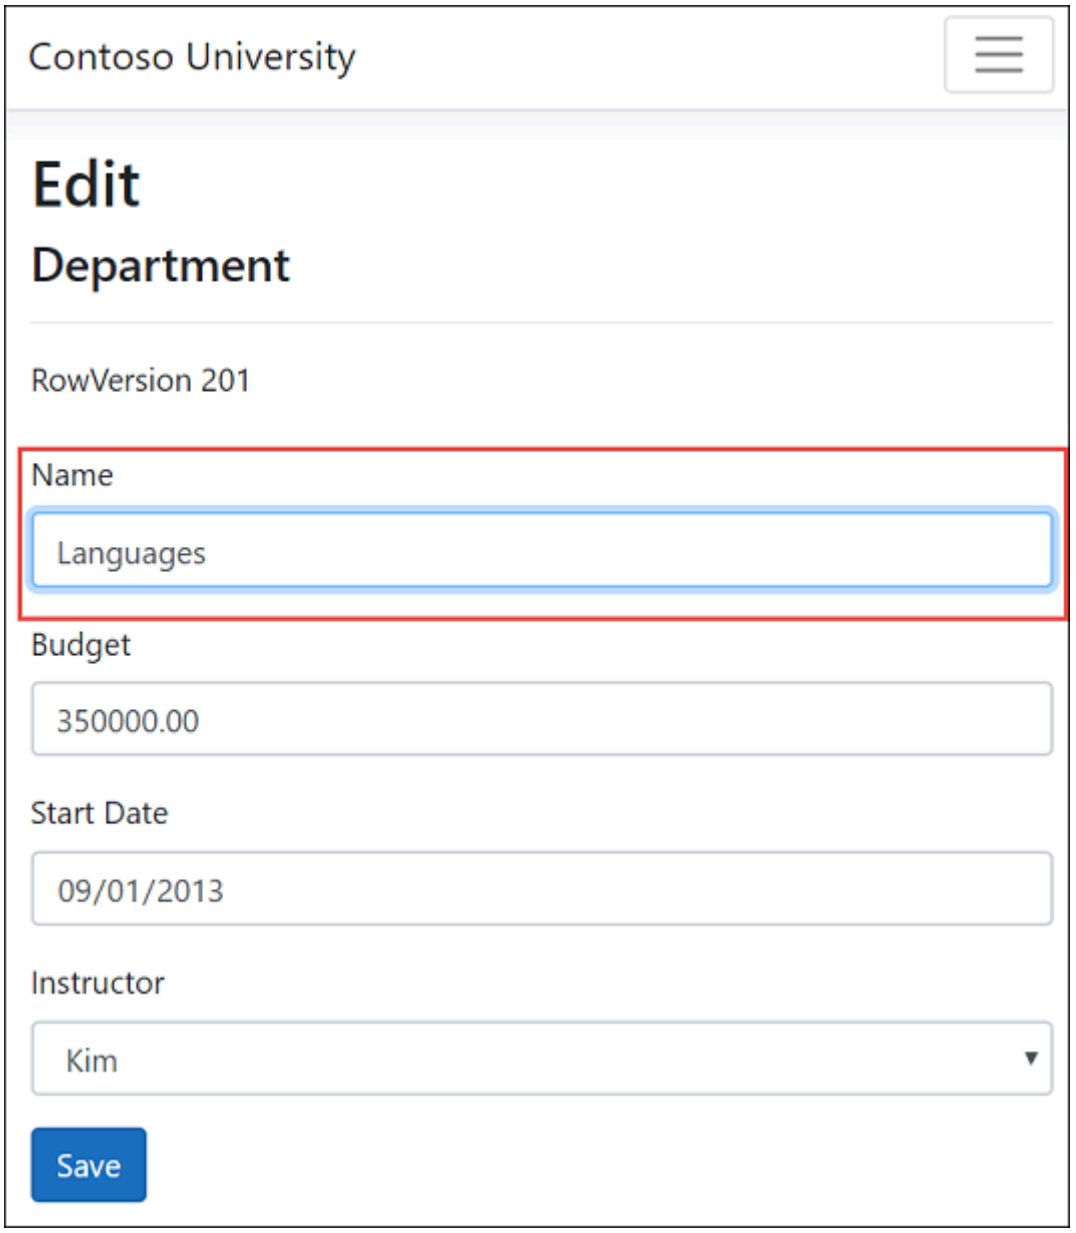
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>
<div>
    <a asp-page="./Index">Back to List</a>
</div>
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

The preceding code:

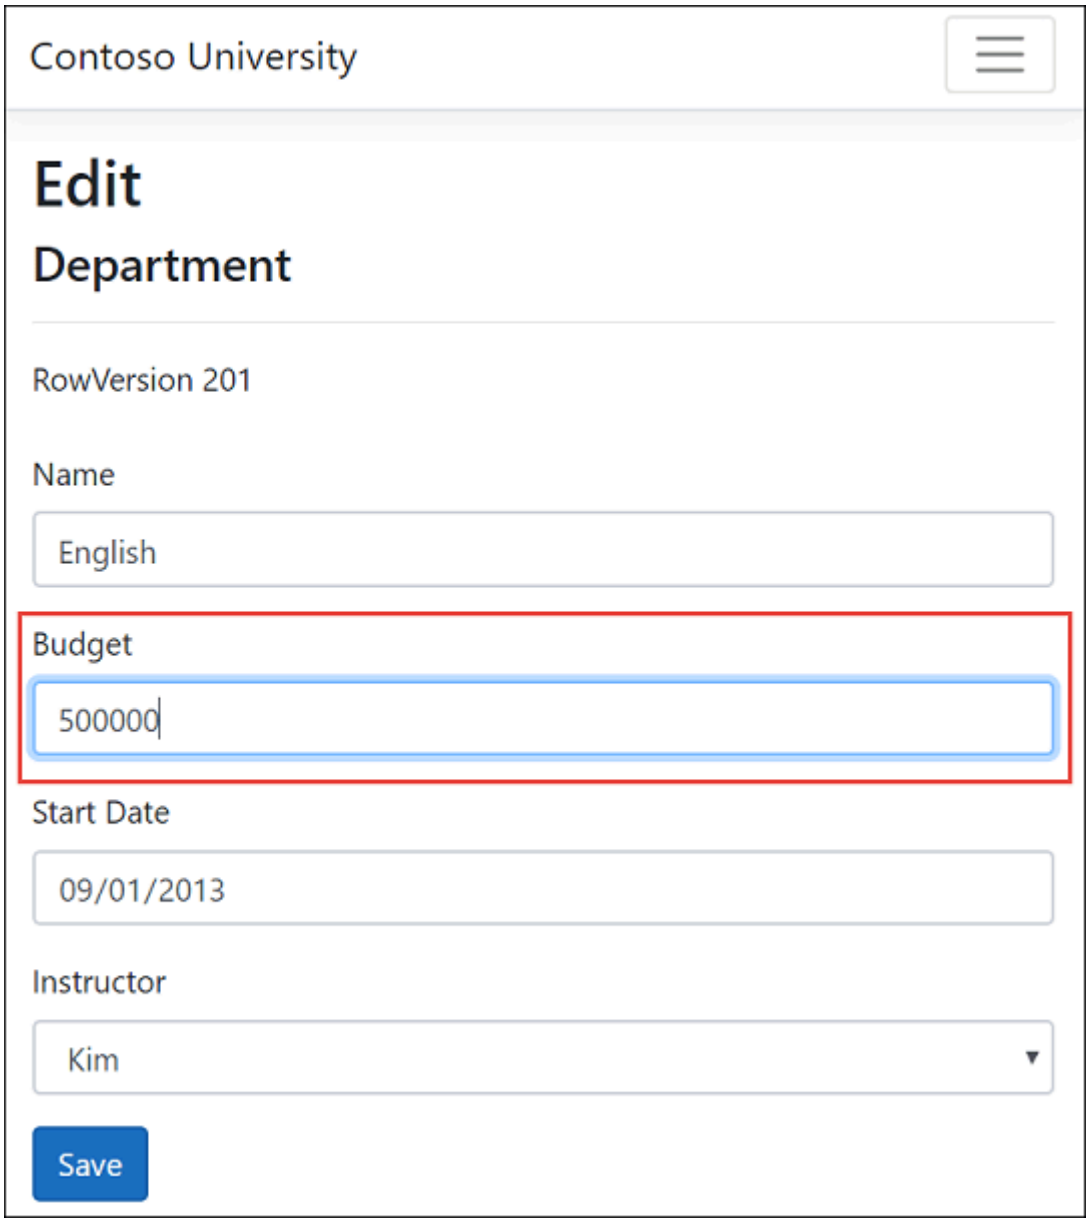
- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds a hidden row version. `ConcurrencyToken` must be added so postback binds the value.
- Displays the last byte of `ConcurrencyToken` for debugging purposes.
- Replaces `ViewData` with the strongly-typed `InstructorNameSL`.



Test concurrency conflicts with the Edit page

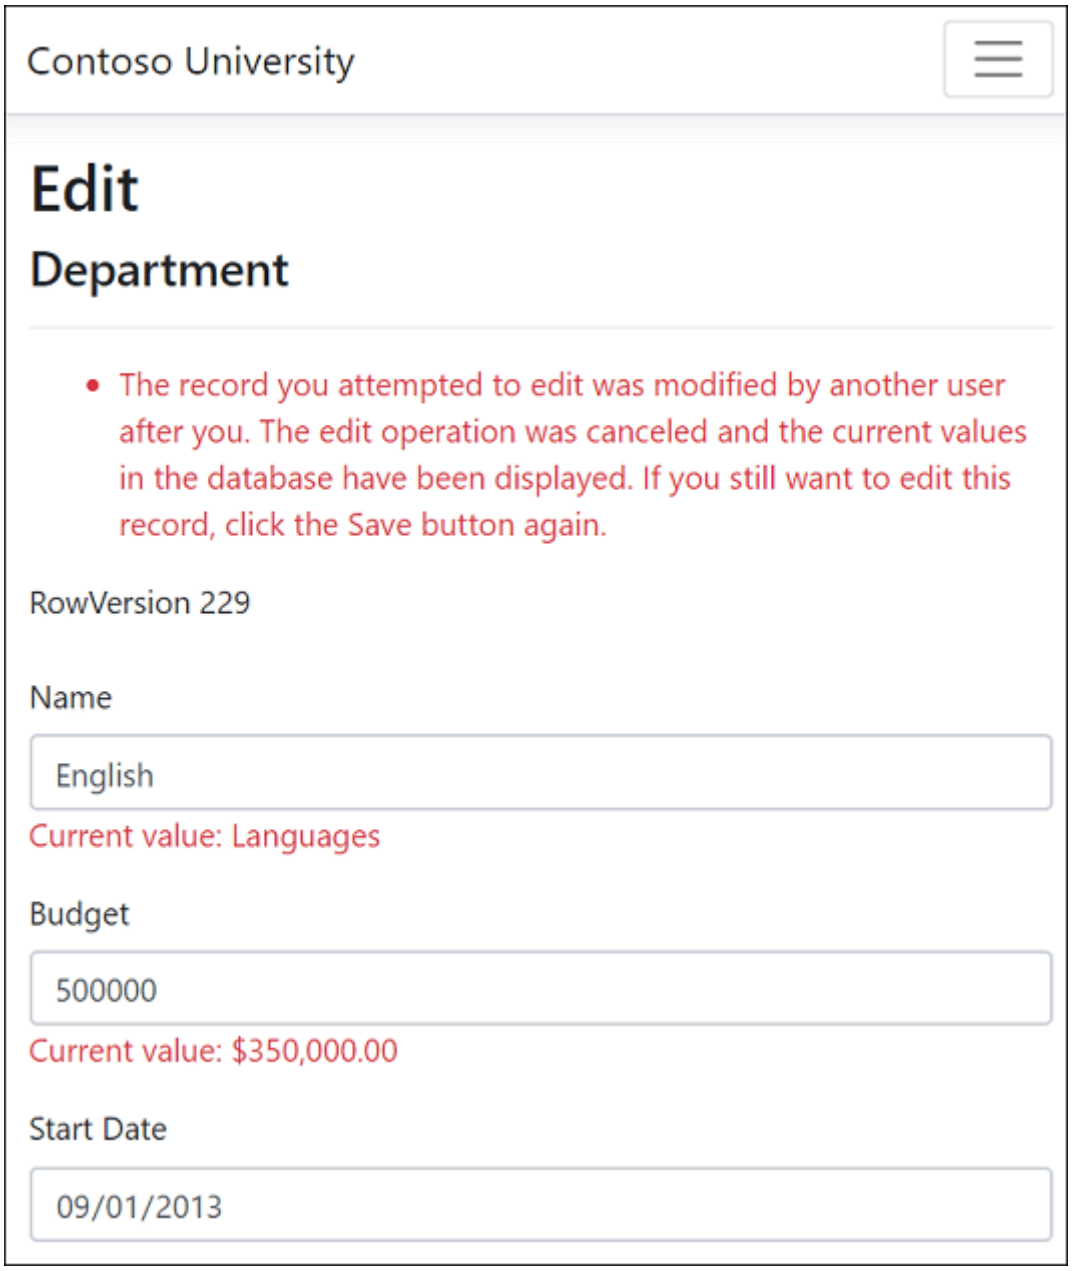
Open two browsers instances of Edit on the English department:

- Run the app and select Departments.
- Right-click the **Edit** hyperlink for the English department and select **Open in new tab**.
- In the first tab, click the **Edit** hyperlink for the English department.



The two browser tabs display the same information.

Change the name in the first browser tab and click **Save**.



The browser shows the Index page with the changed value and updated `ConcurrencyToken` indicator. Note the updated `ConcurrencyToken` indicator, it's displayed on the second postback in the other tab.

Change a different field in the second browser tab.

Click **Save**. You see error messages for all fields that don't match the database values:

This browser window didn't intend to change the Name field. Copy and paste the current value (Languages) into the Name field. Tab out. Client-side validation removes the error message.

Click **Save** again. The value you entered in the second browser tab is saved. You see the saved values in the Index page.

Update the Delete page model

Update `Pages/Departments/Delete.cshtml.cs` with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
```

```
using Microsoft.EntityFrameworkCore;
using System.Threading.Tasks;

namespace ContosoUniversity.Pages.Departments
{
    public class DeleteModel : PageModel
    {
        private readonly ContosoUniversity.Data.SchoolContext _context;

        public DeleteModel(ContosoUniversity.Data.SchoolContext context)
        {
            _context = context;
        }

        [BindProperty]
        public Department Department { get; set; }
        public string ConcurrencyErrorMessage { get; set; }

        public async Task<IActionResult> OnGetAsync(int id, bool?
concurrencyError)
        {
            Department = await _context.Departments
                .Include(d => d.Administrator)
                .AsNoTracking()
                .FirstOrDefaultAsync(m => m.DepartmentID == id);

            if (Department == null)
            {
                 return NotFound();
            }

            if (concurrencyError.GetValueOrDefault())
            {
                ConcurrencyErrorMessage = "The record you attempted to
delete "
                  + "was modified by another user after you selected delete.
"
                  + "The delete operation was canceled and the current
values in the "
                  + "database have been displayed. If you still want to
delete this "
                  + "record, click the Delete button again.";
            }
            return Page();
        }

        public async Task<IActionResult> OnPostAsync(int id)
        {
            try
            {
                if (await _context.Departments.AnyAsync(
                    m => m.DepartmentID == id))
                {
                    // Department.ConcurrencyToken value is from when the
entity
```

```
                    // was fetched. If it doesn't match the DB, a
                    // DbUpdateConcurrencyException exception is thrown.
                    _context.Departments.Remove(Department);
                    await _context.SaveChangesAsync();
                }
                return RedirectToPage("./Index");
            }
            catch (DbUpdateConcurrencyException)
            {
                return RedirectToPage("./Delete",
                    new { concurrencyError = true, id = id });
            }
        }
    }
}
```

The Delete page detects concurrency conflicts when the entity has changed after it was fetched. `Department.ConcurrencyToken` is the row version when the entity was fetched. When EF Core creates the `SQL DELETE` command, it includes a WHERE clause with `ConcurrencyToken`. If the `SQL DELETE` command results in zero rows affected:

- The `ConcurrencyToken` in the `SQL DELETE` command doesn't match `ConcurrencyToken` in the database.
- A `DbUpdateConcurrencyException` exception is thrown.
- `OnGetAsync` is called with the `concurrencyError`.

Update the Delete Razor page

Update `Pages/Departments/Delete.cshtml` with the following code:

CSHTML

```
@page "{id:int}"
@model ContosoUniversity.Pages.Departments.DeleteModel

@{
    ViewData["Title"] = "Delete";
}

<h1>Delete</h1>

<p class="text-danger">@Model.ConcurrencyErrorMessage</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
```

```
            @Html.DisplayNameFor(model => model.Department.Name)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Department.Name)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department.Budget)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Department.Budget)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department.StartDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Department.StartDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department.ConcurrencyToken)
        </dt>
        <dd class="col-sm-10">
            @Utility.GetLastChars(Model.Department.ConcurrencyToken)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department.Administrator)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model =>
model.Department.Administrator.FullName)
        </dd>
    </dl>

    <form method="post">
        <input type="hidden" asp-for="Department.DepartmentID" />
        <input type="hidden" asp-for="Department.ConcurrencyToken" />
        <input type="submit" value="Delete" class="btn btn-danger" /> |
        <a asp-page="./Index">Back to List</a>
    </form>
</div>
```

The preceding code makes the following changes:

- Updates the `page` directive from `@page` to `@page "{id:int}"`.
- Adds an error message.
- Replaces FirstMidName with FullName in the **Administrator** field.
- Changes `ConcurrencyToken` to display the last byte.
- Adds a hidden row version. `ConcurrencyToken` must be added so postback binds the value.

Test concurrency conflicts

Create a test department.

Open two browsers instances of Delete on the test department:

- Run the app and select Departments.
- Right-click the **Delete** hyperlink for the test department and select **Open in new tab**.
- Click the **Edit** hyperlink for the test department.

The two browser tabs display the same information.

Change the budget in the first browser tab and click **Save**.

The browser shows the Index page with the changed value and updated `ConcurrencyToken` indicator. Note the updated `ConcurrencyToken` indicator, it's displayed on the second postback in the other tab.

Delete the test department from the second tab. A concurrency error is display with the current values from the database. Clicking **Delete** deletes the entity, unless `ConcurrencyToken` has been updated.

- Handle concurrency in EF Core
- Debugging ASP.NET Core 2.x source

Next steps

This is the last tutorial in the series. Additional topics are covered in the MVC version of this tutorial series.

Previous tutorial

ASP.NET Core MVC with EF Core - tutorial series

Article • 04/10/2024

This tutorial teaches ASP.NET Core MVC and Entity Framework Core with controllers and views. Razor Pages is an alternative programming model. For new development, we recommend Razor Pages over MVC with controllers and views. See the Razor Pages version of this tutorial. Each tutorial covers some material the other doesn't:

Some things this MVC tutorial has that the Razor Pages tutorial doesn't:

- Implement inheritance in the data model
- Perform raw SQL queries
- Use dynamic LINQ to simplify code

Some things the Razor Pages tutorial has that this one doesn't:

- Use Select method to load related data
- Best practices for EF.

1. Get started
2. Create, Read, Update, and Delete operations
3. Sorting, filtering, paging, and grouping
4. Migrations
5. Create a complex data model
6. Reading related data
7. Updating related data
8. Handle concurrency conflicts
9. Inheritance
10. Advanced topics

Tutorial: Get started with EF Core in an ASP.NET MVC web app

Article • 04/10/2024

By Tom Dykstra and Rick Anderson

This tutorial teaches ASP.NET Core MVC and Entity Framework Core with controllers and views. Razor Pages is an alternative programming model. For new development, we recommend Razor Pages over MVC with controllers and views. See the Razor Pages version of this tutorial. Each tutorial covers some material the other doesn't:

Some things this MVC tutorial has that the Razor Pages tutorial doesn't:

- Implement inheritance in the data model
- Perform raw SQL queries
- Use dynamic LINQ to simplify code

Some things the Razor Pages tutorial has that this one doesn't:

- Use Select method to load related data
- Best practices for EF.

The Contoso University sample web app demonstrates how to create an ASP.NET Core MVC web app using Entity Framework (EF) Core and Visual Studio.

The sample app is a web site for a fictional Contoso University. It includes functionality such as student admission, course creation, and instructor assignments. This is the first in a series of tutorials that explain how to build the Contoso University sample app.

Prerequisites

- If you're new to ASP.NET Core MVC, go through the Get started with ASP.NET Core MVC tutorial series before starting this one.

- Visual Studio 2022 with the **ASP.NET and web development** workload.
- .NET 6.0 SDK

This tutorial has not been updated for ASP.NET Core 6 or later. The tutorial's instructions will not work correctly if you create a project that targets ASP.NET Core 6 or later. For example, the ASP.NET Core 6 and later web templates use the minimal hosting model, which unifies `Startup.cs` and `Program.cs` into a single `Program.cs` file.

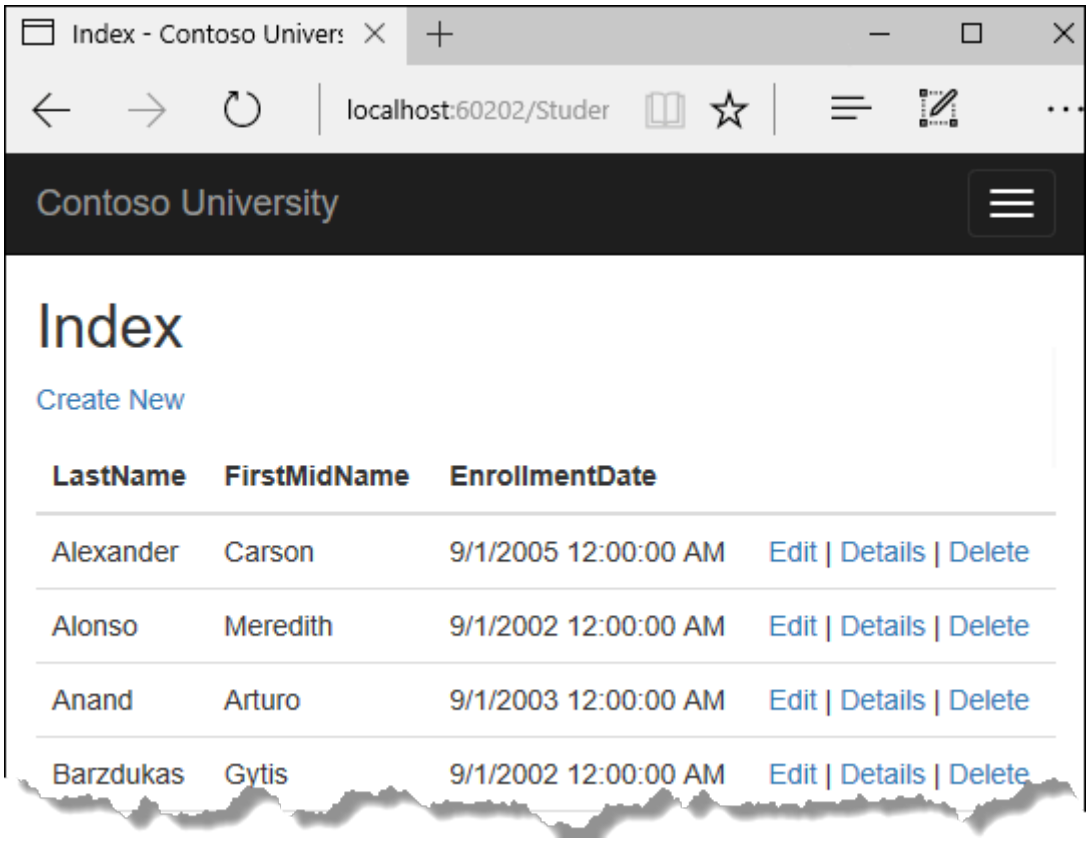
Another difference introduced in .NET 6 is the NRT (nullable reference types) feature. The project templates enable this feature by default. Problems can happen where EF considers a property to be required in .NET 6 which is nullable in .NET 5. For example, the Create Student page will fail silently unless the `Enrollments` property is made nullable or the `asp-validation-summary` helper tag is changed from `ModelOnly` to `All`.

We recommend that you install and use the .NET 5 SDK for this tutorial. Until this tutorial is updated, see Razor Pages with Entity Framework Core in ASP.NET Core - Tutorial 1 of 8 on how to use Entity Framework with ASP.NET Core 6 or later.

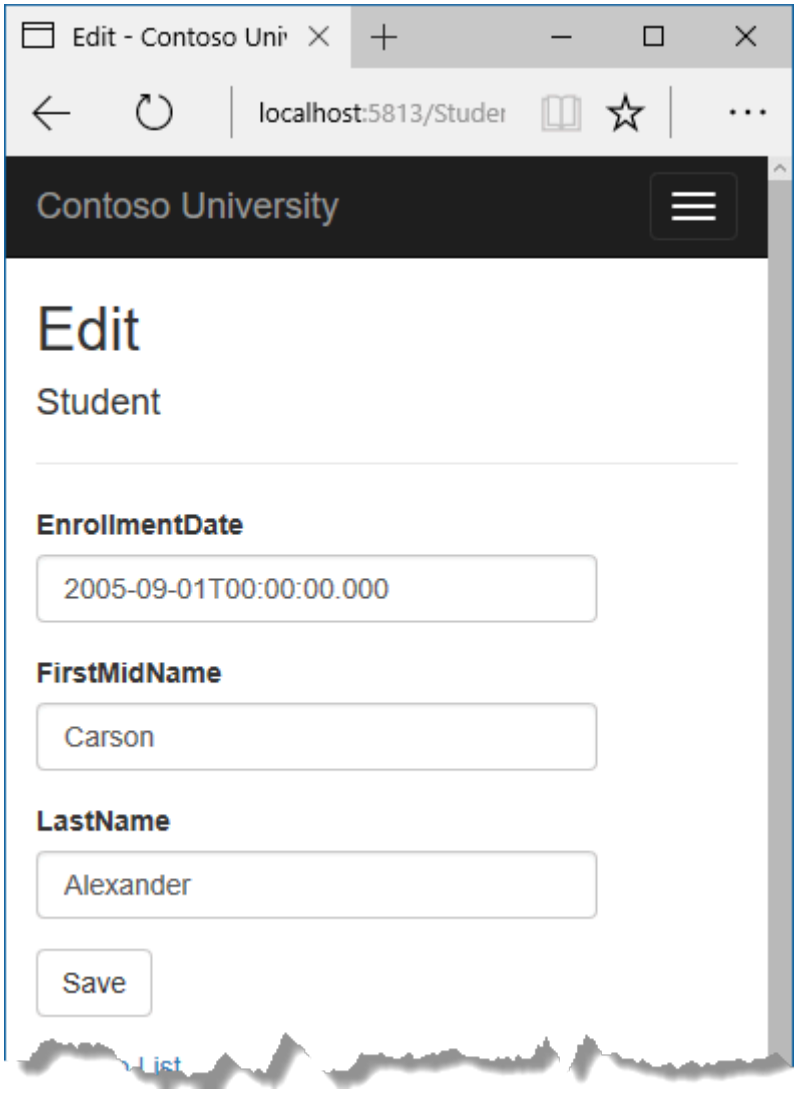
Database engines

The Visual Studio instructions use SQL Server LocalDB, a version of SQL Server Express that runs only on Windows.

Solve problems and troubleshoot



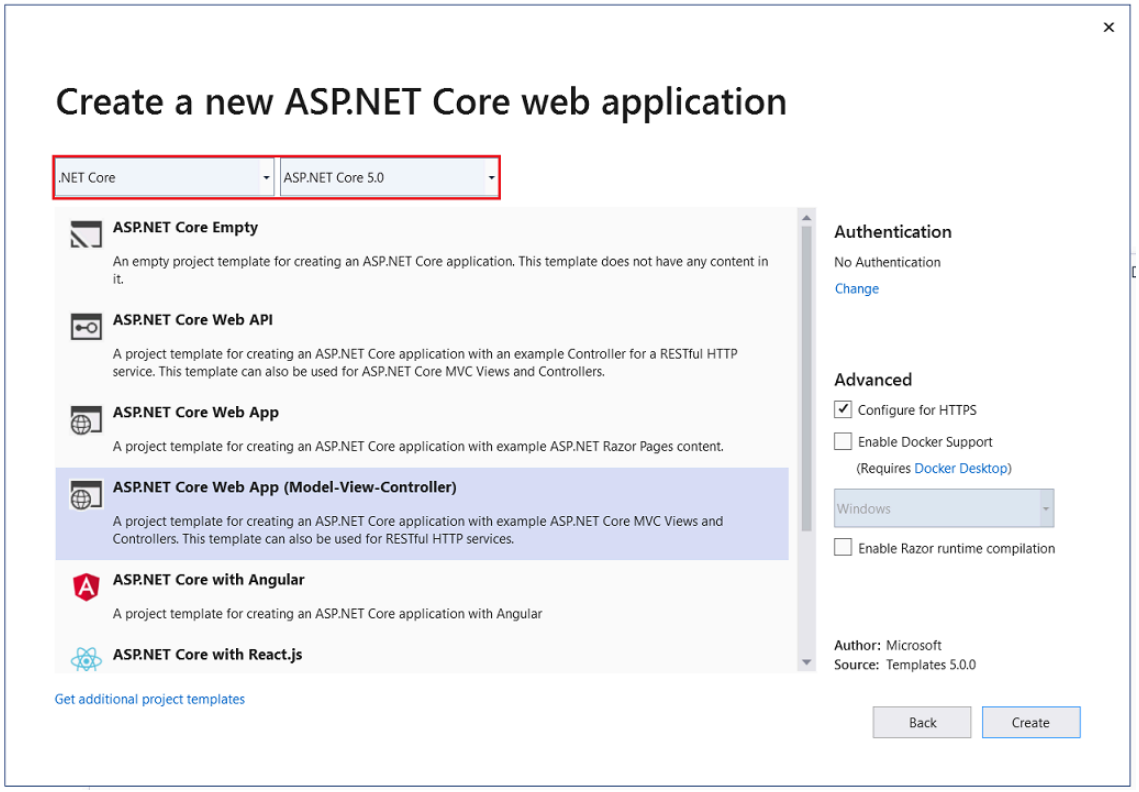
If you run into a problem you can't resolve, you can generally find the solution by comparing your code to the completed project. For a list of common errors and how to solve them, see the Troubleshooting section of the last tutorial in the series. If you don't find what you need there, you can post a question to StackOverflow.com for ASP.NET Core or EF Core.



> **Tip**
>
> This is a series of 10 tutorials, each of which builds on what is done in earlier tutorials. Consider saving a copy of the project after each successful tutorial completion. Then if you run into problems, you can start over from the previous tutorial instead of going back to the beginning of the whole series.

Contoso University web app

The app built in these tutorials is a basic university web site.



Users can view and update student, course, and instructor information. Here are a few of the screens in the app:

Index - Contoso Univers
localhost:60202/Studer
Contoso University
Index

Save

Create web app

1. Start Visual Studio and select **Create a new project**.
2. In the **Create a new project** dialog, select **ASP.NET Core Web Application** > **Next**.
3. In the **Configure your new project** dialog, enter `ContosoUniversity` for **Project name**. It's important to use this exact name including capitalization, so each `namespace` matches when code is copied.
4. Select **Create**.
5. In the **Create a new ASP.NET Core web application** dialog, select:
   a. **.NET Core** and **ASP.NET Core 5.0** in the dropdowns.
   b. **ASP.NET Core Web App (Model-View-Controller)**.
   c. **Create**

Set up the site style

A few basic changes set up the site menu, layout, and home page.

Open `Views/Shared/_Layout.cshtml` and make the following changes:

- Change each occurrence of `ContosoUniversity` to `Contoso University`. There are three occurrences.
- Add menu entries for **About**, **Students**, **Courses**, **Instructors**, and **Departments**, and delete the **Privacy** menu entry.

The preceding changes are highlighted in the following code:

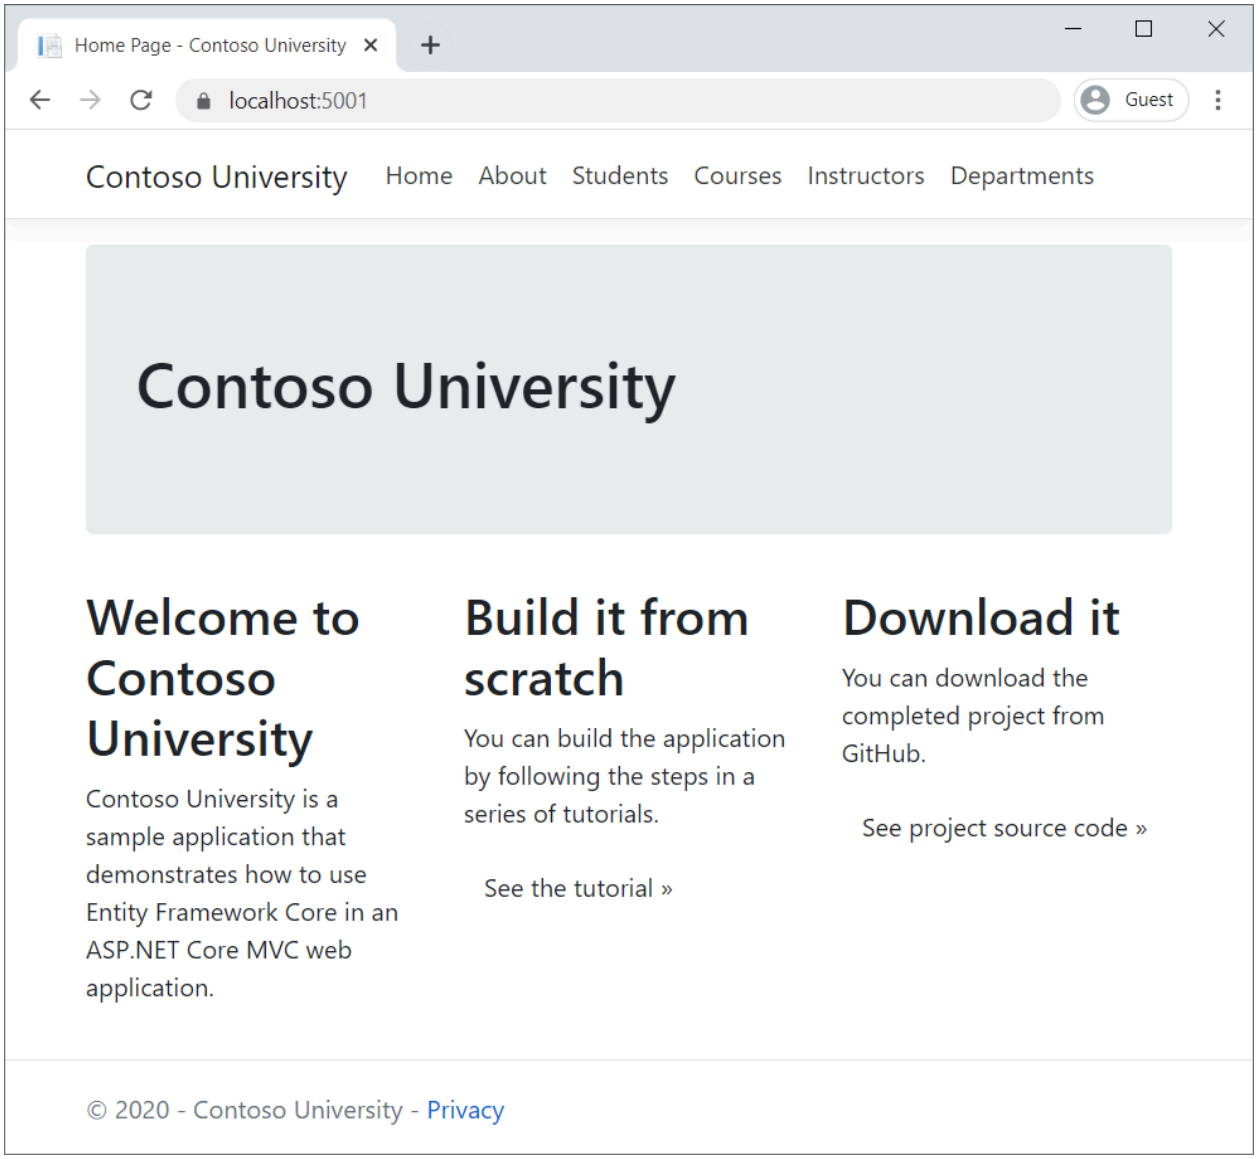
CSHTML

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - Contoso University</title>
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
    <link rel="stylesheet" href="~/css/site.css" />
</head>
<body>
    <header>
        <nav class="navbar navbar-expand-sm navbar-toggleable-sm navbar-
light bg-white border-bottom box-shadow mb-3">
            <div class="container">
                <a class="navbar-brand" asp-area="" asp-controller="Home"
asp-action="Index">Contoso University</a>
                <button class="navbar-toggler" type="button" data-
toggle="collapse" data-target=".navbar-collapse" aria-
controls="navbarSupportedContent"
                        aria-expanded="false" aria-label="Toggle
navigation">
                    <span class="navbar-toggler-icon"></span>
                </button>
                <div class="navbar-collapse collapse d-sm-inline-flex
justify-content-between">
                    <ul class="navbar-nav flex-grow-1">
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Home" asp-action="Index">Home</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Home" asp-action="About">About</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Students" asp-action="Index">Students</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Courses" asp-action="Index">Courses</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Instructors" asp-action="Index">Instructors</a>
                        </li>
                        <li class="nav-item">
                            <a class="nav-link text-dark" asp-area="" asp-
controller="Departments" asp-action="Index">Departments</a>
                        </li>
                    </ul>
                </div>
```

```
            </div>
        </nav>
    </header>
    <div class="container">
        <main role="main" class="pb-3">
            @RenderBody()
        </main>
    </div>

    <footer class="border-top footer text-muted">
        <div class="container">
            &copy; 2020 - Contoso University - <a asp-area="" asp-
controller="Home" asp-action="Privacy">Privacy</a>
        </div>
    </footer>
    <script src="~/lib/jquery/dist/jquery.js"></script>
    <script src="~/lib/bootstrap/dist/js/bootstrap.bundle.js"></script>
    <script src="~/js/site.js" asp-append-version="true"></script>
    @await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```

In `Views/Home/Index.cshtml`, replace the contents of the file with the following markup:



CSHTML

```
@{
    ViewData["Title"] = "Home Page";
}

<div class="jumbotron">
    <h1>Contoso University</h1>
</div>
<div class="row">
    <div class="col-md-4">
        <h2>Welcome to Contoso University</h2>
        <p>
            Contoso University is a sample application that
            demonstrates how to use Entity Framework Core in an
            ASP.NET Core MVC web application.
        </p>
    </div>
    <div class="col-md-4">
        <h2>Build it from scratch</h2>
        <p>You can build the application by following the steps in a series
of tutorials.</p>
        <p><a class="btn btn-default"
href="https://docs.asp.net/en/latest/data/ef-mvc/intro.html">See the
tutorial &raquo;</a></p>
    </div>
    <div class="col-md-4">
        <h2>Download it</h2>
        <p>You can download the completed project from GitHub.</p>
```

```
        <p><a class="btn btn-default"
href="https://github.com/dotnet/AspNetCore.Docs/tree/main/aspnetcore/data/ef
-mvc/intro/samples/5cu-final">See project source code &raquo;</a></p>
    </div>
</div>
```

Press CTRL+F5 to run the project or choose **Debug** > **Start Without Debugging** from the menu. The home page is displayed with tabs for the pages created in this tutorial.

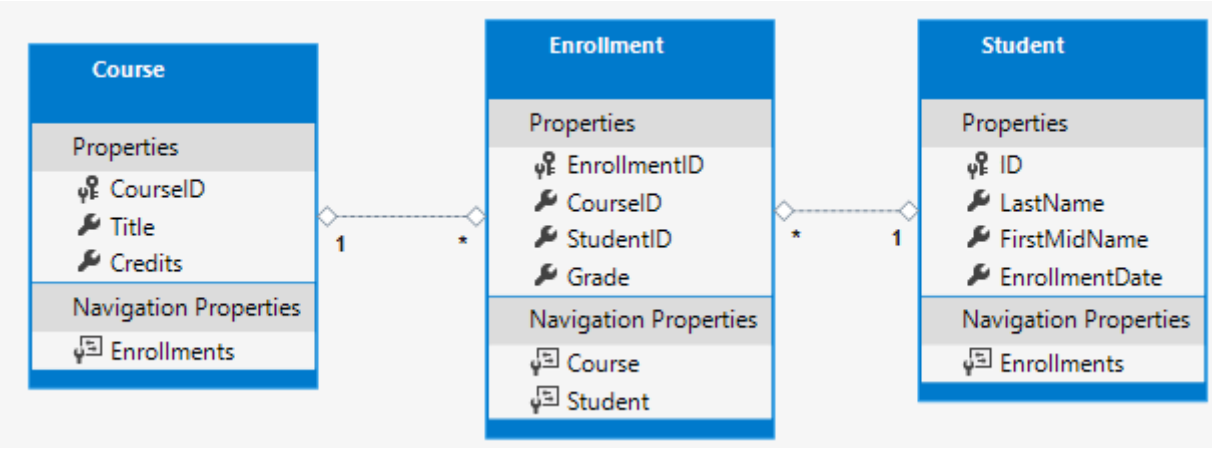
EF Core NuGet packages

This tutorial uses SQL Server, and the provider package is Microsoft.EntityFrameworkCore.SqlServer.

The EF SQL Server package and its dependencies, `Microsoft.EntityFrameworkCore` and `Microsoft.EntityFrameworkCore.Relational`, provide runtime support for EF.

Add the Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore NuGet package. In the Package Manager Console (PMC), enter the following commands to add the NuGet packages:

```
PowerShell



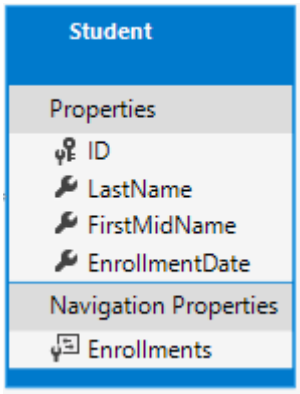
Install-Package Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore
Install-Package Microsoft.EntityFrameworkCore.SqlServer
```

The `Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore` NuGet package provides ASP.NET Core middleware for EF Core error pages. This middleware helps to detect and diagnose errors with EF Core migrations.

For information about other database providers that are available for EF Core, see Database providers.

Create the data model

The following entity classes are created for this app:



The preceding entities have the following relationships:

- A one-to-many relationship between `Student` and `Enrollment` entities. A student can be enrolled in any number of courses.
- A one-to-many relationship between `Course` and `Enrollment` entities. A course can have any number of students enrolled in it.

In the following sections, a class is created for each of these entities.

The Student entity

In the *Models* folder, create the `Student` class with the following code:

C#

```
using System;
using System.Collections.Generic;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
        public DateTime EnrollmentDate { get; set; }

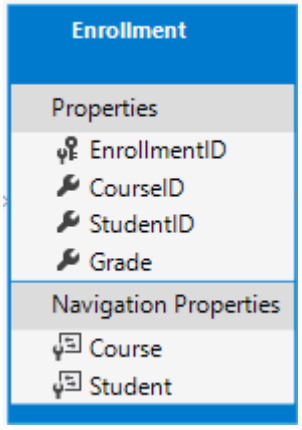
        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `ID` property is the primary key (**PK**) column of the database table that corresponds to this class. By default, EF interprets a property that's named `ID` or `classnameID` as the primary key. For example, the PK could be named `StudentID` rather than `ID`.

The `Enrollments` property is a navigation property. Navigation properties hold other entities that are related to this entity. The `Enrollments` property of a `Student` entity:

- Contains all of the `Enrollment` entities that are related to that `Student` entity.
- If a specific `Student` row in the database has two related `Enrollment` rows:
  - That `Student` entity's `Enrollments` navigation property contains those two `Enrollment` entities.

`Enrollment` rows contain a student's PK value in the `StudentID` foreign key (**FK**) column.



If a navigation property can hold multiple entities:

- The type must be a list, such as `ICollection<T>`, `List<T>`, or `HashSet<T>`.

- Entities can be added, deleted, and updated.

Many-to-many and one-to-many navigation relationships can contain multiple entities. When `ICollection<T>` is used, EF creates a `HashSet<T>` collection by default.

The Enrollment entity

In the *Models* folder, create the `Enrollment` class with the following code:

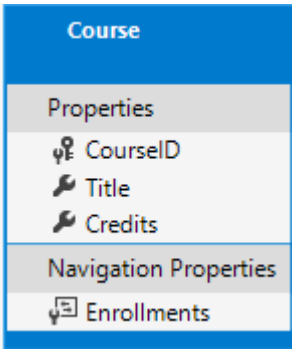
C#

```
namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

The `EnrollmentID` property is the PK. This entity uses the `classnameID` pattern instead of `ID` by itself. The `Student` entity used the `ID` pattern. Some developers prefer to use one pattern throughout the data model. In this tutorial, the variation illustrates that either pattern can be used. A later tutorial shows how using `ID` without classname makes it easier to implement inheritance in the data model.



The `Grade` property is an `enum`. The `?` after the `Grade` type declaration indicates that the `Grade` property is nullable. A grade that's `null` is different from a zero grade. `null` means a grade isn't known or hasn't been assigned yet.

The `StudentID` property is a foreign key (FK), and the corresponding navigation property is `Student`. An `Enrollment` entity is associated with one `Student` entity, so the property can only hold a single `Student` entity. This differs from the `Student.Enrollments` navigation property, which can hold multiple `Enrollment` entities.

The `CourseID` property is a FK, and the corresponding navigation property is `Course`. An `Enrollment` entity is associated with one `Course` entity.

Entity Framework interprets a property as a FK property if it's named `<`navigation property name`><`primary key property name`>`. For example, `StudentID` for the `Student` navigation property since the `Student` entity's PK is `ID`. FK properties can also be named `<`primary key property name`>`. For example, `CourseID` because the `Course` entity's PK is `CourseID`.

The Course entity

In the *Models* folder, create the `Course` class with the following code:

C#

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        public int CourseID { get; set; }
        public string Title { get; set; }
        public int Credits { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
```

```
    }
}
```

The `Enrollments` property is a navigation property. A `Course` entity can be related to any number of `Enrollment` entities.

The DatabaseGenerated attribute is explained in a later tutorial. This attribute allows entering the PK for the course rather than having the database generate it.

Create the database context

The main class that coordinates EF functionality for a given data model is the DbContext database context class. This class is created by deriving from the `Microsoft.EntityFrameworkCore.DbContext` class. The `DbContext` derived class specifies which entities are included in the data model. Some EF behaviors can be customized. In this project, the class is named `SchoolContext`.

In the project folder, create a folder named `Data`.

In the *Data* folder create a `SchoolContext` class with the following code:

C#

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) :
base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
    }
}
```

The preceding code creates a `DbSet` property for each entity set. In EF terminology:

- An entity set typically corresponds to a database table.
- An entity corresponds to a row in the table.

The `DbSet<Enrollment>` and `DbSet<Course>` statements could be omitted and it would work the same. EF would include them implicitly because:

- The `Student` entity references the `Enrollment` entity.
- The `Enrollment` entity references the `Course` entity.

When the database is created, EF creates tables that have names the same as the `DbSet` property names. Property names for collections are typically plural. For example, `Students` rather than `Student`. Developers disagree about whether table names should be pluralized or not. For these tutorials, the default behavior is overridden by specifying singular table names in the `DbContext`. To do that, add the following highlighted code after the last DbSet property.

C#

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) :
base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
        }
    }
}
```

Register the `SchoolContext`

ASP.NET Core includes dependency injection. Services, such as the EF database context, are registered with dependency injection during app startup. Components that require these services, such as MVC controllers, are provided these services via constructor

parameters. The controller constructor code that gets a context instance is shown later in this tutorial.

To register `SchoolContext` as a service, open `Startup.cs`, and add the highlighted lines to the `ConfigureServices` method.

C#

```
using ContosoUniversity.Data;
using Microsoft.EntityFrameworkCore;
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Configuration;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.Extensions.Hosting;

namespace ContosoUniversity
{
    public class Startup
    {
        public Startup(IConfiguration configuration)
        {
            Configuration = configuration;
        }

        public IConfiguration Configuration { get; }

        public void ConfigureServices(IServiceCollection services)
        {
            services.AddDbContext<SchoolContext>(options =>

options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection"))
);

            services.AddControllersWithViews();
        }
```

The name of the connection string is passed in to the context by calling a method on a `DbContextOptionsBuilder` object. For local development, the ASP.NET Core configuration system reads the connection string from the `appsettings.json` file.

Open the `appsettings.json` file and add a connection string as shown in the following markup:

JSON

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\mssqllocaldb;Database=ContosoUniversity1;Trusted_Connection=True;
MultipleActiveResultSets=true"
  },
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

Add the database exception filter

Add AddDatabaseDeveloperPageExceptionFilter to `ConfigureServices` as shown in the following code:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddDbContext<SchoolContext>(options =>

options.UseSqlServer(Configuration.GetConnectionString("DefaultConnection"))
);

    services.AddDatabaseDeveloperPageExceptionFilter();

    services.AddControllersWithViews();
}
```

The `AddDatabaseDeveloperPageExceptionFilter` provides helpful error information in the development environment.

SQL Server Express LocalDB

The connection string specifies SQL Server LocalDB. LocalDB is a lightweight version of the SQL Server Express Database Engine and is intended for app development, not production use. LocalDB starts on demand and runs in user mode, so there's no complex configuration. By default, LocalDB creates *.mdf* DB files in the `C:/Users/<user>` directory.

Initialize DB with test data

EF creates an empty database. In this section, a method is added that's called after the database is created in order to populate it with test data.

The `EnsureCreated` method is used to automatically create the database. In a later tutorial, you see how to handle model changes by using Code First Migrations to change the database schema instead of dropping and re-creating the database.

In the *Data* folder, create a new class named `DbInitializer` with the following code:

C#

```
using ContosoUniversity.Models;
using System;
using System.Linq;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
            new
Student{FirstMidName="Carson",LastName="Alexander",EnrollmentDate=DateTime.P
arse("2005-09-01")},
            new
Student{FirstMidName="Meredith",LastName="Alonso",EnrollmentDate=DateTime.Pa
rse("2002-09-01")},
            new
Student{FirstMidName="Arturo",LastName="Anand",EnrollmentDate=DateTime.Parse
("2003-09-01")},
            new
Student{FirstMidName="Gytis",LastName="Barzdukas",EnrollmentDate=DateTime.Pa
rse("2002-09-01")},
            new
Student{FirstMidName="Yan",LastName="Li",EnrollmentDate=DateTime.Parse("2002
-09-01")},
            new
Student{FirstMidName="Peggy",LastName="Justice",EnrollmentDate=DateTime.Pars
e("2001-09-01")},
            new
```

```
Student{FirstMidName="Laura",LastName="Norman",EnrollmentDate=DateTime.Parse
("2003-09-01")},
            new
Student{FirstMidName="Nino",LastName="Olivetto",EnrollmentDate=DateTime.Pars
e("2005-09-01")}
            };
            foreach (Student s in students)
            {
                context.Students.Add(s);
            }
            context.SaveChanges();

            var courses = new Course[]
            {
            new Course{CourseID=1050,Title="Chemistry",Credits=3},
            new Course{CourseID=4022,Title="Microeconomics",Credits=3},
            new Course{CourseID=4041,Title="Macroeconomics",Credits=3},
            new Course{CourseID=1045,Title="Calculus",Credits=4},
            new Course{CourseID=3141,Title="Trigonometry",Credits=4},
            new Course{CourseID=2021,Title="Composition",Credits=3},
            new Course{CourseID=2042,Title="Literature",Credits=4}
            };
            foreach (Course c in courses)
            {
                context.Courses.Add(c);
            }
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
            new Enrollment{StudentID=1,CourseID=1050,Grade=Grade.A},
            new Enrollment{StudentID=1,CourseID=4022,Grade=Grade.C},
            new Enrollment{StudentID=1,CourseID=4041,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=1045,Grade=Grade.B},
            new Enrollment{StudentID=2,CourseID=3141,Grade=Grade.F},
            new Enrollment{StudentID=2,CourseID=2021,Grade=Grade.F},
            new Enrollment{StudentID=3,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=1050},
            new Enrollment{StudentID=4,CourseID=4022,Grade=Grade.F},
            new Enrollment{StudentID=5,CourseID=4041,Grade=Grade.C},
            new Enrollment{StudentID=6,CourseID=1045},
            new Enrollment{StudentID=7,CourseID=3141,Grade=Grade.A},
            };
            foreach (Enrollment e in enrollments)
            {
                context.Enrollments.Add(e);
            }
            context.SaveChanges();
        }
    }
}
```

The preceding code checks if the database exists:

- If the database is not found;
  - It is created and loaded with test data. It loads test data into arrays rather than `List<T>` collections to optimize performance.
- If the database is found, it takes no action.

Update `Program.cs` with the following code:

C#

```
using ContosoUniversity.Data;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.AspNetCore.Hosting;
using Microsoft.Extensions.Hosting;
using Microsoft.Extensions.Logging;
using System;

namespace ContosoUniversity
{
    public class Program
    {
        public static void Main(string[] args)
        {
            var host = CreateHostBuilder(args).Build();

            CreateDbIfNotExists(host);

            host.Run();
        }

        private static void CreateDbIfNotExists(IHost host)
        {
            using (var scope = host.Services.CreateScope())
            {
                var services = scope.ServiceProvider;
                try
                {
                    var context = services.GetRequiredService<SchoolContext>
();
                    DbInitializer.Initialize(context);
                }
                catch (Exception ex)
                {
                    var logger =
services.GetRequiredService<ILogger<Program>>();
                    logger.LogError(ex, "An error occurred creating the
DB.");
                }
            }
        }

        public static IHostBuilder CreateHostBuilder(string[] args) =>
            Host.CreateDefaultBuilder(args)
                .ConfigureWebHostDefaults(webBuilder =>
```

```
                {
                    webBuilder.UseStartup<Startup>();
                });
    }
}
```

`Program.cs` does the following on app startup:

- Get a database context instance from the dependency injection container.
- Call the `DbInitializer.Initialize` method.
- Dispose the context when the `Initialize` method completes as shown in the following code:

C#

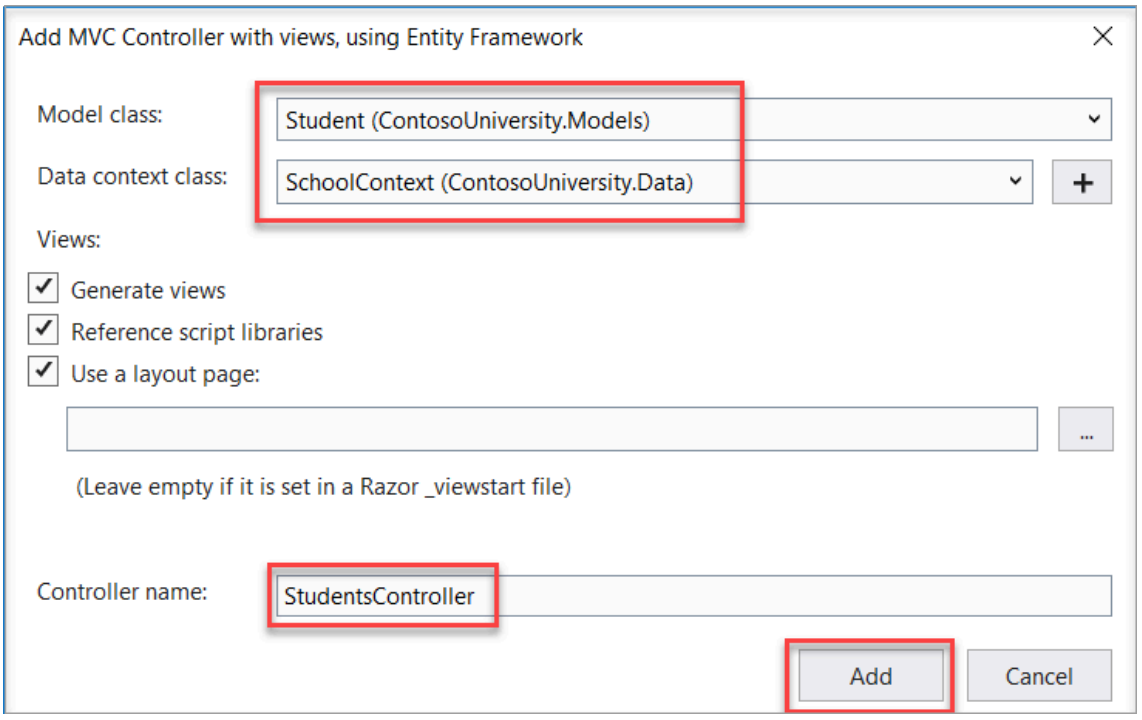
```
public static void Main(string[] args)
{
     var host = CreateWebHostBuilder(args).Build();

    using (var scope = host.Services.CreateScope())
    {
        var services = scope.ServiceProvider;
        try
        {
            var context = services.GetRequiredService<SchoolContext>();
            DbInitializer.Initialize(context);
        }
        catch (Exception ex)
        {
            var logger = services.GetRequiredService<ILogger<Program>>();
            logger.LogError(ex, "An error occurred while seeding the
database.");
        }
    }

    host.Run();
}
```

The first time the app is run, the database is created and loaded with test data. Whenever the data model changes:

- Delete the database.
- Update the seed method, and start afresh with a new database.



In later tutorials, the database is modified when the data model changes, without deleting and re-creating it. No data is lost when the data model changes.

Create controller and views

Use the scaffolding engine in Visual Studio to add an MVC controller and views that will use EF to query and save data.

The automatic creation of CRUD action methods and views is known as scaffolding.

- In **Solution Explorer**, right-click the `Controllers` folder and select **Add** > **New Scaffolded Item**.
- In the **Add Scaffold** dialog box:
  - Select **MVC controller with views, using Entity Framework**.
  - Click **Add**. The **Add MVC Controller with views, using Entity Framework** dialog box appears:

  - In **Model class**, select **Student**.
  - In **Data context class**, select **SchoolContext**.
  - Accept the default **StudentsController** as the name.
  - Click **Add**.

The Visual Studio scaffolding engine creates a `StudentsController.cs` file and a set of views (`*.cshtml` files) that work with the controller.

Notice the controller takes a `SchoolContext` as a constructor parameter.

C#

```
namespace ContosoUniversity.Controllers
{
    public class StudentsController : Controller
    {
```

```
        private readonly SchoolContext _context;

        public StudentsController(SchoolContext context)
        {
            _context = context;
        }
```

ASP.NET Core dependency injection takes care of passing an instance of `SchoolContext` into the controller. You configured that in the `Startup` class.

The controller contains an `Index` action method, which displays all students in the database. The method gets a list of students from the Students entity set by reading the `Students` property of the database context instance:

C#

```
public async Task<IActionResult> Index()
{
    return View(await _context.Students.ToListAsync());
}
```

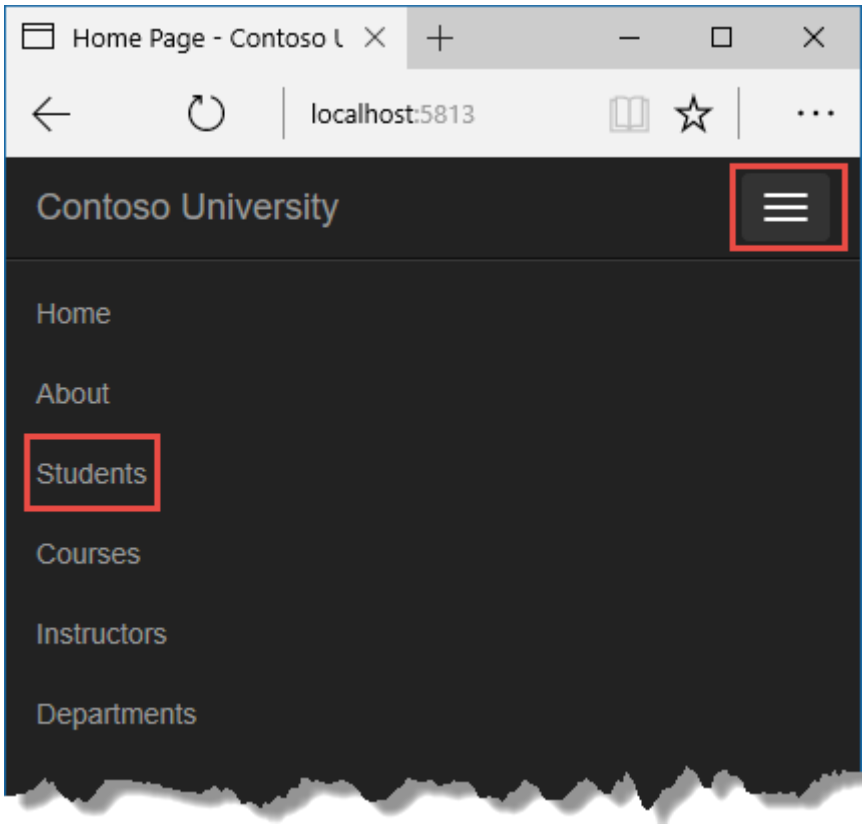
The asynchronous programming elements in this code are explained later in the tutorial.

The `Views/Students/Index.cshtml` view displays this list in a table:

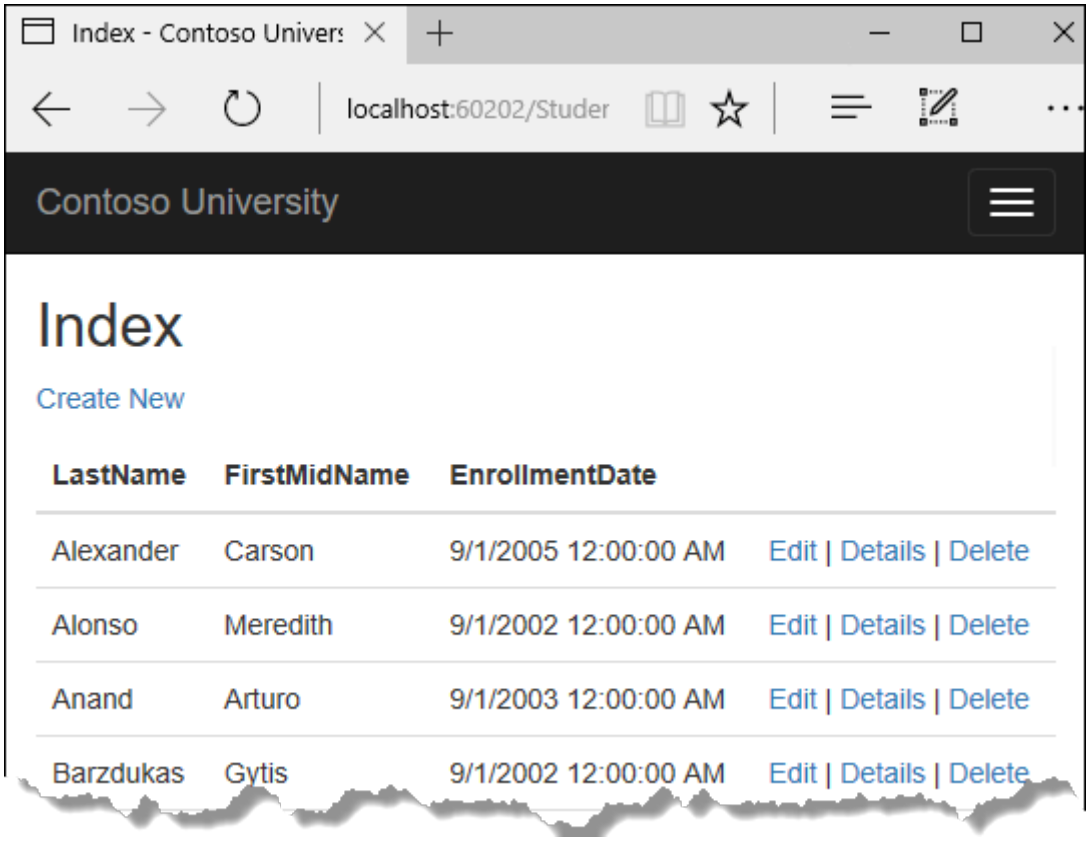
CSHTML

```
@model IEnumerable<ContosoUniversity.Models.Student>

@{
    ViewData["Title"] = "Index";
}



<h2>Index</h2>



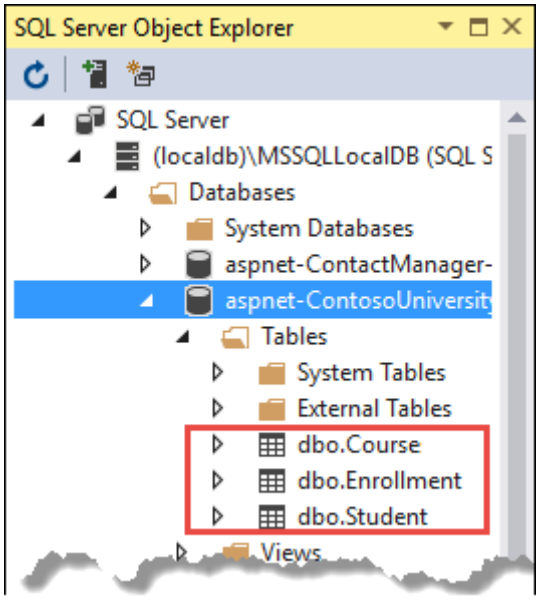
<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    @Html.DisplayNameFor(model => model.LastName)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.FirstMidName)
                </th>
                <th>
                    @Html.DisplayNameFor(model => model.EnrollmentDate)
                </th>
```

```
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.LastName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.FirstMidName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.ID">Details</a>
|
                <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

Press CTRL+F5 to run the project or choose **Debug** > **Start Without Debugging** from the menu.

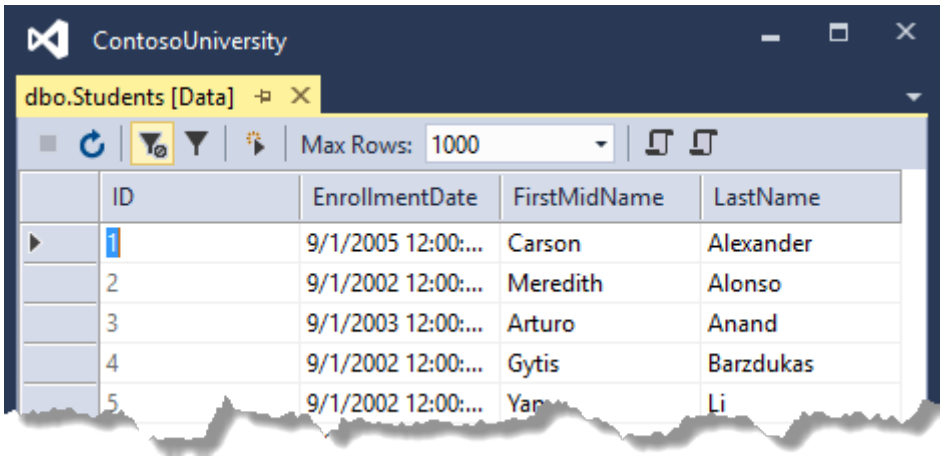
Click the Students tab to see the test data that the `DbInitializer.Initialize` method inserted. Depending on how narrow your browser window is, you'll see the `Students` tab link at the top of the page or you'll have to click the navigation icon in the upper right corner to see the link.

View the database



When the app is started, the `DbInitializer.Initialize` method calls `EnsureCreated`. EF saw that there was no database:

- So it created a database.



- The `Initialize` method code populated the database with data.

Use **SQL Server Object Explorer** (SSOX) to view the database in Visual Studio:

- Select **SQL Server Object Explorer** from the **View** menu in Visual Studio.
- In SSOX, select **(localdb)\MSSQLLocalDB** > **Databases**.
- Select `ContosoUniversity1`, the entry for the database name that's in the connection string in the `appsettings.json` file.
- Expand the **Tables** node to see the tables in the database.

Right-click the **Student** table and click **View Data** to see the data in the table.

The `*.mdf` and `*.ldf` database files are in the *C:\Users\<username>* folder.

Because `EnsureCreated` is called in the initializer method that runs on app start, you could:

- Make a change to the `Student` class.
- Delete the database.

- Stop, then start the app. The database is automatically re-created to match the change.

For example, if an `EmailAddress` property is added to the `Student` class, a new `EmailAddress` column in the re-created table. The view won't display the new `EmailAddress` property.

Conventions

The amount of code written in order for the EF to create a complete database is minimal because of the use of the conventions EF uses:

- The names of `DbSet` properties are used as table names. For entities not referenced by a `DbSet` property, entity class names are used as table names.
- Entity property names are used for column names.
- Entity properties that are named `ID` or `classnameID` are recognized as PK properties.
- A property is interpreted as a FK property if it's named `<`navigation property name`><`PK property name`>`. For example, `StudentID` for the `Student` navigation property since the `Student` entity's PK is `ID`. FK properties can also be named `<`primary key property name`>`. For example, `EnrollmentID` since the `Enrollment` entity's PK is `EnrollmentID`.

Conventional behavior can be overridden. For example, table names can be explicitly specified, as shown earlier in this tutorial. Column names and any property can be set as a PK or FK.

Asynchronous code

Asynchronous programming is the default mode for ASP.NET Core and EF Core.

A web server has a limited number of threads available, and in high load situations all of the available threads might be in use. When that happens, the server can't process new requests until the threads are freed up. With synchronous code, many threads may be tied up while they aren't actually doing any work because they're waiting for I/O to complete. With asynchronous code, when a process is waiting for I/O to complete, its thread is freed up for the server to use for processing other requests. As a result, asynchronous code enables server resources to be used more efficiently, and the server is enabled to handle more traffic without delays.

Asynchronous code does introduce a small amount of overhead at run time, but for low traffic situations the performance hit is negligible, while for high traffic situations, the potential performance improvement is substantial.

In the following code, `async`, `Task<T>`, `await`, and `ToListAsync` make the code execute asynchronously.

```
C#

public async Task<IActionResult> Index()
{
    return View(await _context.Students.ToListAsync());
}
```

- The `async` keyword tells the compiler to generate callbacks for parts of the method body and to automatically create the `Task<IActionResult>` object that's returned.
- The return type `Task<IActionResult>` represents ongoing work with a result of type `IActionResult`.
- The `await` keyword causes the compiler to split the method into two parts. The first part ends with the operation that's started asynchronously. The second part is put into a callback method that's called when the operation completes.
- `ToListAsync` is the asynchronous version of the `ToList` extension method.

Some things to be aware of when writing asynchronous code that uses EF:

- Only statements that cause queries or commands to be sent to the database are executed asynchronously. That includes, for example, `ToListAsync`, `SingleOrDefaultAsync`, and `SaveChangesAsync`. It doesn't include, for example, statements that just change an `IQueryable`, such as `var students = context.Students.Where(s => s.LastName == "Davolio")`.
- An EF context isn't thread safe: don't try to do multiple operations in parallel. When you call any async EF method, always use the `await` keyword.
- To take advantage of the performance benefits of async code, make sure that any library packages used also use async if they call any EF methods that cause queries to be sent to the database.

For more information about asynchronous programming in .NET, see Async Overview.

Limit entities fetched

See Performance considerations for information on limiting the number of entities returned from a query.

SQL Logging of Entity Framework Core

Logging configuration is commonly provided by the `Logging` section of `appsettings.{Environment}.json` files. To log SQL statements, add `"Microsoft.EntityFrameworkCore.Database.Command": "Information"` to the `appsettings.Development.json` file:

JSON

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=(localdb)\\mssqllocaldb;Database=MyDB-
2;Trusted_Connection=True;MultipleActiveResultSets=true"
  },
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft": "Warning",
      "Microsoft.Hosting.Lifetime": "Information"
     ,"Microsoft.EntityFrameworkCore.Database.Command": "Information"
    }
  },
  "AllowedHosts": "*"
}
```

With the preceding JSON, SQL statements are displayed on the command line and in the Visual Studio output window.

For more information, see Logging in .NET Core and ASP.NET Core and this GitHub issue.

Advance to the next tutorial to learn how to perform basic CRUD (create, read, update, delete) operations.

Implement basic CRUD functionality

Tutorial: Implement CRUD Functionality - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorial, you created an MVC application that stores and displays data using the Entity Framework and SQL Server LocalDB. In this tutorial, you'll review and customize the CRUD (create, read, update, delete) code that the MVC scaffolding automatically creates for you in controllers and views.

> **Note**
>
> It's a common practice to implement the repository pattern in order to create an abstraction layer between your controller and the data access layer. To keep these tutorials simple and focused on teaching how to use the Entity Framework itself, they don't use repositories. For information about repositories with EF, see the last tutorial in this series.

In this tutorial, you:

- ✓ Customize the Details page
- ✓ Update the Create page
- ✓ Update the Edit page
- ✓ Update the Delete page
- ✓ Close database connections

Prerequisites

- Get started with EF Core and ASP.NET Core MVC

Customize the Details page

The scaffolded code for the Students Index page left out the `Enrollments` property, because that property holds a collection. In the **Details** page, you'll display the contents of the collection in an HTML table.

In `Controllers/StudentsController.cs`, the action method for the Details view uses the `FirstOrDefaultAsync` method to retrieve a single `Student` entity. Add code that calls

`Include`. `ThenInclude`, and `AsNoTracking` methods, as shown in the following highlighted code.

C#

```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var student = await _context.Students
        .Include(s => s.Enrollments)
            .ThenInclude(e => e.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);

    if (student == null)
    {
        return NotFound();
    }

    return View(student);
}
```

The `Include` and `ThenInclude` methods cause the context to load the `Student.Enrollments` navigation property, and within each enrollment the `Enrollment.Course` navigation property. You'll learn more about these methods in the read related data tutorial.

The `AsNoTracking` method improves performance in scenarios where the entities returned won't be updated in the current context's lifetime. You'll learn more about `AsNoTracking` at the end of this tutorial.

Route data

The key value that's passed to the `Details` method comes from *route data*. Route data is data that the model binder found in a segment of the URL. For example, the default route specifies controller, action, and id segments:

C#

```
app.UseEndpoints(endpoints =>
{
    endpoints.MapControllerRoute(
        name: "default",
```

```
        pattern: "{controller=Home}/{action=Index}/{id?}");
});
```

In the following URL, the default route maps Instructor as the controller, Index as the action, and 1 as the id; these are route data values.

```
http://localhost:1230/Instructor/Index/1?courseID=2021
```

The last part of the URL ("?courseID=2021") is a query string value. The model binder will also pass the ID value to the `Index` method `id` parameter if you pass it as a query string value:

```
http://localhost:1230/Instructor/Index?id=1&CourseID=2021
```

In the Index page, hyperlink URLs are created by tag helper statements in the Razor view. In the following Razor code, the `id` parameter matches the default route, so `id` is added to the route data.

HTML

```
<a asp-action="Edit" asp-route-id="@item.ID">Edit</a>
```

This generates the following HTML when `item.ID` is 6:

HTML

```
<a href="/Students/Edit/6">Edit</a>
```

In the following Razor code, `studentID` doesn't match a parameter in the default route, so it's added as a query string.

HTML

```
<a asp-action="Edit" asp-route-studentID="@item.ID">Edit</a>
```

This generates the following HTML when `item.ID` is 6:

HTML

```
<a href="/Students/Edit?studentID=6">Edit</a>
```

For more information about tag helpers, see Tag Helpers in ASP.NET Core.

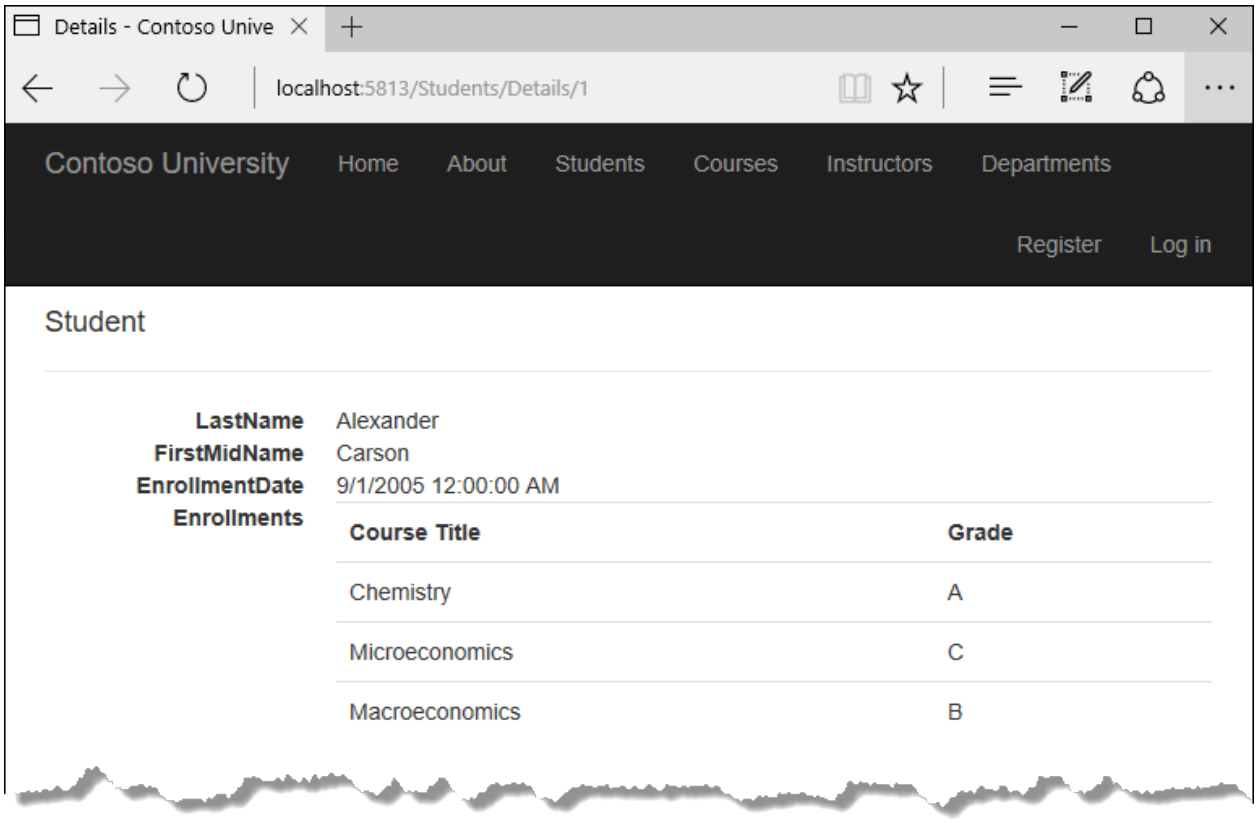
Add enrollments to the Details view

Open `Views/Students/Details.cshtml`. Each field is displayed using `DisplayNameFor` and `DisplayFor` helpers, as shown in the following example:

CSHTML

```
<dt class="col-sm-2">
    @Html.DisplayNameFor(model => model.LastName)
</dt>
<dd class="col-sm-10">
    @Html.DisplayFor(model => model.LastName)
</dd>
```

After the last field and immediately before the closing `</dl>` tag, add the following code to display a list of enrollments:



CSHTML

```
<dt class="col-sm-2">
    @Html.DisplayNameFor(model => model.Enrollments)
</dt>
<dd class="col-sm-10">
    <table class="table">
        <tr>
            <th>Course Title</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Course.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
</dd>
```

If code indentation is wrong after you paste the code, press CTRL-K-D to correct it.

This code loops through the entities in the `Enrollments` navigation property. For each enrollment, it displays the course title and the grade. The course title is retrieved from the Course entity that's stored in the `Course` navigation property of the Enrollments entity.

Run the app, select the **Students** tab, and click the **Details** link for a student. You see the list of courses and grades for the selected student:

Update the Create page

In `StudentsController.cs`, modify the HttpPost `Create` method by adding a try-catch block and removing ID from the `Bind` attribute.

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create(
    [Bind("EnrollmentDate,FirstMidName,LastName")] Student student)
{
    try
    {
        if (ModelState.IsValid)
        {
            _context.Add(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
```

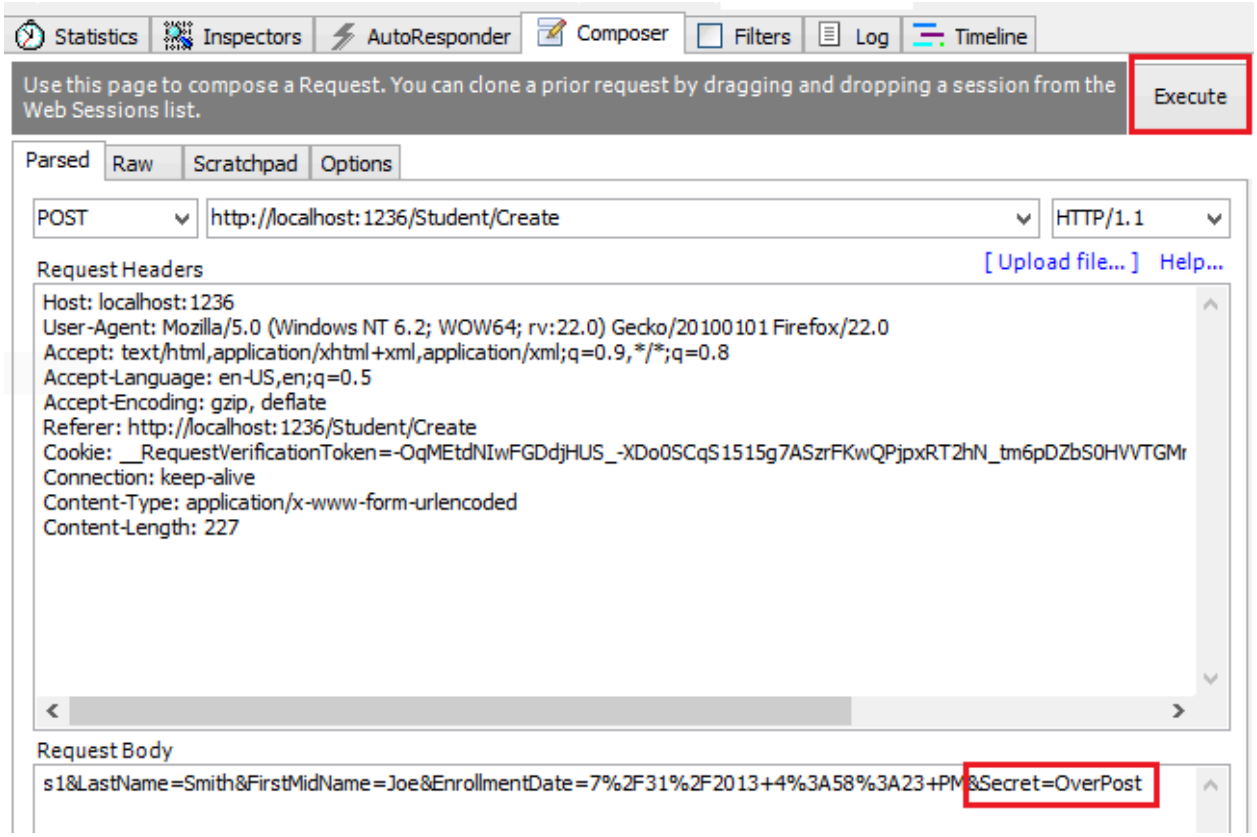
```
            }
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists " +
                "see your system administrator.");
        }
        return View(student);
    }
```

This code adds the Student entity created by the ASP.NET Core MVC model binder to the Students entity set and then saves the changes to the database. (Model binder refers to the ASP.NET Core MVC functionality that makes it easier for you to work with data submitted by a form; a model binder converts posted form values to CLR types and passes them to the action method in parameters. In this case, the model binder instantiates a Student entity for you using property values from the Form collection.)

You removed `ID` from the `Bind` attribute because ID is the primary key value which SQL Server will set automatically when the row is inserted. Input from the user doesn't set the ID value.

Other than the `Bind` attribute, the try-catch block is the only change you've made to the scaffolded code. If an exception that derives from `DbUpdateException` is caught while the changes are being saved, a generic error message is displayed. `DbUpdateException` exceptions are sometimes caused by something external to the application rather than a programming error, so the user is advised to try again. Although not implemented in this sample, a production quality application would log the exception. For more information, see the **Log for insight** section in Monitoring and Telemetry (Building Real-World Cloud Apps with Azure).

The `ValidateAntiForgeryToken` attribute helps prevent cross-site request forgery (CSRF) attacks. The token is automatically injected into the view by the FormTagHelper and is included when the form is submitted by the user. The token is validated by the `ValidateAntiForgeryToken` attribute. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.



Security note about overposting

The `Bind` attribute that the scaffolded code includes on the `Create` method is one way to protect against overposting in create scenarios. For example, suppose the Student entity includes a `Secret` property that you don't want this web page to set.

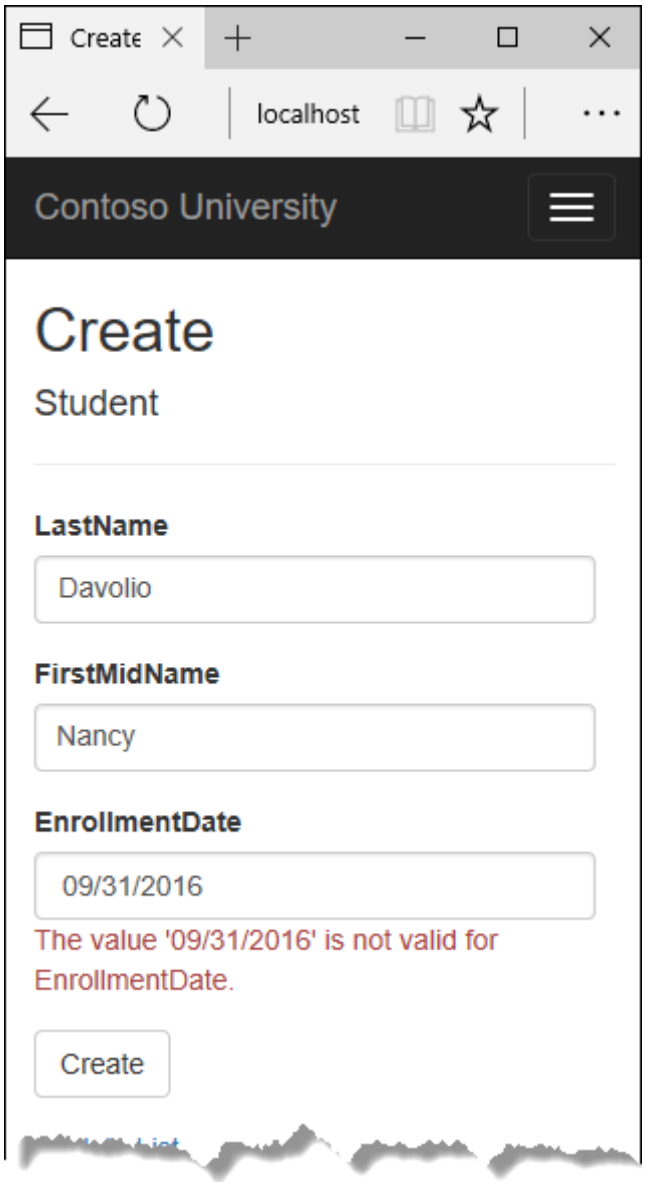
C#

```
public class Student
{
    public int ID { get; set; }
    public string LastName { get; set; }
    public string FirstMidName { get; set; }
    public DateTime EnrollmentDate { get; set; }
    public string Secret { get; set; }
}
```

Even if you don't have a `Secret` field on the web page, a hacker could use a tool such as Fiddler, or write some JavaScript, to post a `Secret` form value. Without the `Bind` attribute limiting the fields that the model binder uses when it creates a Student instance, the model binder would pick up that `Secret` form value and use it to create the Student entity instance. Then whatever value the hacker specified for the `Secret` form field would be updated in your database. The following image shows the Fiddler tool adding the `Secret` field (with the value "OverPost") to the posted form values.

The value "OverPost" would then be successfully added to the `Secret` property of the inserted row, although you never intended that the web page be able to set that property.

You can prevent overposting in edit scenarios by reading the entity from the database first and then calling `TryUpdateModel`, passing in an explicit allowed properties list. That's the method used in these tutorials.



An alternative way to prevent overposting that's preferred by many developers is to use view models rather than entity classes with model binding. Include only the properties you want to update in the view model. Once the MVC model binder has finished, copy the view model properties to the entity instance, optionally using a tool such as AutoMapper. Use `_context.Entry` on the entity instance to set its state to `Unchanged`, and then set `Property("PropertyName").IsModified` to true on each entity property that's included in the view model. This method works in both edit and create scenarios.

Test the Create page

The code in `Views/Students/Create.cshtml` uses `label`, `input`, and `span` (for validation messages) tag helpers for each field.

Run the app, select the **Students** tab, and click **Create New**.

Enter names and a date. Try entering an invalid date if your browser lets you do that. (Some browsers force you to use a date picker.) Then click **Create** to see the error message.

This is server-side validation that you get by default; in a later tutorial you'll see how to add attributes that will generate code for client-side validation also. The following highlighted code shows the model validation check in the `Create` method.

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Create(
    [Bind("EnrollmentDate,FirstMidName,LastName")] Student student)
{
    try
    {
        if (ModelState.IsValid)
        {
            _context.Add(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
    }
    catch (DbUpdateException /* ex */)
```

```
    {
        //Log the error (uncomment ex variable name and write a log.
        ModelState.AddModelError("", "Unable to save changes. " +
            "Try again, and if the problem persists " +
            "see your system administrator.");
    }
    return View(student);
}
```

Change the date to a valid value and click **Create** to see the new student appear in the **Index** page.

Update the Edit page

In `StudentController.cs`, the HttpGet `Edit` method (the one without the `HttpPost` attribute) uses the `FirstOrDefaultAsync` method to retrieve the selected Student entity, as you saw in the `Details` method. You don't need to change this method.

Recommended HttpPost Edit code: Read and update

Replace the HttpPost Edit action method with the following code.

C#

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }
    var studentToUpdate = await _context.Students.FirstOrDefaultAsync(s =>
s.ID == id);
    if (await TryUpdateModelAsync<Student>(
        studentToUpdate,
        "",
        s => s.FirstMidName, s => s.LastName, s => s.EnrollmentDate))
    {
        try
        {
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
```

```
                "see your system administrator.");
        }
    }
    return View(studentToUpdate);
}
```

These changes implement a security best practice to prevent overposting. The scaffolder generated a `Bind` attribute and added the entity created by the model binder to the entity set with a `Modified` flag. That code isn't recommended for many scenarios because the `Bind` attribute clears out any pre-existing data in fields not listed in the `Include` parameter.

The new code reads the existing entity and calls `TryUpdateModel` to update fields in the retrieved entity based on user input in the posted form data. The Entity Framework's automatic change tracking sets the `Modified` flag on the fields that are changed by form input. When the `SaveChanges` method is called, the Entity Framework creates SQL statements to update the database row. Concurrency conflicts are ignored, and only the table columns that were updated by the user are updated in the database. (A later tutorial shows how to handle concurrency conflicts.)

As a best practice to prevent overposting, the fields that you want to be updateable by the **Edit** page are declared in the `TryUpdateModel` parameters. (The empty string preceding the list of fields in the parameter list is for a prefix to use with the form fields names.) Currently there are no extra fields that you're protecting, but listing the fields that you want the model binder to bind ensures that if you add fields to the data model in the future, they're automatically protected until you explicitly add them here.

As a result of these changes, the method signature of the HttpPost `Edit` method is the same as the HttpGet `Edit` method; therefore you've renamed the method `EditPost`.

Alternative HttpPost Edit code: Create and attach

The recommended HttpPost edit code ensures that only changed columns get updated and preserves data in properties that you don't want included for model binding. However, the read-first approach requires an extra database read, and can result in more complex code for handling concurrency conflicts. An alternative is to attach an entity created by the model binder to the EF context and mark it as modified. (Don't update your project with this code, it's only shown to illustrate an optional approach.)

C#

```
public async Task<IActionResult> Edit(int id,
[Bind("ID,EnrollmentDate,FirstMidName,LastName")] Student student)
```

```
{
    if (id != student.ID)
    {
        return NotFound();
    }
    if (ModelState.IsValid)
    {
        try
        {
            _context.Update(student);
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
    }
    return View(student);
}
```

You can use this approach when the web page UI includes all of the fields in the entity and can update any of them.

The scaffolded code uses the create-and-attach approach but only catches `DbUpdateConcurrencyException` exceptions and returns 404 error codes. The example shown catches any database update exception and displays an error message.

Entity States

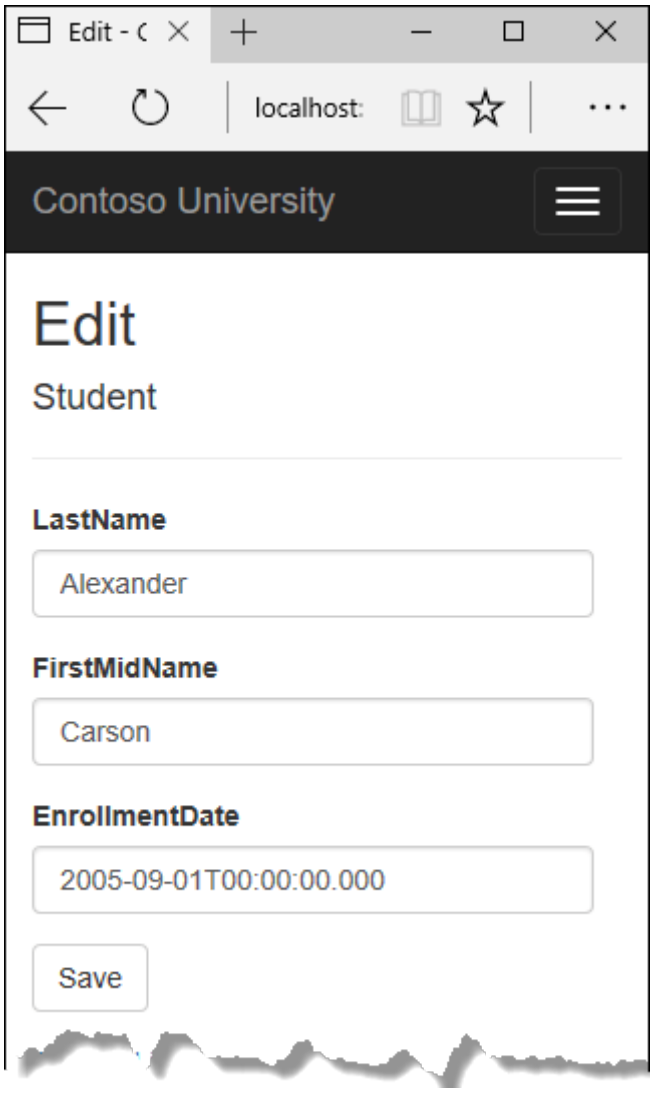
The database context keeps track of whether entities in memory are in sync with their corresponding rows in the database, and this information determines what happens when you call the `SaveChanges` method. For example, when you pass a new entity to the `Add` method, that entity's state is set to `Added`. Then when you call the `SaveChanges` method, the database context issues a SQL INSERT command.

An entity may be in one of the following states:

- `Added`. The entity doesn't yet exist in the database. The `SaveChanges` method issues an INSERT statement.
- `Unchanged`. Nothing needs to be done with this entity by the `SaveChanges` method. When you read an entity from the database, the entity starts out with this status.

- `Modified`. Some or all of the entity's property values have been modified. The `SaveChanges` method issues an UPDATE statement.
- `Deleted`. The entity has been marked for deletion. The `SaveChanges` method issues a DELETE statement.
- `Detached`. The entity isn't being tracked by the database context.

In a desktop application, state changes are typically set automatically. You read an entity and make changes to some of its property values. This causes its entity state to automatically be changed to `Modified`. Then when you call `SaveChanges`, the Entity Framework generates a SQL UPDATE statement that updates only the actual properties that you changed.



In a web app, the `DbContext` that initially reads an entity and displays its data to be edited is disposed after a page is rendered. When the HttpPost `Edit` action method is called, a new web request is made and you have a new instance of the `DbContext`. If you re-read the entity in that new context, you simulate desktop processing.

But if you don't want to do the extra read operation, you have to use the entity object created by the model binder. The simplest way to do this is to set the entity state to Modified as is done in the alternative HttpPost Edit code shown earlier. Then when you call `SaveChanges`, the Entity Framework updates all columns of the database row, because the context has no way to know which properties you changed.

If you want to avoid the read-first approach, but you also want the SQL UPDATE statement to update only the fields that the user actually changed, the code is more complex. You have to save the original values in some way (such as by using hidden fields) so that they're available when the HttpPost `Edit` method is called. Then you can create a Student entity using the original values, call the `Attach` method with that original version of the entity, update the entity's values to the new values, and then call `SaveChanges`.

Test the Edit page

Run the app, select the **Students** tab, then click an **Edit** hyperlink.

Change some of the data and click **Save**. The **Index** page opens and you see the changed data.

Update the Delete page

In `StudentController.cs`, the template code for the HttpGet `Delete` method uses the `FirstOrDefaultAsync` method to retrieve the selected Student entity, as you saw in the Details and Edit methods. However, to implement a custom error message when the call to `SaveChanges` fails, you'll add some functionality to this method and its corresponding view.

As you saw for update and create operations, delete operations require two action methods. The method that's called in response to a GET request displays a view that gives the user a chance to approve or cancel the delete operation. If the user approves it, a POST request is created. When that happens, the HttpPost `Delete` method is called and then that method actually performs the delete operation.

You'll add a try-catch block to the HttpPost `Delete` method to handle any errors that might occur when the database is updated. If an error occurs, the HttpPost Delete

method calls the HttpGet Delete method, passing it a parameter that indicates that an error has occurred. The HttpGet Delete method then redisplays the confirmation page along with the error message, giving the user an opportunity to cancel or try again.

Replace the HttpGet `Delete` action method with the following code, which manages error reporting.

C#

```
public async Task<IActionResult> Delete(int? id, bool? saveChangesError =
false)
{
    if (id == null)
    {
        return NotFound();
    }

    var student = await _context.Students
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (student == null)
    {
        return NotFound();
    }

    if (saveChangesError.GetValueOrDefault())
    {
        ViewData["ErrorMessage"] =
            "Delete failed. Try again, and if the problem persists " +
            "see your system administrator.";
    }

    return View(student);
}
```

This code accepts an optional parameter that indicates whether the method was called after a failure to save changes. This parameter is false when the HttpGet `Delete` method is called without a previous failure. When it's called by the HttpPost `Delete` method in response to a database update error, the parameter is true and an error message is passed to the view.

The read-first approach to HttpPost Delete

Replace the HttpPost `Delete` action method (named `DeleteConfirmed`) with the following code, which performs the actual delete operation and catches any database update errors.

C#

```
[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    var student = await _context.Students.FindAsync(id);
    if (student == null)
    {
        return RedirectToAction(nameof(Index));
    }

    try
    {
        _context.Students.Remove(student);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { id = id,
saveChangesError = true });
    }
}
```

This code retrieves the selected entity, then calls the `Remove` method to set the entity's status to `Deleted`. When `SaveChanges` is called, a SQL DELETE command is generated.

The create-and-attach approach to HttpPost Delete

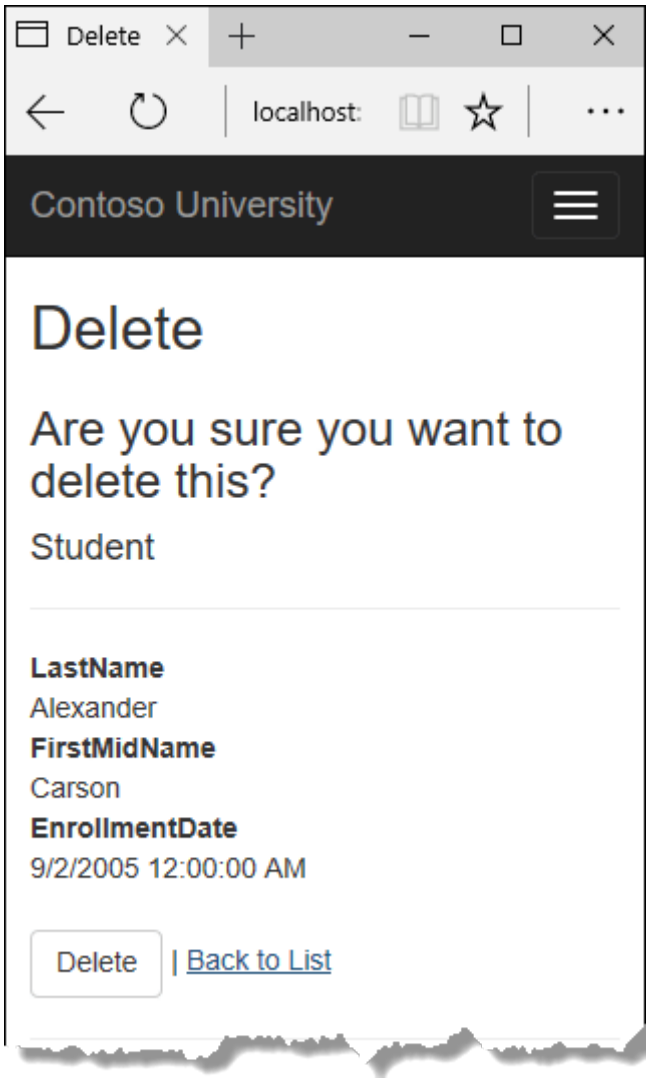
If improving performance in a high-volume application is a priority, you could avoid an unnecessary SQL query by instantiating a Student entity using only the primary key value and then setting the entity state to `Deleted`. That's all that the Entity Framework needs in order to delete the entity. (Don't put this code in your project; it's here just to illustrate an alternative.)

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    try
    {
        Student studentToDelete = new Student() { ID = id };
        _context.Entry(studentToDelete).State = EntityState.Deleted;
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
```

```
    }
    catch (DbUpdateException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { id = id,
saveChangesError = true });
    }
}
```

If the entity has related data that should also be deleted, make sure that cascade delete is configured in the database. With this approach to entity deletion, EF might not realize there are related entities to be deleted.



Update the Delete view

In `Views/Student/Delete.cshtml`, add an error message between the h2 heading and the h3 heading, as shown in the following example:

CSHTML

```
<h2>Delete</h2>
<p class="text-danger">@ViewData["ErrorMessage"]</p>
<h3>Are you sure you want to delete this?</h3>
```

Run the app, select the **Students** tab, and click a **Delete** hyperlink:

Click **Delete**. The Index page is displayed without the deleted student. (You'll see an example of the error handling code in action in the concurrency tutorial.)

Close database connections

To free up the resources that a database connection holds, the context instance must be disposed as soon as possible when you are done with it. The ASP.NET Core built-in dependency injection takes care of that task for you.

In `Startup.cs`, you call the AddDbContext extension method to provision the `DbContext` class in the ASP.NET Core DI container. That method sets the service lifetime to `Scoped` by default. `Scoped` means the context object lifetime coincides with the web request life time, and the `Dispose` method will be called automatically at the end of the web request.

Handle transactions

By default the Entity Framework implicitly implements transactions. In scenarios where you make changes to multiple rows or tables and then call `SaveChanges`, the Entity Framework automatically makes sure that either all of your changes succeed or they all fail. If some changes are done first and then an error happens, those changes are automatically rolled back. For scenarios where you need more control -- for example, if you want to include operations done outside of Entity Framework in a transaction -- see Transactions.

No-tracking queries

When a database context retrieves table rows and creates entity objects that represent them, by default it keeps track of whether the entities in memory are in sync with what's in the database. The data in memory acts as a cache and is used when you update an entity. This caching is often unnecessary in a web application because context instances are typically short-lived (a new one is created and disposed for each request) and the context that reads an entity is typically disposed before that entity is used again.

You can disable tracking of entity objects in memory by calling the `AsNoTracking` method. Typical scenarios in which you might want to do that include the following:

- During the context lifetime you don't need to update any entities, and you don't need EF to automatically load navigation properties with entities retrieved by separate queries. Frequently these conditions are met in a controller's HttpGet action methods.
- You are running a query that retrieves a large volume of data, and only a small portion of the returned data will be updated. It may be more efficient to turn off tracking for the large query, and run a query later for the few entities that need to be updated.
- You want to attach an entity in order to update it, but earlier you retrieved the same entity for a different purpose. Because the entity is already being tracked by the database context, you can't attach the entity that you want to change. One way to handle this situation is to call `AsNoTracking` on the earlier query.

For more information, see Tracking vs. No-Tracking.

Get the code

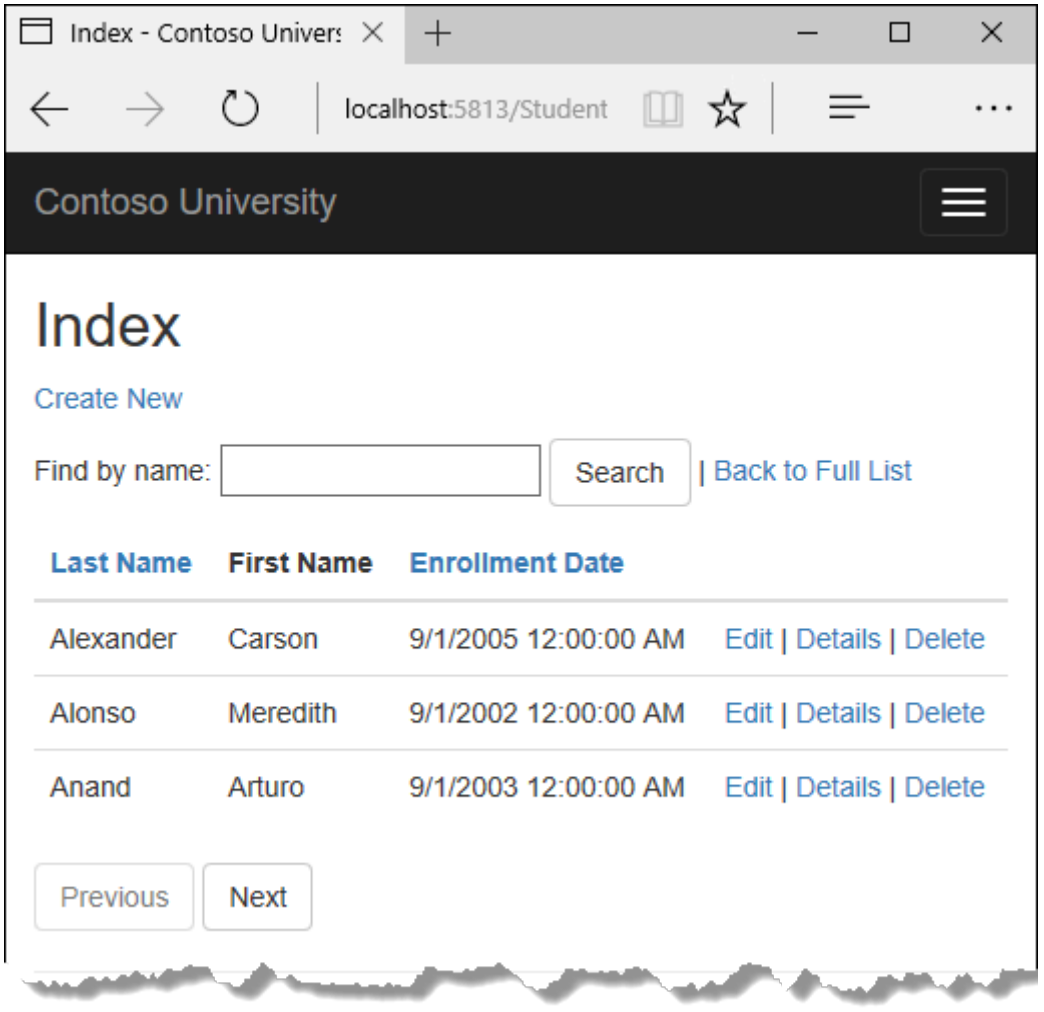
Download or view the completed application.

Next steps

In this tutorial, you:

- ✓ Customized the Details page
- ✓ Updated the Create page
- ✓ Updated the Edit page
- ✓ Updated the Delete page
- ✓ Closed database connections

Advance to the next tutorial to learn how to expand the functionality of the **Index** page by adding sorting, filtering, and paging.



Next: Sorting, filtering, and paging

Tutorial: Add sorting, filtering, and paging - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorial, you implemented a set of web pages for basic CRUD operations for Student entities. In this tutorial you'll add sorting, filtering, and paging functionality to the Students Index page. You'll also create a page that does simple grouping.

The following illustration shows what the page will look like when you're done. The column headings are links that the user can click to sort by that column. Clicking a column heading repeatedly toggles between ascending and descending sort order.

In this tutorial, you:

- ✓ Add column sort links
- ✓ Add a Search box
- ✓ Add paging to Students Index
- ✓ Add paging to Index method
- ✓ Add paging links

✔ Create an About page

Prerequisites

- Implement CRUD Functionality

Add column sort links

To add sorting to the Student Index page, you'll change the `Index` method of the Students controller and add code to the Student Index view.

Add sorting Functionality to the Index method

In `StudentsController.cs`, replace the `Index` method with the following code:

C#

```
public async Task<IActionResult> Index(string sortOrder)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc"
: "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    var students = from s in _context.Students
                   select s;
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

This code receives a `sortOrder` parameter from the query string in the URL. The query string value is provided by ASP.NET Core MVC as a parameter to the action method. The parameter will be a string that's either "Name" or "Date", optionally followed by an

underscore and the string "desc" to specify descending order. The default sort order is ascending.

The first time the Index page is requested, there's no query string. The students are displayed in ascending order by last name, which is the default as established by the fall-through case in the `switch` statement. When the user clicks a column heading hyperlink, the appropriate `sortOrder` value is provided in the query string.

The two `ViewData` elements (NameSortParm and DateSortParm) are used by the view to configure the column heading hyperlinks with the appropriate query string values.

C#

```
public async Task<IActionResult> Index(string sortOrder)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc"
: "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    var students = from s in _context.Students
                   select s;
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

These are ternary statements. The first one specifies that if the `sortOrder` parameter is null or empty, NameSortParm should be set to "name_desc"; otherwise, it should be set to an empty string. These two statements enable the view to set the column heading hyperlinks as follows:

Expand table

Current sort order	Last Name Hyperlink	Date Hyperlink
Last Name ascending	descending	ascending

Current sort order	Last Name Hyperlink	Date Hyperlink
Last Name descending	ascending	ascending
Date ascending	ascending	descending
Date descending	ascending	ascending

The method uses LINQ to Entities to specify the column to sort by. The code creates an `IQueryable` variable before the switch statement, modifies it in the switch statement, and calls the `ToListAsync` method after the `switch` statement. When you create and modify `IQueryable` variables, no query is sent to the database. The query isn't executed until you convert the `IQueryable` object into a collection by calling a method such as `ToListAsync`. Therefore, this code results in a single query that's not executed until the `return View` statement.

This code could get verbose with a large number of columns. The last tutorial in this series shows how to write code that lets you pass the name of the `OrderBy` column in a string variable.

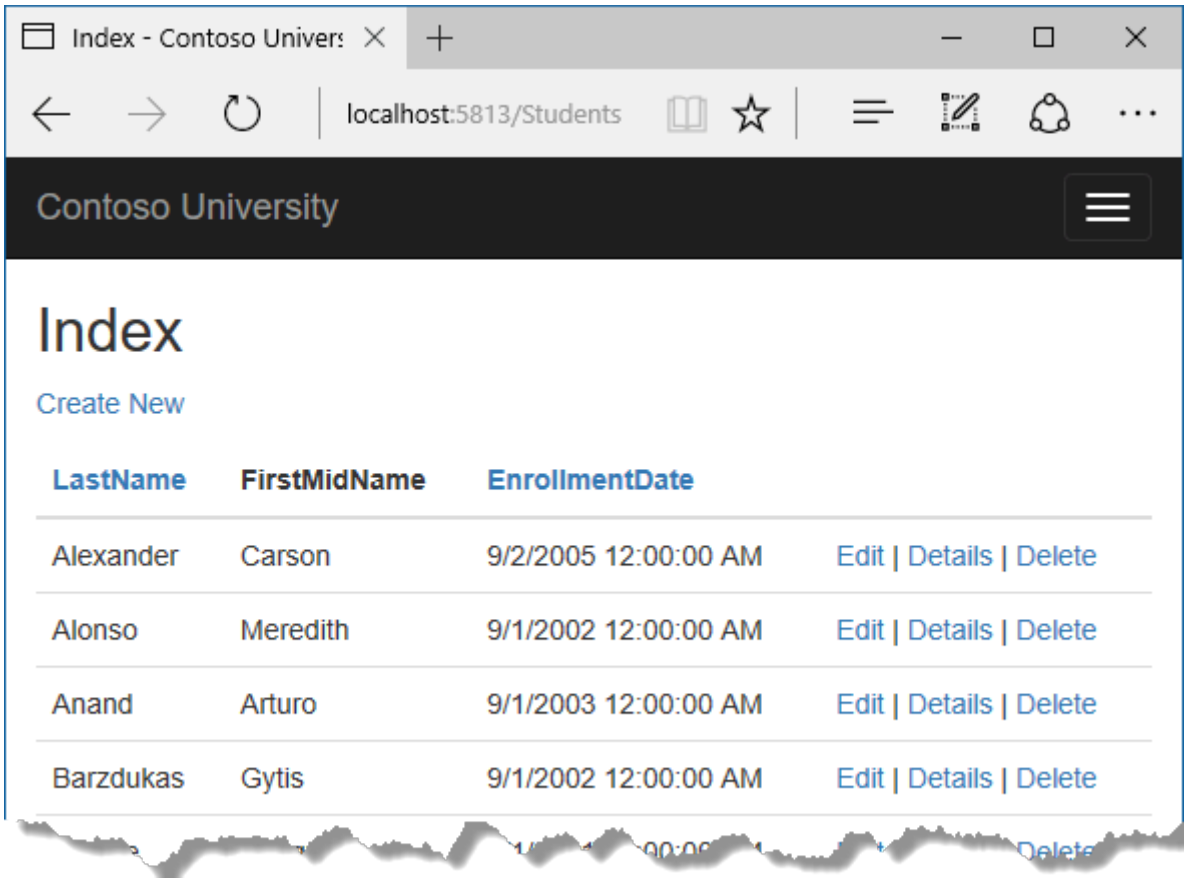
Add column heading hyperlinks to the Student Index view

Replace the code in `Views/Students/Index.cshtml`, with the following code to add column heading hyperlinks. The changed lines are highlighted.

CSHTML

```
@model IEnumerable<ContosoUniversity.Models.Student>

@{
    ViewData["Title"] = "Index";
}



<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
                <th>
                    <a asp-action="Index" asp-route-
sortOrder="@ViewData["NameSortParm"]">@Html.DisplayNameFor(model =>
model.LastName)</a>
                </th>
```

```
                <th>
                    @Html.DisplayNameFor(model => model.FirstMidName)
                </th>
                <th>
                    <a asp-action="Index" asp-route-
sortOrder="@ViewData["DateSortParm"]">@Html.DisplayNameFor(model =>
model.EnrollmentDate)</a>
                </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
@foreach (var item in Model) {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.LastName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.FirstMidName)
            </td>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                <a asp-action="Details" asp-route-id="@item.ID">Details</a>
|
                <a asp-action="Delete" asp-route-id="@item.ID">Delete</a>
            </td>
        </tr>
}
    </tbody>
</table>
```

This code uses the information in `ViewData` properties to set up hyperlinks with the appropriate query string values.

Run the app, select the **Students** tab, and click the **Last Name** and **Enrollment Date** column headings to verify that sorting works.

Add a Search box

To add filtering to the Students Index page, you'll add a text box and a submit button to the view and make corresponding changes in the `Index` method. The text box will let you enter a string to search for in the first name and last name fields.

Add filtering functionality to the Index method

In `StudentsController.cs`, replace the `Index` method with the following code (the changes are highlighted).

C#

```
public async Task<IActionResult> Index(string sortOrder, string
searchString)
{
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc"
: "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
    ViewData["CurrentFilter"] = searchString;

    var students = from s in _context.Students
                   select s;
```

```
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }
    return View(await students.AsNoTracking().ToListAsync());
}
```

You've added a `searchString` parameter to the `Index` method. The search string value is received from a text box that you'll add to the Index view. You've also added to the LINQ statement a where clause that selects only students whose first name or last name contains the search string. The statement that adds the where clause is executed only if there's a value to search for.

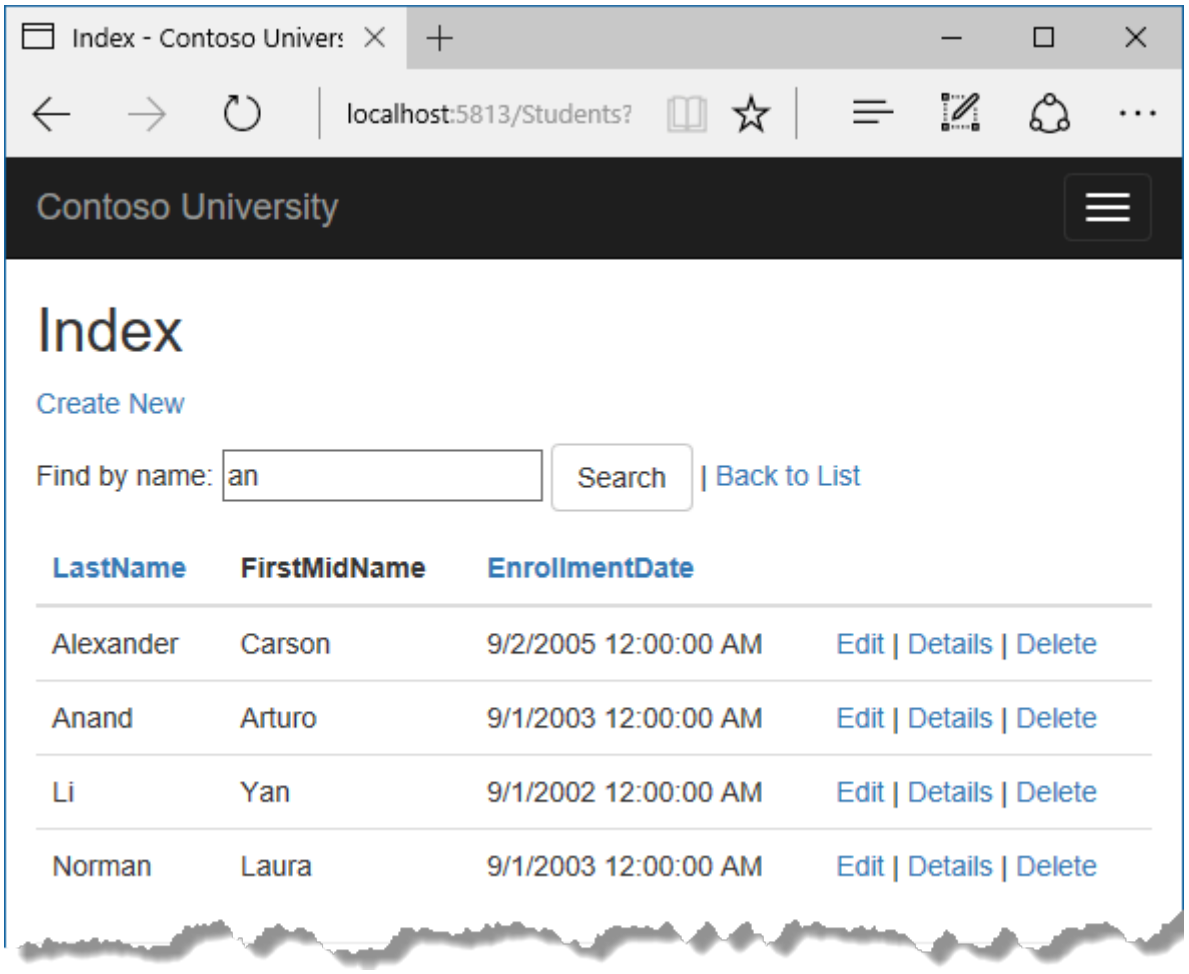
> ⓘ **Note**
>
> Here you are calling the `Where` method on an `IQueryable` object, and the filter will be processed on the server. In some scenarios you might be calling the `Where` method as an extension method on an in-memory collection. (For example, suppose you change the reference to `_context.Students` so that instead of an EF `DbSet` it references a repository method that returns an `IEnumerable` collection.) The result would normally be the same but in some cases may be different.
>
> For example, the .NET Framework implementation of the `Contains` method performs a case-sensitive comparison by default, but in SQL Server this is determined by the collation setting of the SQL Server instance. That setting defaults to case-insensitive. You could call the `ToUpper` method to make the test explicitly case-insensitive: *Where(s => s.LastName.ToUpper().Contains(searchString.ToUpper())*. That would ensure that results stay the same if you change the code later to use a repository which returns an `IEnumerable` collection instead of an `IQueryable` object. (When you call the `Contains` method on an `IEnumerable` collection, you get the

.NET Framework implementation; when you call it on an `IQueryable` object, you get the database provider implementation.) However, there's a performance penalty for this solution. The `ToUpper` code would put a function in the WHERE clause of the TSQL SELECT statement. That would prevent the optimizer from using an index. Given that SQL is mostly installed as case-insensitive, it's best to avoid the `ToUpper` code until you migrate to a case-sensitive data store.

Add a Search Box to the Student Index View

In `Views/Student/Index.cshtml`, add the highlighted code immediately before the opening table tag in order to create a caption, a text box, and a **Search** button.

CSHTML



```
<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-action="Index" method="get">
    <div class="form-actions no-color">
        <p>
            <label>Find by name: <input type="text" name="SearchString"
value="@ViewData["CurrentFilter"]" /></label>
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-action="Index">Back to Full List</a>
        </p>
    </div>
</form>

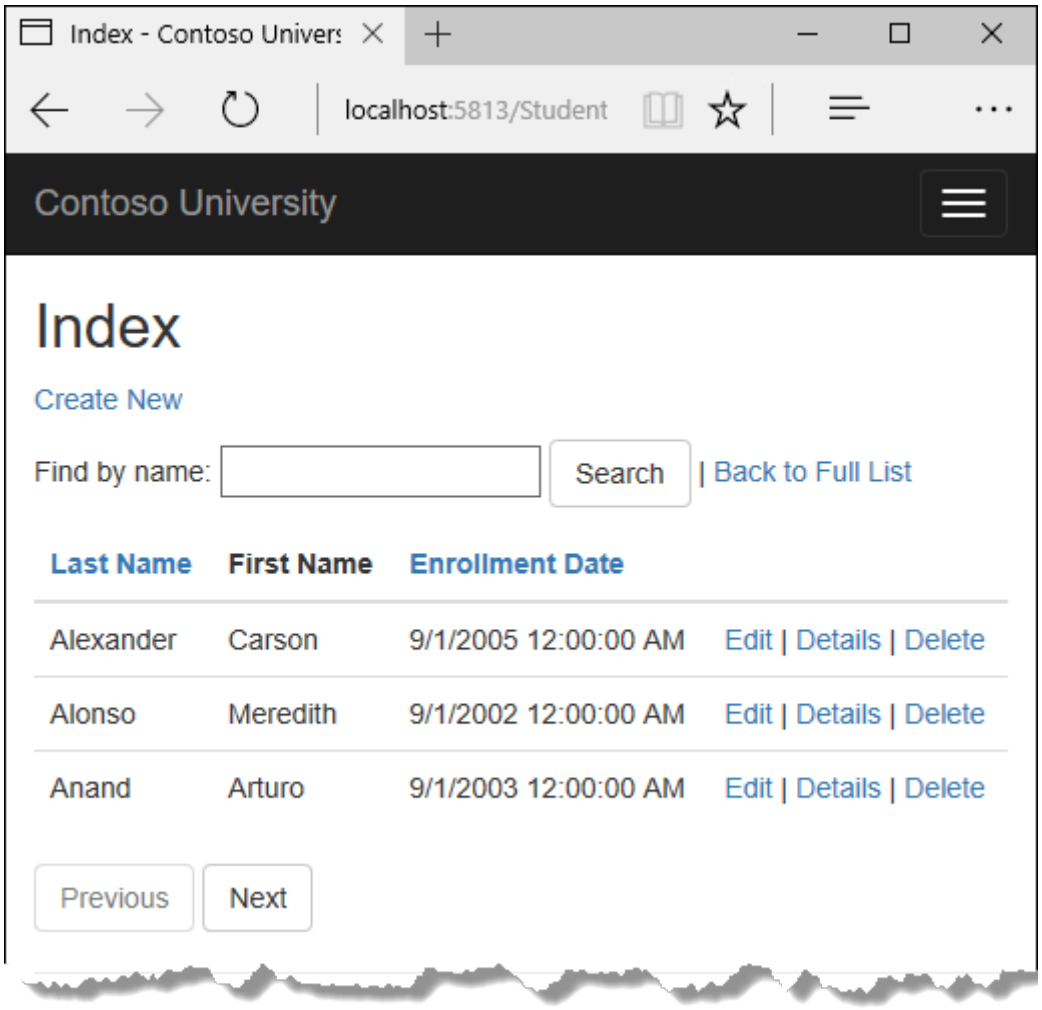
<table class="table">
```

This code uses the `<form>` tag helper to add the search text box and button. By default, the `<form>` tag helper submits form data with a POST, which means that parameters are passed in the HTTP message body and not in the URL as query strings. When you specify HTTP GET, the form data is passed in the URL as query strings, which enables users to bookmark the URL. The W3C guidelines recommend that you should use GET when the action doesn't result in an update.

Run the app, select the **Students** tab, enter a search string, and click Search to verify that filtering is working.

Notice that the URL contains the search string.

```
HTML
```



```
http://localhost:5813/Students?SearchString=an
```

If you bookmark this page, you'll get the filtered list when you use the bookmark. Adding `method="get"` to the `form` tag is what caused the query string to be generated.

At this stage, if you click a column heading sort link you'll lose the filter value that you entered in the **Search** box. You'll fix that in the next section.

Add paging to Students Index

To add paging to the Students Index page, you'll create a `PaginatedList` class that uses `Skip` and `Take` statements to filter data on the server instead of always retrieving all rows of the table. Then you'll make additional changes in the `Index` method and add paging buttons to the `Index` view. The following illustration shows the paging buttons.

In the project folder, create `PaginatedList.cs`, and then replace the template code with the following code.

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity
{
    public class PaginatedList<T> : List<T>
    {
        public int PageIndex { get; private set; }
        public int TotalPages { get; private set; }

        public PaginatedList(List<T> items, int count, int pageIndex, int
pageSize)
        {
            PageIndex = pageIndex;
            TotalPages = (int)Math.Ceiling(count / (double)pageSize);

            this.AddRange(items);
        }
```

```
        public bool HasPreviousPage => PageIndex > 1;

        public bool HasNextPage => PageIndex < TotalPages;

        public static async Task<PaginatedList<T>> CreateAsync(IQueryable<T>
source, int pageIndex, int pageSize)
        {
            var count = await source.CountAsync();
            var items = await source.Skip((pageIndex - 1) *
pageSize).Take(pageSize).ToListAsync();
            return new PaginatedList<T>(items, count, pageIndex, pageSize);
        }
    }
}
```

The `CreateAsync` method in this code takes page size and page number and applies the appropriate `Skip` and `Take` statements to the `IQueryable`. When `ToListAsync` is called on the `IQueryable`, it will return a List containing only the requested page. The properties `HasPreviousPage` and `HasNextPage` can be used to enable or disable **Previous** and **Next** paging buttons.

A `CreateAsync` method is used instead of a constructor to create the `PaginatedList<T>` object because constructors can't run asynchronous code.

Add paging to Index method

In `StudentsController.cs`, replace the `Index` method with the following code.

C#

```
public async Task<IActionResult> Index(
    string sortOrder,
    string currentFilter,
    string searchString,
    int? pageNumber)
{
    ViewData["CurrentSort"] = sortOrder;
    ViewData["NameSortParm"] = String.IsNullOrEmpty(sortOrder) ? "name_desc"
: "";
    ViewData["DateSortParm"] = sortOrder == "Date" ? "date_desc" : "Date";
```

```
    if (searchString != null)
    {
        pageNumber = 1;
    }
    else
    {
        searchString = currentFilter;
    }

    ViewData["CurrentFilter"] = searchString;

    var students = from s in _context.Students
                   select s;
    if (!String.IsNullOrEmpty(searchString))
    {
        students = students.Where(s => s.LastName.Contains(searchString)
                               || s.FirstMidName.Contains(searchString));
    }
    switch (sortOrder)
    {
        case "name_desc":
            students = students.OrderByDescending(s => s.LastName);
            break;
        case "Date":
            students = students.OrderBy(s => s.EnrollmentDate);
            break;
        case "date_desc":
            students = students.OrderByDescending(s => s.EnrollmentDate);
            break;
        default:
            students = students.OrderBy(s => s.LastName);
            break;
    }

    int pageSize = 3;
    return View(await
PaginatedList<Student>.CreateAsync(students.AsNoTracking(), pageNumber ?? 1,
pageSize));
}
```

This code adds a page number parameter, a current sort order parameter, and a current filter parameter to the method signature.

C#

```
public async Task<IActionResult> Index(
    string sortOrder,
    string currentFilter,
    string searchString,
    int? pageNumber)
```

The first time the page is displayed, or if the user hasn't clicked a paging or sorting link, all the parameters will be null. If a paging link is clicked, the page variable will contain the page number to display.

The `ViewData` element named CurrentSort provides the view with the current sort order, because this must be included in the paging links in order to keep the sort order the same while paging.

The `ViewData` element named CurrentFilter provides the view with the current filter string. This value must be included in the paging links in order to maintain the filter settings during paging, and it must be restored to the text box when the page is redisplayed.

If the search string is changed during paging, the page has to be reset to 1, because the new filter can result in different data to display. The search string is changed when a value is entered in the text box and the Submit button is pressed. In that case, the `searchString` parameter isn't null.

C#

```
if (searchString != null)
{
    pageNumber = 1;
}
else
{
    searchString = currentFilter;
}
```

At the end of the `Index` method, the `PaginatedList.CreateAsync` method converts the student query to a single page of students in a collection type that supports paging. That single page of students is then passed to the view.

C#

```
return View(await
PaginatedList<Student>.CreateAsync(students.AsNoTracking(), pageNumber ?? 1,
pageSize));
```

The `PaginatedList.CreateAsync` method takes a page number. The two question marks represent the null-coalescing operator. The null-coalescing operator defines a default value for a nullable type; the expression `(pageNumber ?? 1)` means return the value of `pageNumber` if it has a value, or return 1 if `pageNumber` is null.

Add paging links

In `Views/Students/Index.cshtml`, replace the existing code with the following code. The changes are highlighted.

CSHTML

```
@model PaginatedList<ContosoUniversity.Models.Student>

@{
    ViewData["Title"] = "Index";
}

<h2>Index</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>

<form asp-action="Index" method="get">
    <div class="form-actions no-color">
        <p>
            <label>Find by name: <input type="text" name="SearchString"
value="@ViewData["CurrentFilter"]" /></label>
            <input type="submit" value="Search" class="btn btn-default" /> |
            <a asp-action="Index">Back to Full List</a>
        </p>
    </div>
</form>

<table class="table">
    <thead>
        <tr>
            <th>
                <a asp-action="Index" asp-route-
sortOrder="@ViewData["NameSortParm"]" asp-route-
currentFilter="@ViewData["CurrentFilter"]">Last Name</a>
            </th>
            <th>
                First Name
            </th>
            <th>
                <a asp-action="Index" asp-route-
sortOrder="@ViewData["DateSortParm"]" asp-route-
currentFilter="@ViewData["CurrentFilter"]">Enrollment Date</a>
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
```

```
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.EnrollmentDate)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

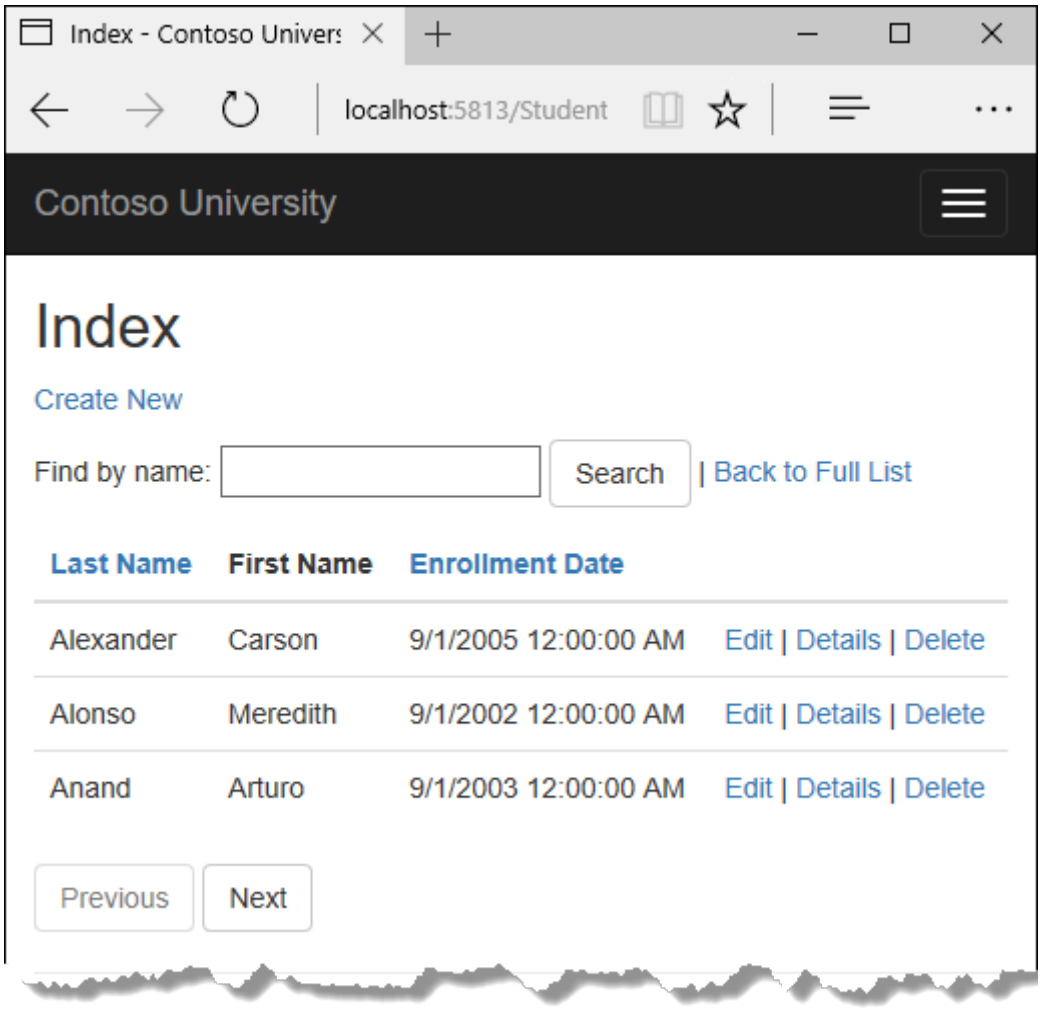
```
@{
    var prevDisabled = !Model.HasPreviousPage ? "disabled" : "";
    var nextDisabled = !Model.HasNextPage ? "disabled" : "";
}

<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex - 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @prevDisabled">
    Previous
</a>
<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex + 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @nextDisabled">
    Next
</a>
```

The `@model` statement at the top of the page specifies that the view now gets a `PaginatedList<T>` object instead of a `List<T>` object.

The column header links use the query string to pass the current search string to the controller so that the user can sort within filter results:

HTML



```
<a asp-action="Index" asp-route-sortOrder="@ViewData["DateSortParm"]" asp-
route-currentFilter ="@ViewData["CurrentFilter"]">Enrollment Date</a>
```

The paging buttons are displayed by tag helpers:

HTML

```
<a asp-action="Index"
   asp-route-sortOrder="@ViewData["CurrentSort"]"
   asp-route-pageNumber="@(Model.PageIndex - 1)"
   asp-route-currentFilter="@ViewData["CurrentFilter"]"
   class="btn btn-default @prevDisabled">
   Previous
</a>
```

Run the app and go to the Students page.

Click the paging links in different sort orders to make sure paging works. Then enter a search string and try paging again to verify that paging also works correctly with sorting and filtering.

Create an About page

For the Contoso University website's **About** page, you'll display how many students have enrolled for each enrollment date. This requires grouping and simple calculations

on the groups. To accomplish this, you'll do the following:

- Create a view model class for the data that you need to pass to the view.
- Create the About method in the Home controller.
- Create the About view.

Create the view model

Create a *SchoolViewModels* folder in the *Models* folder.

In the new folder, add a class file `EnrollmentDateGroup.cs` and replace the template code with the following code:

C#

```
using System;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class EnrollmentDateGroup
    {
        [DataType(DataType.Date)]
        public DateTime? EnrollmentDate { get; set; }

        public int StudentCount { get; set; }
    }
}
```

Modify the Home Controller

In `HomeController.cs`, add the following using statements at the top of the file:

C#

```
using Microsoft.EntityFrameworkCore;
using ContosoUniversity.Data;
using ContosoUniversity.Models.SchoolViewModels;
using Microsoft.Extensions.Logging;
```

Add a class variable for the database context immediately after the opening curly brace for the class, and get an instance of the context from ASP.NET Core DI:

C#

```
public class HomeController : Controller
{
    private readonly ILogger<HomeController> _logger;
    private readonly SchoolContext _context;

    public HomeController(ILogger<HomeController> logger, SchoolContext
context)
    {
        _logger = logger;
        _context = context;
    }
```

Add an `About` method with the following code:

C#

```
public async Task<ActionResult> About()
{
    IQueryable<EnrollmentDateGroup> data =
        from student in _context.Students
        group student by student.EnrollmentDate into dateGroup
        select new EnrollmentDateGroup()
        {
            EnrollmentDate = dateGroup.Key,
            StudentCount = dateGroup.Count()
        };
    return View(await data.AsNoTracking().ToListAsync());
}
```

The LINQ statement groups the student entities by enrollment date, calculates the number of entities in each group, and stores the results in a collection of `EnrollmentDateGroup` view model objects.

Create the About View

Add a `Views/Home/About.cshtml` file with the following code:

CSHTML

```
@model
IEnumerable<ContosoUniversity.Models.SchoolViewModels.EnrollmentDateGroup>

@{
    ViewData["Title"] = "Student Body Statistics";
}

<h2>Student Body Statistics</h2>
```

```
<table>
    <tr>
        <th>
            Enrollment Date
        </th>
        <th>
            Students
        </th>
    </tr>

    @foreach (var item in Model)
    {
        <tr>
            <td>
                @Html.DisplayFor(modelItem => item.EnrollmentDate)
            </td>
            <td>
                @item.StudentCount
            </td>
        </tr>
    }
</table>
```

Run the app and go to the About page. The count of students for each enrollment date is displayed in a table.

Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- ✓ Added column sort links
- ✓ Added a Search box
- ✓ Added paging to Students Index
- ✓ Added paging to Index method
- ✓ Added paging links
- ✓ Created an About page

Advance to the next tutorial to learn how to handle data model changes by using migrations.

Next: Handle data model changes

Tutorial: Part 5, apply migrations to the Contoso University sample

Article • 05/31/2024

In this tutorial, you start using the EF Core migrations feature for managing data model changes. In later tutorials, you'll add more migrations as you change the data model.

In this tutorial, you:

- ✓ Learn about migrations
- ✓ Create an initial migration
- ✓ Examine Up and Down methods
- ✓ Learn about the data model snapshot
- ✓ Apply the migration

Prerequisites

- Sorting, filtering, and paging

About migrations

When you develop a new application, your data model changes frequently, and each time the model changes, it gets out of sync with the database. You started these tutorials by configuring the Entity Framework to create the database if it doesn't exist. Then each time you change the data model -- add, remove, or change entity classes or change your DbContext class -- you can delete the database and EF creates a new one that matches the model, and seeds it with test data.

This method of keeping the database in sync with the data model works well until you deploy the application to production. When the application is running in production it's usually storing data that you want to keep, and you don't want to lose everything each time you make a change such as adding a new column. The EF Core Migrations feature solves this problem by enabling EF to update the database schema instead of creating a new database.

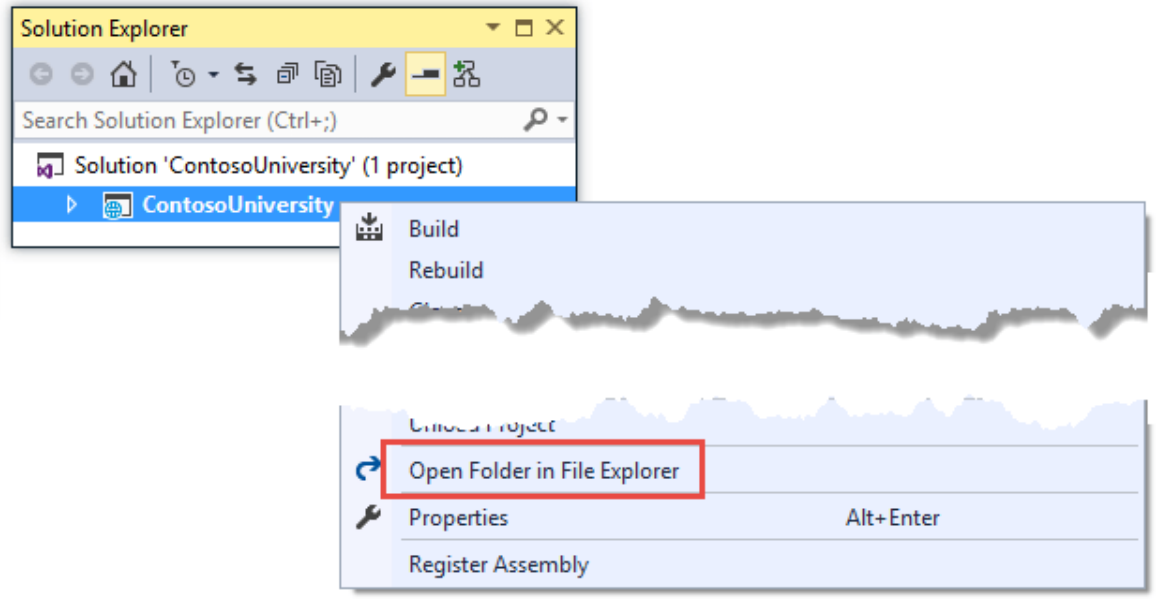
To work with migrations, you can use the **Package Manager Console** (PMC) or the CLI. These tutorials show how to use CLI commands. Information about the PMC is at the end of this tutorial.

Drop the database

Install EF Core tools as a global tool and delete the database:

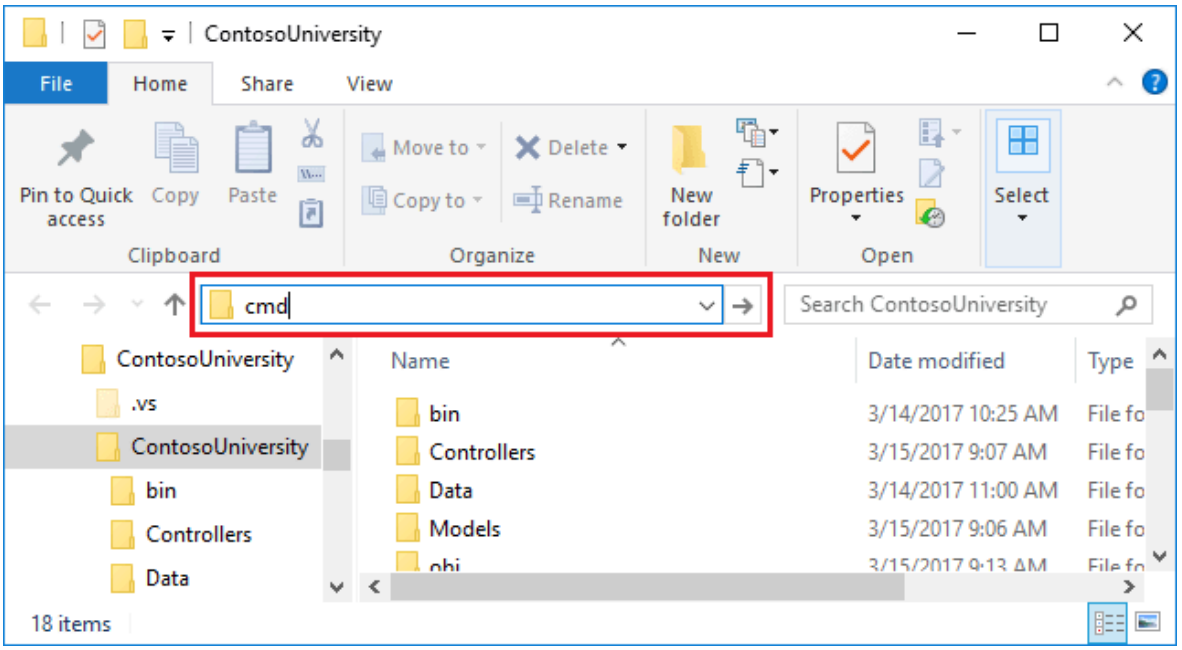
.NET CLI

```
dotnet tool install --global dotnet-ef
dotnet ef database drop
```



> **Note**
>
> By default the architecture of the .NET binaries to install represents the currently running OS architecture. To specify a different OS architecture, see dotnet tool install, --arch option. For more information, see GitHub issue dotnet/AspNetCore.Docs #29262.

The following section explains how to run CLI commands.



Create an initial migration

Save your changes and build the project. Then open a command window and navigate to the project folder. Here's a quick way to do that:

- In **Solution Explorer**, right-click the project and choose **Open Folder in File Explorer** from the context menu.

- Enter "cmd" in the address bar and press Enter.

Enter the following command in the command window:

.NET CLI

```
dotnet ef migrations add InitialCreate
```

In the preceding commands, output similar to the following is displayed:

Console

```
info: Microsoft.EntityFrameworkCore.Infrastructure[10403]
      Entity Framework Core initialized 'SchoolContext' using provider
'Microsoft.EntityFrameworkCore.SqlServer' with options: None
Done. To undo this action, use 'ef migrations remove'
```

If you see an error message "*cannot access the file ... ContosoUniversity.dll because it is being used by another process.*", find the IIS Express icon in the Windows System Tray, and right-click it, then click **ContosoUniversity** > **Stop Site**.

Examine Up and Down methods

When you executed the `migrations add` command, EF generated the code that will create the database from scratch. This code is in the *Migrations* folder, in the file named `<timestamp>_InitialCreate.cs`. The `Up` method of the `InitialCreate` class creates the database tables that correspond to the data model entity sets, and the `Down` method deletes them, as shown in the following example.

C#

```
public partial class InitialCreate : Migration
{
    protected override void Up(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.CreateTable(
            name: "Course",
            columns: table => new
            {
                CourseID = table.Column<int>(nullable: false),
                Credits = table.Column<int>(nullable: false),
                Title = table.Column<string>(nullable: true)
            },
            constraints: table =>
            {
                table.PrimaryKey("PK_Course", x => x.CourseID);
            });

        // Additional code not shown
    }

    protected override void Down(MigrationBuilder migrationBuilder)
    {
        migrationBuilder.DropTable(
            name: "Enrollment");
        // Additional code not shown
    }
}
```

Migrations calls the `Up` method to implement the data model changes for a migration. When you enter a command to roll back the update, Migrations calls the `Down` method.

This code is for the initial migration that was created when you entered the `migrations add InitialCreate` command. The migration name parameter ("InitialCreate" in the example) is used for the file name and can be whatever you want. It's best to choose a word or phrase that summarizes what is being done in the migration. For example, you might name a later migration "AddDepartmentTable".

If you created the initial migration when the database already exists, the database creation code is generated but it doesn't have to run because the database already matches the data model. When you deploy the app to another environment where the database doesn't exist yet, this code will run to create your database, so it's a good idea to test it first. That's why you dropped the database earlier -- so that migrations can create a new one from scratch.

The data model snapshot

Migrations creates a *snapshot* of the current database schema in `Migrations/SchoolContextModelSnapshot.cs`. When you add a migration, EF determines what changed by comparing the data model to the snapshot file.

Use the dotnet ef migrations remove command to remove a migration. `dotnet ef migrations remove` deletes the migration and ensures the snapshot is correctly reset. If `dotnet ef migrations remove` fails, use `dotnet ef migrations remove -v` to get more information on the failure.

See EF Core Migrations in Team Environments for more information about how the snapshot file is used.

Apply the migration

In the command window, enter the following command to create the database and tables in it.

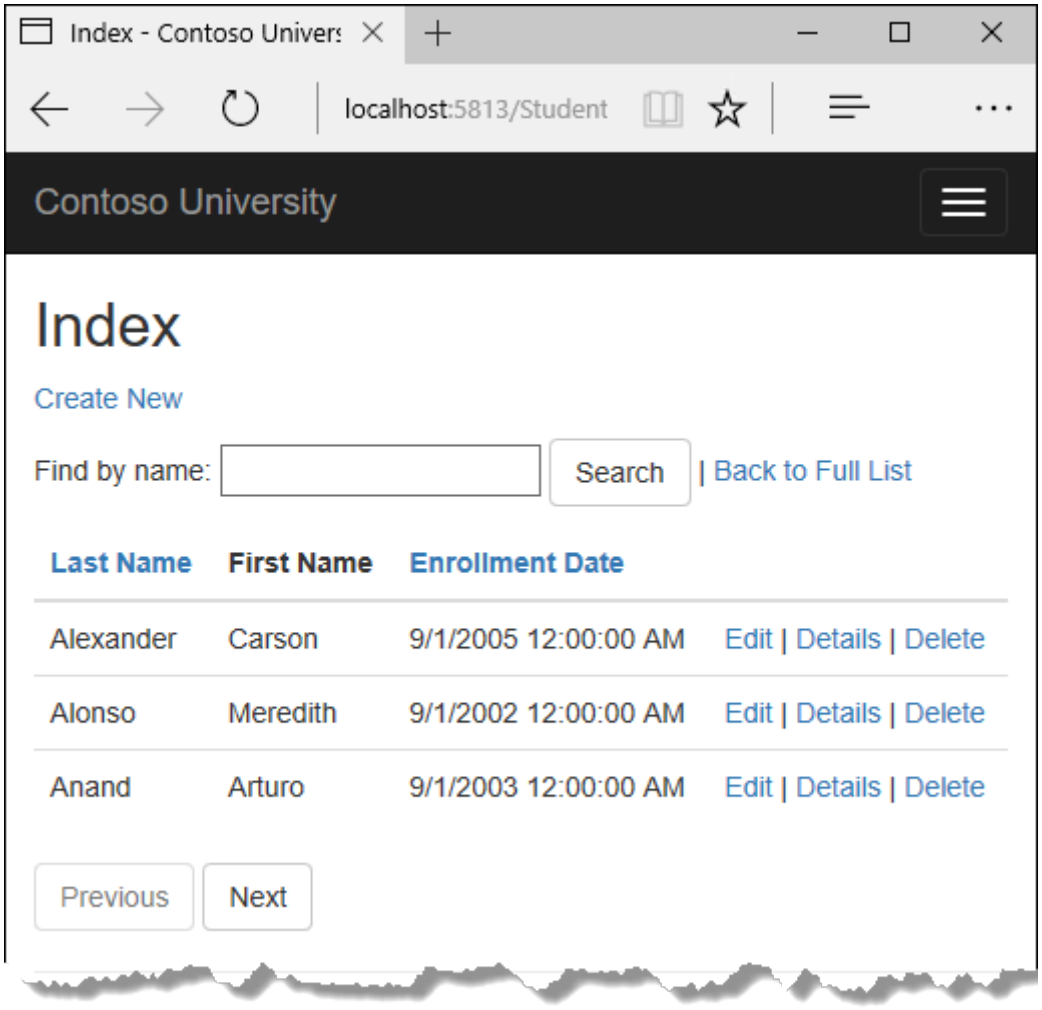
.NET CLI

```
dotnet ef database update
```

The output from the command is similar to the `migrations add` command, except that you see logs for the SQL commands that set up the database. Most of the logs are omitted in the following sample output. If you prefer not to see this level of detail in log messages, you can change the log level in the `appsettings.Development.json` file. For more information, see Logging in .NET Core and ASP.NET Core.

text

```
info: Microsoft.EntityFrameworkCore.Infrastructure[10403]
      Entity Framework Core initialized 'SchoolContext' using provider
'Microsoft.EntityFrameworkCore.SqlServer' with options: None
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (274ms) [Parameters=[], CommandType='Text',
CommandTimeout='60']
      CREATE DATABASE [ContosoUniversity2];
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (60ms) [Parameters=[], CommandType='Text',
CommandTimeout='60']
      IF SERVERPROPERTY('EngineEdition') <> 5
      BEGIN
          ALTER DATABASE [ContosoUniversity2] SET READ_COMMITTED_SNAPSHOT
ON;
      END;
info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (15ms) [Parameters=[], CommandType='Text',
```



```
CommandTimeout='30']
      CREATE TABLE [__EFMigrationsHistory] (
          [MigrationId] nvarchar(150) NOT NULL,
          [ProductVersion] nvarchar(32) NOT NULL,
          CONSTRAINT [PK___EFMigrationsHistory] PRIMARY KEY ([MigrationId])
      );

<logs omitted for brevity>

info: Microsoft.EntityFrameworkCore.Database.Command[20101]
      Executed DbCommand (3ms) [Parameters=[], CommandType='Text',
CommandTimeout='30']
      INSERT INTO [__EFMigrationsHistory] ([MigrationId], [ProductVersion])
      VALUES (N'20190327172701_InitialCreate', N'5.0-rtm');
Done.
```

Use **SQL Server Object Explorer** to inspect the database as you did in the first tutorial. You'll notice the addition of an __EFMigrationsHistory table that keeps track of which migrations have been applied to the database. View the data in that table and you'll see one row for the first migration. (The last log in the preceding CLI output example shows the INSERT statement that creates this row.)

Run the application to verify that everything still works the same as before.

Compare CLI and PMC

The EF tooling for managing migrations is available from .NET CLI commands or from PowerShell cmdlets in the Visual Studio **Package Manager Console** (PMC) window. This tutorial shows how to use the CLI, but you can use the PMC if you prefer.

The EF commands for the PMC commands are in the Microsoft.EntityFrameworkCore.Tools package. This package is included in the Microsoft.AspNetCore.App metapackage, so you don't need to add a package reference if your app has a package reference for `Microsoft.AspNetCore.App`.

Important: This isn't the same package as the one you install for the CLI by editing the `.csproj` file. The name of this one ends in `Tools`, unlike the CLI package name which ends in `Tools.DotNet`.

For more information about the CLI commands, see .NET CLI.

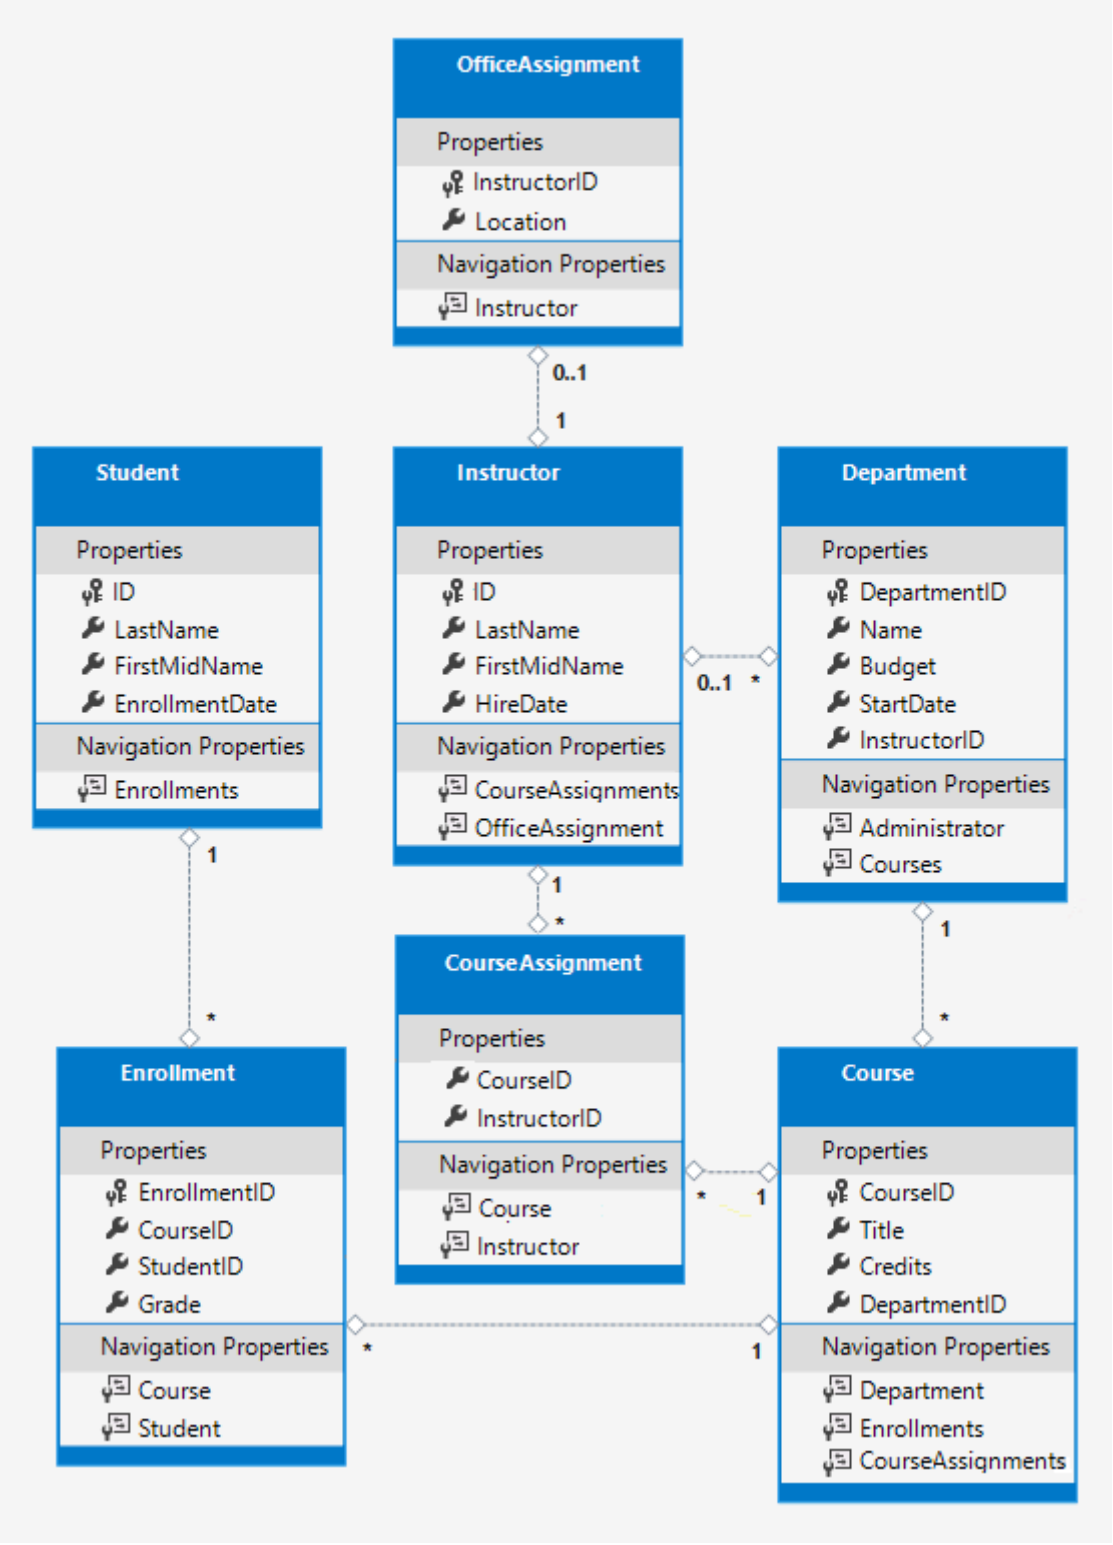
For more information about the PMC commands, see Package Manager Console (Visual Studio).

Get the code

Download or view the completed application.

Next step

Advance to the next tutorial to begin looking at more advanced topics about expanding the data model. Along the way you'll create and apply additional migrations.



Create and apply additional migrations

Tutorial: Create a complex data model - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorials, you worked with a simple data model that was composed of three entities. In this tutorial, you'll add more entities and relationships and you'll customize the data model by specifying formatting, validation, and database mapping rules.

When you're finished, the entity classes will make up the completed data model that's shown in the following illustration:

In this tutorial, you:

- ✓ Customize the Data model
- ✓ Make changes to Student entity
- ✓ Create Instructor entity
- ✓ Create OfficeAssignment entity
- ✓ Modify Course entity
- ✓ Create Department entity
- ✓ Modify Enrollment entity
- ✓ Update the database context

- ✓ Seed database with test data
- ✓ Add a migration
- ✓ Change the connection string
- ✓ Update the database

Prerequisites

- Using EF Core migrations

Customize the Data model

In this section you'll see how to customize the data model by using attributes that specify formatting, validation, and database mapping rules. Then in several of the following sections you'll create the complete School data model by adding attributes to the classes you already created and creating new classes for the remaining entity types in the model.

The DataType attribute

For student enrollment dates, all of the web pages currently display the time along with the date, although all you care about for this field is the date. By using data annotation attributes, you can make one code change that will fix the display format in every view that shows the data. To see an example of how to do that, you'll add an attribute to the `EnrollmentDate` property in the `Student` class.

In `Models/Student.cs`, add a `using` statement for the `System.ComponentModel.DataAnnotations` namespace and add `DataType` and `DisplayFormat` attributes to the `EnrollmentDate` property, as shown in the following example:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        public string LastName { get; set; }
        public string FirstMidName { get; set; }
```

```
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `DataType` attribute is used to specify a data type that's more specific than the database intrinsic type. In this case we only want to keep track of the date, not the date and time. The `DataType` Enumeration provides for many data types, such as Date, Time, PhoneNumber, Currency, EmailAddress, and more. The `DataType` attribute can also enable the application to automatically provide type-specific features. For example, a `mailto:` link can be created for `DataType.EmailAddress`, and a date selector can be provided for `DataType.Date` in browsers that support HTML5. The `DataType` attribute emits HTML 5 `data-` (pronounced data dash) attributes that HTML 5 browsers can understand. The `DataType` attributes don't provide any validation.

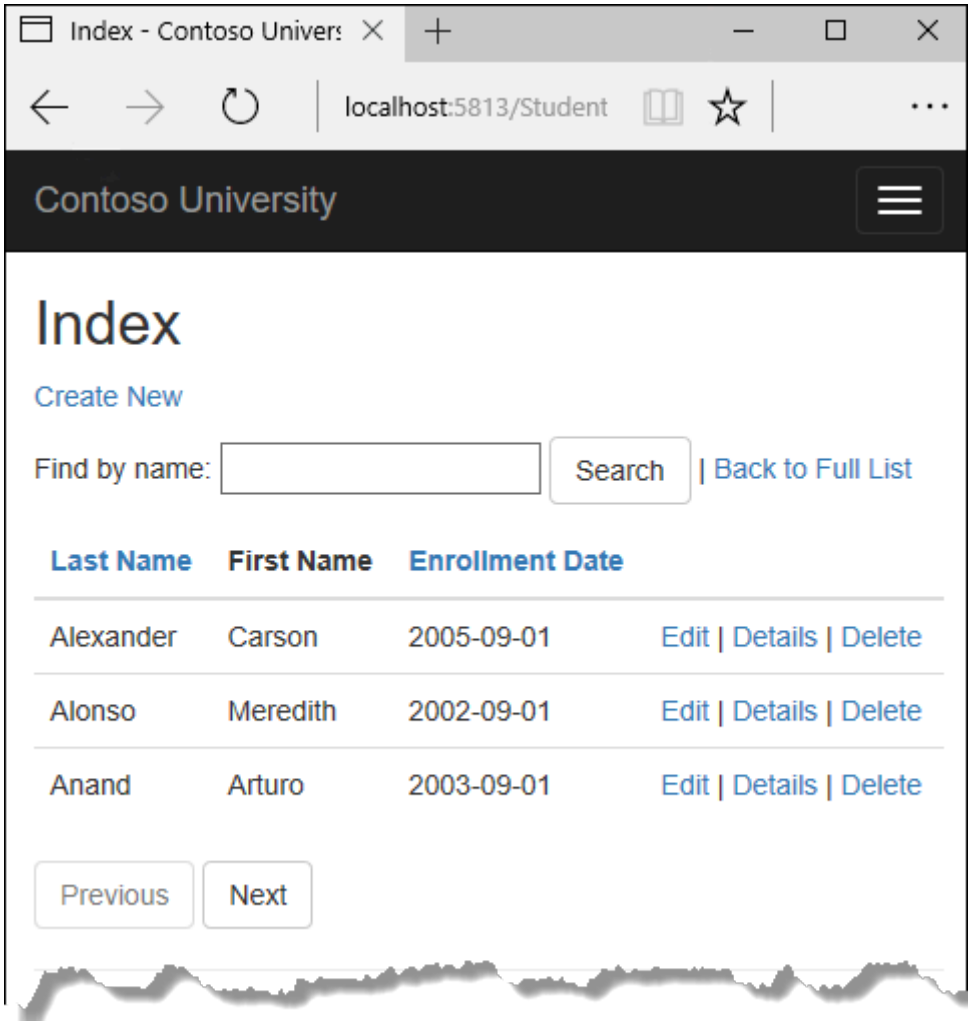
`DataType.Date` doesn't specify the format of the date that's displayed. By default, the data field is displayed according to the default formats based on the server's CultureInfo.

The `DisplayFormat` attribute is used to explicitly specify the date format:

C#

```
[DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}", ApplyFormatInEditMode =
true)]
```

The `ApplyFormatInEditMode` setting specifies that the formatting should also be applied when the value is displayed in a text box for editing. (You might not want that for some fields -- for example, for currency values, you might not want the currency symbol in the text box for editing.)



You can use the `DisplayFormat` attribute by itself, but it's generally a good idea to use the `DataType` attribute also. The `DataType` attribute conveys the semantics of the data as opposed to how to render it on a screen, and provides the following benefits that you don't get with `DisplayFormat`:

- The browser can enable HTML5 features (for example to show a calendar control, the locale-appropriate currency symbol, email links, some client-side input validation, etc.).

- By default, the browser will render data using the correct format based on your locale.

For more information, see the <input> tag helper documentation.

Run the app, go to the Students Index page and notice that times are no longer displayed for the enrollment dates. The same will be true for any view that uses the Student model.

The StringLength attribute

You can also specify data validation rules and validation error messages using attributes. The `StringLength` attribute sets the maximum length in the database and provides client side and server side validation for ASP.NET Core MVC. You can also specify the minimum string length in this attribute, but the minimum value has no impact on the database schema.

Suppose you want to ensure that users don't enter more than 50 characters for a name. To add this limitation, add `StringLength` attributes to the `LastName` and `FirstMidName` properties, as shown in the following example:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50)]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The `StringLength` attribute won't prevent a user from entering white space for a name. You can use the `RegularExpression` attribute to apply restrictions to the input. For example, the following code requires the first character to be upper case and the remaining characters to be alphabetical:

C#

```
[RegularExpression(@"^[A-Z]+[a-zA-Z]*$")]
```

The `MaxLength` attribute provides functionality similar to the `StringLength` attribute but doesn't provide client side validation.

The database model has now changed in a way that requires a change in the database schema. You'll use migrations to update the schema without losing any data that you may have added to the database by using the application UI.

Save your changes and build the project. Then open the command window in the project folder and enter the following commands:

.NET CLI

```
dotnet ef migrations add MaxLengthOnNames
```

.NET CLI

```
dotnet ef database update
```

The `migrations add` command warns that data loss may occur, because the change makes the maximum length shorter for two columns. Migrations creates a file named `<timeStamp>_MaxLengthOnNames.cs`. This file contains code in the `Up` method that will update the database to match the current data model. The `database update` command ran that code.

The timestamp prefixed to the migrations file name is used by Entity Framework to order the migrations. You can create multiple migrations before running the update-database command, and then all of the migrations are applied in the order in which they were created.

Run the app, select the **Students** tab, click **Create New**, and try to enter either name longer than 50 characters. The application should prevent you from doing this.

The Column attribute

You can also use attributes to control how your classes and properties are mapped to the database. Suppose you had used the name `FirstMidName` for the first-name field because the field might also contain a middle name. But you want the database column to be named `FirstName`, because users who will be writing ad-hoc queries against the database are accustomed to that name. To make this mapping, you can use the `Column` attribute.

The `Column` attribute specifies that when the database is created, the column of the `Student` table that maps to the `FirstMidName` property will be named `FirstName`. In other words, when your code refers to `Student.FirstMidName`, the data will come from or be updated in the `FirstName` column of the `Student` table. If you don't specify column names, they're given the same name as the property name.

In the `Student.cs` file, add a `using` statement for `System.ComponentModel.DataAnnotations.Schema` and add the column name attribute to the `FirstMidName` property, as shown in the following highlighted code:

C#

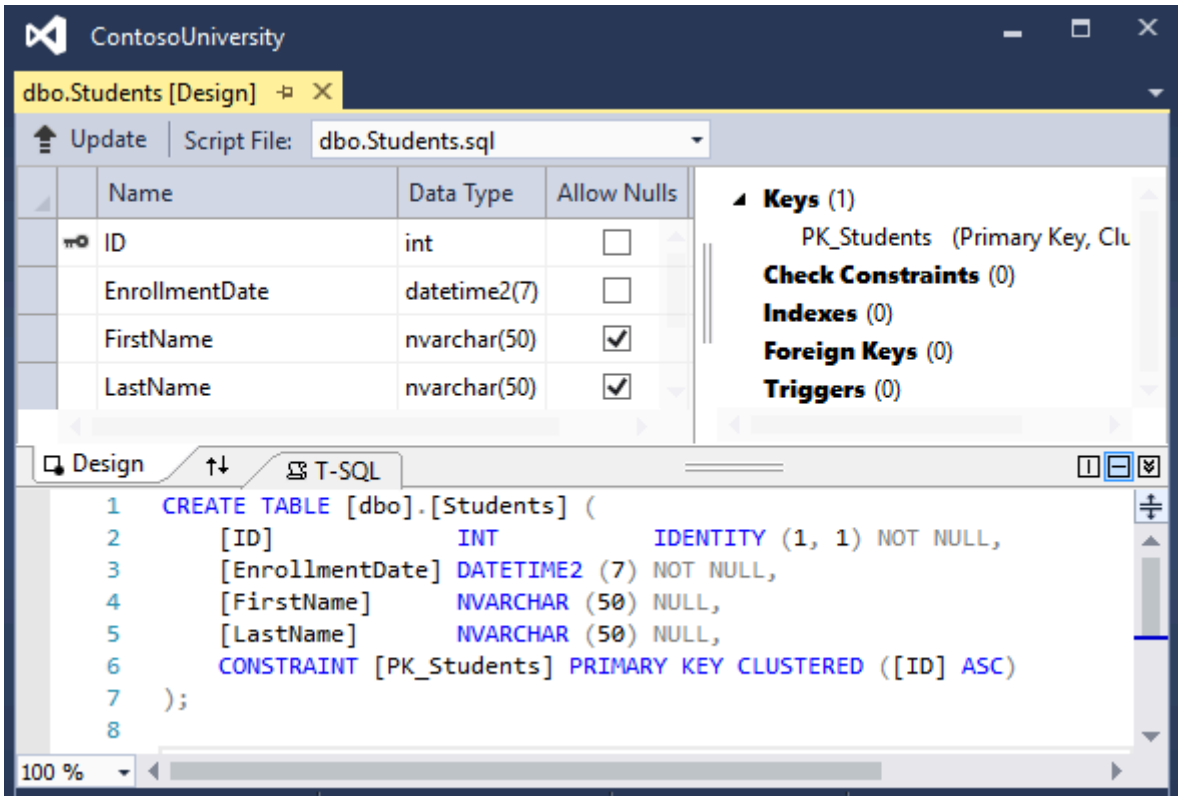
```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;
```

```
namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [StringLength(50)]
        public string LastName { get; set; }
        [StringLength(50)]
        [Column("FirstName")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The addition of the `Column` attribute changes the model backing the `SchoolContext`, so it won't match the database.

Save your changes and build the project. Then open the command window in the project folder and enter the following commands to create another migration:

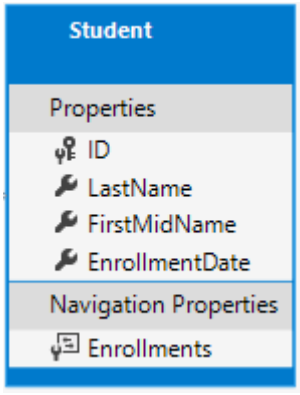


.NET CLI

```
dotnet ef migrations add ColumnFirstName
```

.NET CLI

```
dotnet ef database update
```



In **SQL Server Object Explorer**, open the Student table designer by double-clicking the **Student** table.

Before you applied the first two migrations, the name columns were of type nvarchar(MAX). They're now nvarchar(50) and the column name has changed from FirstMidName to FirstName.

> ⓘ Note
>
> If you try to compile before you finish creating all of the entity classes in the following sections, you might get compiler errors.

Changes to Student entity

In `Models/Student.cs`, replace the code you added earlier with the following code. The changes are highlighted.

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Student
    {
        public int ID { get; set; }
        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50)]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

The Required attribute

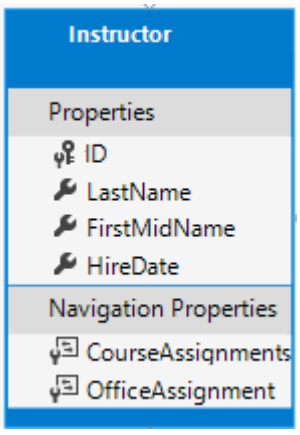
The `Required` attribute makes the name properties required fields. The `Required` attribute isn't needed for non-nullable types such as value types (DateTime, int, double, float, etc.). Types that can't be null are automatically treated as required fields.

The `Required` attribute must be used with `MinimumLength` for the `MinimumLength` to be enforced.

C#

```
[Display(Name = "Last Name")]
[Required]
```

```
[StringLength(50, MinimumLength=2)]
public string LastName { get; set; }
```



The Display attribute

The `Display` attribute specifies that the caption for the text boxes should be "First Name", "Last Name", "Full Name", and "Enrollment Date" instead of the property name in each instance (which has no space dividing the words).

The FullName calculated property

`FullName` is a calculated property that returns a value that's created by concatenating two other properties. Therefore it has only a get accessor, and no `FullName` column will be generated in the database.

Create Instructor entity

Create `Models/Instructor.cs`, replacing the template code with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor
    {
        public int ID { get; set; }

        [Required]
        [Display(Name = "Last Name")]
```

```
        [StringLength(50)]
        public string LastName { get; set; }

        [Required]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        [StringLength(50)]
        public string FirstMidName { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        [Display(Name = "Full Name")]
        public string FullName
        {
            get { return LastName + ", " + FirstMidName; }
        }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Notice that several properties are the same in the Student and Instructor entities. In the Implementing Inheritance tutorial later in this series, you'll refactor this code to eliminate the redundancy.

You can put multiple attributes on one line, so you could also write the `HireDate` attributes as follows:

C#

```
[DataType(DataType.Date),Display(Name = "Hire
Date"),DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
```

The CourseAssignments and OfficeAssignment navigation properties

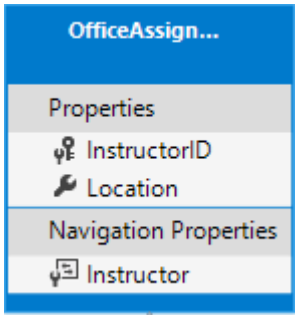
The `CourseAssignments` and `OfficeAssignment` properties are navigation properties.

An instructor can teach any number of courses, so `CourseAssignments` is defined as a collection.

C#

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

If a navigation property can hold multiple entities, its type must be a list in which entries can be added, deleted, and updated. You can specify `ICollection<T>` or a type such as `List<T>` or `HashSet<T>`. If you specify `ICollection<T>`, EF creates a `HashSet<T>` collection by default.



The reason why these are `CourseAssignment` entities is explained below in the section about many-to-many relationships.

Contoso University business rules state that an instructor can only have at most one office, so the `OfficeAssignment` property holds a single OfficeAssignment entity (which may be null if no office is assigned).

C#

```
public OfficeAssignment OfficeAssignment { get; set; }
```

Create OfficeAssignment entity

Create `Models/OfficeAssignment.cs` with the following code:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class OfficeAssignment
    {
        [Key]
        public int InstructorID { get; set; }
        [StringLength(50)]
        [Display(Name = "Office Location")]
        public string Location { get; set; }
```

```
        public Instructor Instructor { get; set; }
    }
}
```

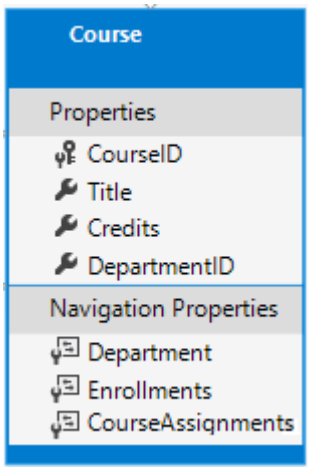
The Key attribute

There's a one-to-zero-or-one relationship between the `Instructor` and the `OfficeAssignment` entities. An office assignment only exists in relation to the instructor it's assigned to, and therefore its primary key is also its foreign key to the `Instructor` entity. But the Entity Framework can't automatically recognize `InstructorID` as the primary key of this entity because its name doesn't follow the `ID` or `classnameID` naming convention. Therefore, the `Key` attribute is used to identify it as the key:

C#

```
[Key]
public int InstructorID { get; set; }
```

You can also use the `Key` attribute if the entity does have its own primary key but you want to name the property something other than classnameID or ID.



By default, EF treats the key as non-database-generated because the column is for an identifying relationship.

The Instructor navigation property

The Instructor entity has a nullable `OfficeAssignment` navigation property (because an instructor might not have an office assignment), and the OfficeAssignment entity has a non-nullable `Instructor` navigation property (because an office assignment can't exist without an instructor -- `InstructorID` is non-nullable). When an Instructor entity has a related OfficeAssignment entity, each entity will have a reference to the other one in its navigation property.

You could put a `[Required]` attribute on the Instructor navigation property to specify that there must be a related instructor, but you don't have to do that because the `InstructorID` foreign key (which is also the key to this table) is non-nullable.

Modify Course entity

In `Models/Course.cs`, replace the code you added earlier with the following code. The changes are highlighted.

C#

```
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Course
    {
        [DatabaseGenerated(DatabaseGeneratedOption.None)]
        [Display(Name = "Number")]
        public int CourseID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Title { get; set; }

        [Range(0, 5)]
        public int Credits { get; set; }

        public int DepartmentID { get; set; }

        public Department Department { get; set; }
        public ICollection<Enrollment> Enrollments { get; set; }
        public ICollection<CourseAssignment> CourseAssignments { get; set; }
    }
}
```

The course entity has a foreign key property `DepartmentID` which points to the related Department entity and it has a `Department` navigation property.

The Entity Framework doesn't require you to add a foreign key property to your data model when you have a navigation property for a related entity. EF automatically creates foreign keys in the database wherever they're needed and creates shadow properties for

them. But having the foreign key in the data model can make updates simpler and more efficient. For example, when you fetch a `Course` entity to edit, the `Department` entity is null if you don't load it, so when you update the `Course` entity, you would have to first fetch the `Department` entity. When the foreign key property `DepartmentID` is included in the data model, you don't need to fetch the `Department` entity before you update.

The DatabaseGenerated attribute

The `DatabaseGenerated` attribute with the `None` parameter on the `CourseID` property specifies that primary key values are provided by the user rather than generated by the database.

C#

```
[DatabaseGenerated(DatabaseGeneratedOption.None)]
[Display(Name = "Number")]
public int CourseID { get; set; }
```

By default, Entity Framework assumes that primary key values are generated by the database. That's what you want in most scenarios. However, for `Course` entities, you'll use a user-specified course number such as a 1000 series for one department, a 2000 series for another department, and so on.

The `DatabaseGenerated` attribute can also be used to generate default values, as in the case of database columns used to record the date a row was created or updated. For more information, see Generated Properties.

Foreign key and navigation properties

The foreign key properties and navigation properties in the `Course` entity reflect the following relationships:

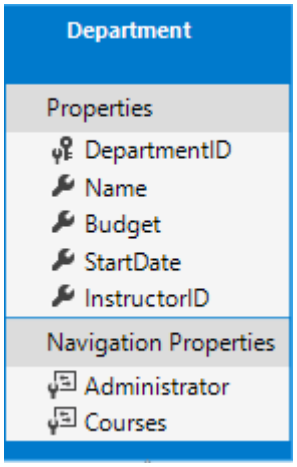
A course is assigned to one department, so there's a `DepartmentID` foreign key and a `Department` navigation property for the reasons mentioned above.

C#

```
public int DepartmentID { get; set; }
public Department Department { get; set; }
```

A course can have any number of students enrolled in it, so the `Enrollments` navigation property is a collection:

C#



```
public ICollection<Enrollment> Enrollments { get; set; }
```

A course may be taught by multiple instructors, so the `CourseAssignments` navigation property is a collection (the type `CourseAssignment` is explained later):

C#

```
public ICollection<CourseAssignment> CourseAssignments { get; set; }
```

Create Department entity

Create `Models/Department.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
```

```
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The Column attribute

Earlier you used the `Column` attribute to change column name mapping. In the code for the `Department` entity, the `Column` attribute is being used to change SQL data type mapping so that the column will be defined using the SQL Server `money` type in the database:

C#

```
[Column(TypeName="money")]
public decimal Budget { get; set; }
```

Column mapping is generally not required, because the Entity Framework chooses the appropriate SQL Server data type based on the CLR type that you define for the property. The CLR `decimal` type maps to a SQL Server `decimal` type. But in this case you know that the column will be holding currency amounts, and the money data type is more appropriate for that.

Foreign key and navigation properties

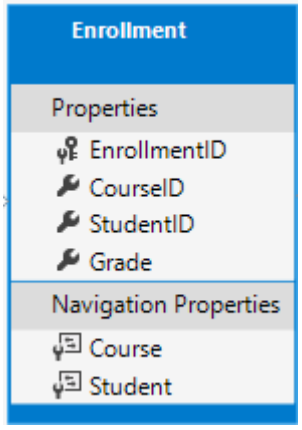
The foreign key and navigation properties reflect the following relationships:

A department may or may not have an administrator, and an administrator is always an instructor. Therefore the `InstructorID` property is included as the foreign key to the Instructor entity, and a question mark is added after the `int` type designation to mark the property as nullable. The navigation property is named `Administrator` but holds an Instructor entity:

C#

```
public int? InstructorID { get; set; }
```

```
public Instructor Administrator { get; set; }
```



A department may have many courses, so there's a Courses navigation property:

C#

```
public ICollection<Course> Courses { get; set; }
```

> **Note**
>
> By convention, the Entity Framework enables cascade delete for non-nullable foreign keys and for many-to-many relationships. This can result in circular cascade delete rules, which will cause an exception when you try to add a migration. For example, if you didn't define the `Department.InstructorID` property as nullable, EF would configure a cascade delete rule to delete the department when you delete the instructor, which isn't what you want to have happen. If your business rules required the `InstructorID` property to be non-nullable, you would have to use the following fluent API statement to disable cascade delete on the relationship:
>
> C#
>
> ```
> modelBuilder.Entity<Department>()
>     .HasOne(d => d.Administrator)
>     .WithMany()
>     .OnDelete(DeleteBehavior.Restrict)
> ```

Modify Enrollment entity

In `Models/Enrollment.cs`, replace the code you added earlier with the following code:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public enum Grade
    {
        A, B, C, D, F
    }

    public class Enrollment
    {
        public int EnrollmentID { get; set; }
        public int CourseID { get; set; }
        public int StudentID { get; set; }
        [DisplayFormat(NullDisplayText = "No grade")]
        public Grade? Grade { get; set; }

        public Course Course { get; set; }
        public Student Student { get; set; }
    }
}
```

Foreign key and navigation properties

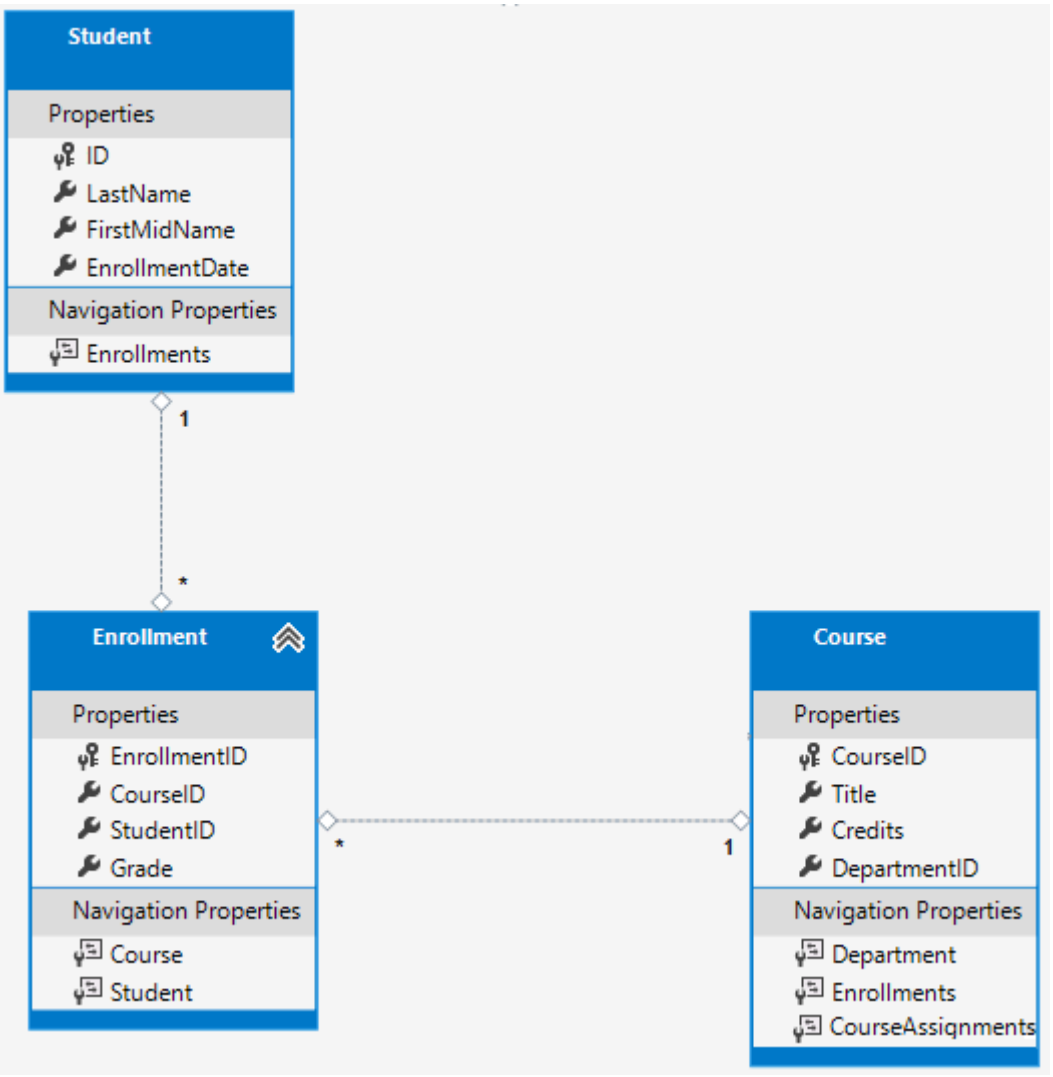
The foreign key properties and navigation properties reflect the following relationships:

An enrollment record is for a single course, so there's a `CourseID` foreign key property and a `Course` navigation property:

C#

```
public int CourseID { get; set; }
public Course Course { get; set; }
```

An enrollment record is for a single student, so there's a `StudentID` foreign key property and a `Student` navigation property:



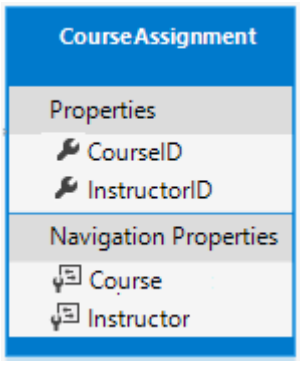
C#

```
public int StudentID { get; set; }
public Student Student { get; set; }
```

Many-to-Many relationships

There's a many-to-many relationship between the `Student` and `Course` entities, and the `Enrollment` entity functions as a many-to-many join table *with payload* in the database. "With payload" means that the `Enrollment` table contains additional data besides foreign keys for the joined tables (in this case, a primary key and a `Grade` property).

The following illustration shows what these relationships look like in an entity diagram. (This diagram was generated using the Entity Framework Power Tools for EF 6.x; creating the diagram isn't part of the tutorial, it's just being used here as an illustration.)



Each relationship line has a 1 at one end and an asterisk (*) at the other, indicating a one-to-many relationship.

If the `Enrollment` table didn't include grade information, it would only need to contain the two foreign keys `CourseID` and `StudentID`. In that case, it would be a many-to-many join table without payload (or a pure join table) in the database. The `Instructor` and `Course` entities have that kind of many-to-many relationship, and your next step is to create an entity class to function as a join table without payload.

EF Core supports implicit join tables for many-to-many relationships, but this tutoral has not been updated to use an implicit join table. See Many-to-Many Relationships, the

Razor Pages version of this tutorial which has been updated.

The CourseAssignment entity

Create `Models/CourseAssignment.cs` with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class CourseAssignment
    {
        public int InstructorID { get; set; }
        public int CourseID { get; set; }
        public Instructor Instructor { get; set; }
        public Course Course { get; set; }
    }
}
```

Join entity names

A join table is required in the database for the Instructor-to-Courses many-to-many relationship, and it has to be represented by an entity set. It's common to name a join entity `EntityName1EntityName2`, which in this case would be `CourseInstructor`. However, we recommend that you choose a name that describes the relationship. Data models start out simple and grow, with no-payload joins frequently getting payloads later. If you start with a descriptive entity name, you won't have to change the name later. Ideally, the join entity would have its own natural (possibly single word) name in the business domain. For example, Books and Customers could be linked through Ratings. For this relationship, `CourseAssignment` is a better choice than `CourseInstructor`.

Composite key

Since the foreign keys are not nullable and together uniquely identify each row of the table, there's no need for a separate primary key. The `InstructorID` and `CourseID` properties should function as a composite primary key. The only way to identify composite primary keys to EF is by using the *fluent API* (it can't be done by using attributes). You'll see how to configure the composite primary key in the next section.

The composite key ensures that while you can have multiple rows for one course, and multiple rows for one instructor, you can't have multiple rows for the same instructor and course. The `Enrollment` join entity defines its own primary key, so duplicates of this sort are possible. To prevent such duplicates, you could add a unique index on the foreign key fields, or configure `Enrollment` with a primary composite key similar to `CourseAssignment`. For more information, see Indexes.

Update the database context

Add the following highlighted code to the `Data/SchoolContext.cs` file:

C#

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) :
base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
```

```
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>
().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>
().ToTable("CourseAssignment");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

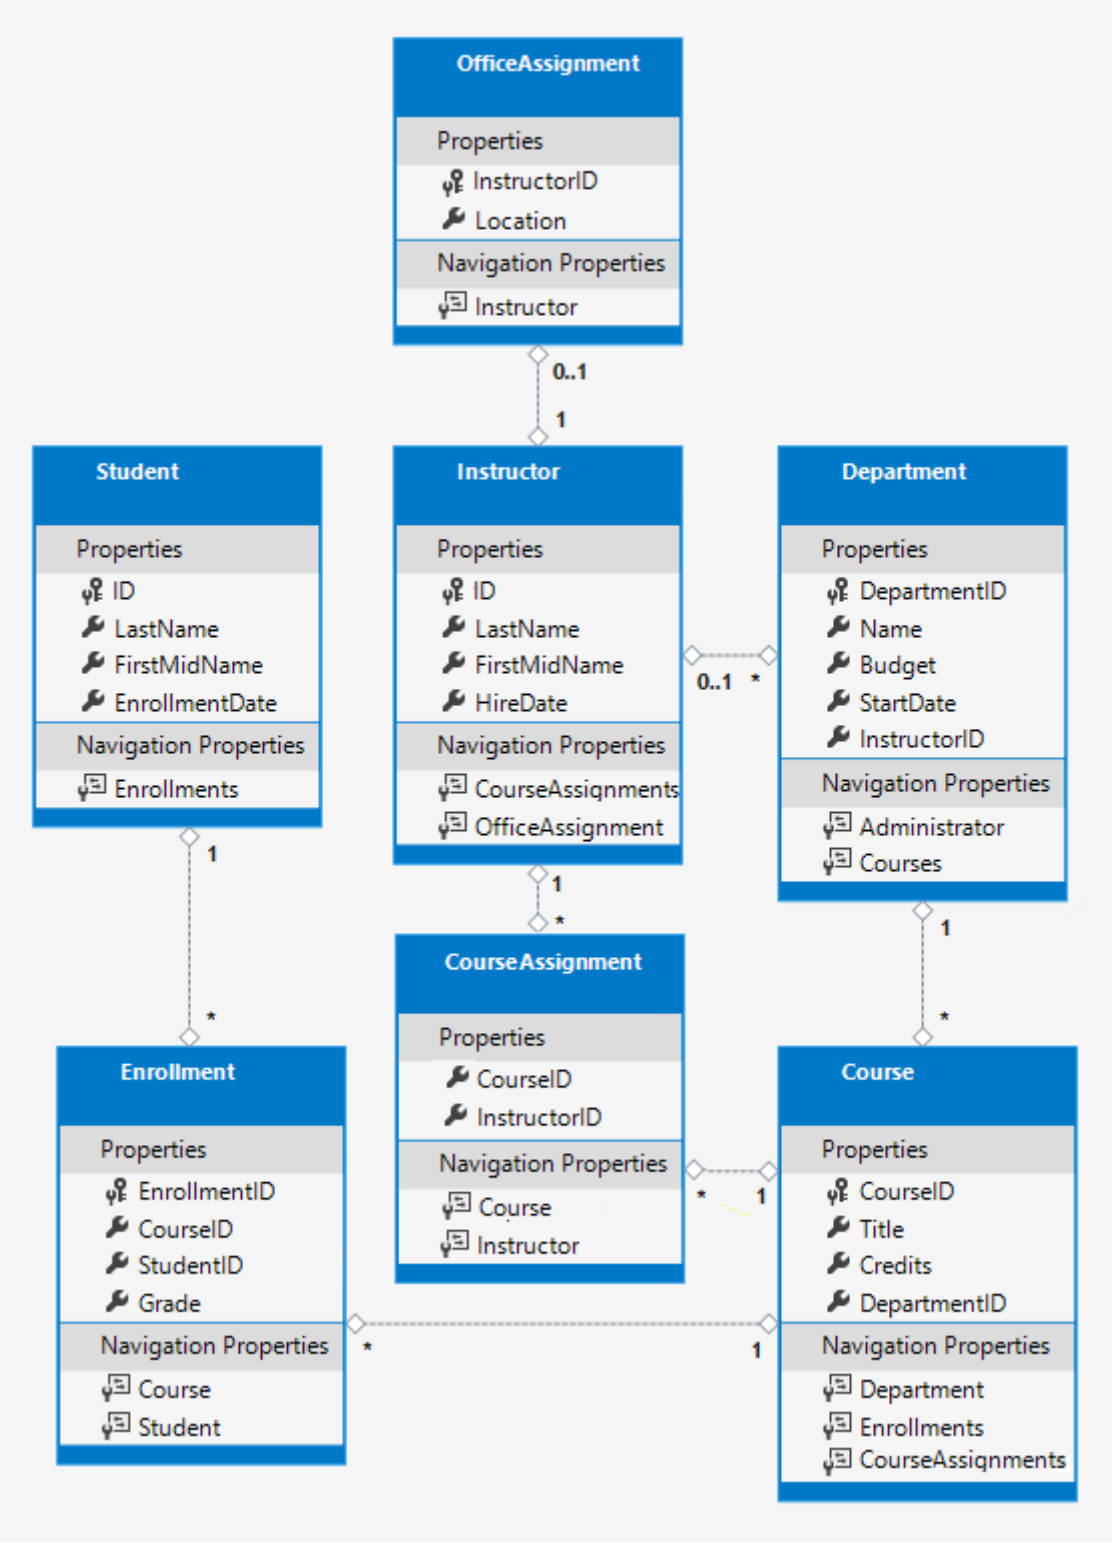
This code adds the new entities and configures the CourseAssignment entity's composite primary key.

About a fluent API alternative

The code in the `OnModelCreating` method of the `DbContext` class uses the *fluent API* to configure EF behavior. The API is called "fluent" because it's often used by stringing a series of method calls together into a single statement, as in this example from the EF Core documentation:

C#

```
protected override void OnModelCreating(ModelBuilder modelBuilder)
{
    modelBuilder.Entity<Blog>()
        .Property(b => b.Url)
        .IsRequired();
}
```



In this tutorial, you're using the fluent API only for database mapping that you can't do with attributes. However, you can also use the fluent API to specify most of the formatting, validation, and mapping rules that you can do by using attributes. Some attributes such as `MinimumLength` can't be applied with the fluent API. As mentioned previously, `MinimumLength` doesn't change the schema, it only applies a client and server side validation rule.

Some developers prefer to use the fluent API exclusively so that they can keep their entity classes "clean." You can mix attributes and fluent API if you want, and there are a few customizations that can only be done by using fluent API, but in general the recommended practice is to choose one of these two approaches and use that consistently as much as possible. If you do use both, note that wherever there's a conflict, Fluent API overrides attributes.

For more information about attributes vs. fluent API, see Methods of configuration.

Entity Diagram Showing Relationships

The following illustration shows the diagram that the Entity Framework Power Tools create for the completed School model.

Besides the one-to-many relationship lines (1 to *), you can see here the one-to-zero-or-one relationship line (1 to 0..1) between the `Instructor` and `OfficeAssignment`

entities and the zero-or-one-to-many relationship line (0..1 to *) between the Instructor and Department entities.

Seed database with test data

Replace the code in the `Data/DbInitializer.cs` file with the following code in order to provide seed data for the new entities you've created.

C#

```
using System;
using System.Linq;
using Microsoft.EntityFrameworkCore;
using Microsoft.Extensions.DependencyInjection;
using ContosoUniversity.Models;

namespace ContosoUniversity.Data
{
    public static class DbInitializer
    {
        public static void Initialize(SchoolContext context)
        {
            //context.Database.EnsureCreated();

            // Look for any students.
            if (context.Students.Any())
            {
                return;   // DB has been seeded
            }

            var students = new Student[]
            {
                new Student { FirstMidName = "Carson",   LastName =
"Alexander",
                    EnrollmentDate = DateTime.Parse("2010-09-01") },
                new Student { FirstMidName = "Meredith", LastName =
"Alonso",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Arturo",   LastName = "Anand",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
                new Student { FirstMidName = "Gytis",    LastName =
"Barzdukas",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Yan",      LastName = "Li",
                    EnrollmentDate = DateTime.Parse("2012-09-01") },
                new Student { FirstMidName = "Peggy",    LastName =
"Justice",
                    EnrollmentDate = DateTime.Parse("2011-09-01") },
                new Student { FirstMidName = "Laura",    LastName =
"Norman",
                    EnrollmentDate = DateTime.Parse("2013-09-01") },
```

```
                new Student { FirstMidName = "Nino",     LastName =
"Olivetto",
                    EnrollmentDate = DateTime.Parse("2005-09-01") }
            };

            foreach (Student s in students)
            {
                context.Students.Add(s);
            }
            context.SaveChanges();

            var instructors = new Instructor[]
            {
                new Instructor { FirstMidName = "Kim",     LastName =
"Abercrombie",
                    HireDate = DateTime.Parse("1995-03-11") },
                new Instructor { FirstMidName = "Fadi",    LastName =
"Fakhouri",
                    HireDate = DateTime.Parse("2002-07-06") },
                new Instructor { FirstMidName = "Roger",   LastName =
"Harui",
                    HireDate = DateTime.Parse("1998-07-01") },
                new Instructor { FirstMidName = "Candace", LastName =
"Kapoor",
                    HireDate = DateTime.Parse("2001-01-15") },
                new Instructor { FirstMidName = "Roger",   LastName =
"Zheng",
                    HireDate = DateTime.Parse("2004-02-12") }
            };

            foreach (Instructor i in instructors)
            {
                context.Instructors.Add(i);
            }
            context.SaveChanges();

            var departments = new Department[]
            {
                new Department { Name = "English",     Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName ==
"Abercrombie").ID },
                new Department { Name = "Mathematics", Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName ==
"Fakhouri").ID },
                new Department { Name = "Engineering", Budget = 350000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName ==
"Harui").ID },
                new Department { Name = "Economics",   Budget = 100000,
                    StartDate = DateTime.Parse("2007-09-01"),
                    InstructorID  = instructors.Single( i => i.LastName ==
"Kapoor").ID }
            };
```

```
            foreach (Department d in departments)
            {
                context.Departments.Add(d);
            }
            context.SaveChanges();

            var courses = new Course[]
            {
                new Course {CourseID = 1050, Title = "Chemistry",
Credits = 3,
                    DepartmentID = departments.Single( s => s.Name ==
"Engineering").DepartmentID
                },
                new Course {CourseID = 4022, Title = "Microeconomics",
Credits = 3,
                    DepartmentID = departments.Single( s => s.Name ==
"Economics").DepartmentID
                },
                new Course {CourseID = 4041, Title = "Macroeconomics",
Credits = 3,
                    DepartmentID = departments.Single( s => s.Name ==
"Economics").DepartmentID
                },
                new Course {CourseID = 1045, Title = "Calculus",
Credits = 4,
                    DepartmentID = departments.Single( s => s.Name ==
"Mathematics").DepartmentID
                },
                new Course {CourseID = 3141, Title = "Trigonometry",
Credits = 4,
                    DepartmentID = departments.Single( s => s.Name ==
"Mathematics").DepartmentID
                },
                new Course {CourseID = 2021, Title = "Composition",
Credits = 3,
                    DepartmentID = departments.Single( s => s.Name ==
"English").DepartmentID
                },
                new Course {CourseID = 2042, Title = "Literature",
Credits = 4,
                    DepartmentID = departments.Single( s => s.Name ==
"English").DepartmentID
                },
            };

            foreach (Course c in courses)
            {
                context.Courses.Add(c);
            }
            context.SaveChanges();

            var officeAssignments = new OfficeAssignment[]
            {
                new OfficeAssignment {
```

```
                    InstructorID = instructors.Single( i => i.LastName ==
"Fakhouri").ID,
                    Location = "Smith 17" },
                new OfficeAssignment {
                    InstructorID = instructors.Single( i => i.LastName ==
"Harui").ID,
                    Location = "Gowan 27" },
                new OfficeAssignment {
                    InstructorID = instructors.Single( i => i.LastName ==
"Kapoor").ID,
                    Location = "Thompson 304" },
            };

            foreach (OfficeAssignment o in officeAssignments)
            {
                context.OfficeAssignments.Add(o);
            }
            context.SaveChanges();

            var courseInstructors = new CourseAssignment[]
            {
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Chemistry"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Kapoor").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Chemistry"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Harui").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title ==
"Microeconomics" ).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Zheng").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title ==
"Macroeconomics" ).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Zheng").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Calculus"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Fakhouri").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Trigonometry"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
```

```
"Harui").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Composition"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Abercrombie").ID
                    },
                new CourseAssignment {
                    CourseID = courses.Single(c => c.Title == "Literature"
).CourseID,
                    InstructorID = instructors.Single(i => i.LastName ==
"Abercrombie").ID
                    },
            };

            foreach (CourseAssignment ci in courseInstructors)
            {
                context.CourseAssignments.Add(ci);
            }
            context.SaveChanges();

            var enrollments = new Enrollment[]
            {
                new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Alexander").ID,
                    CourseID = courses.Single(c => c.Title == "Chemistry"
).CourseID,
                    Grade = Grade.A
                },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Alexander").ID,
                    CourseID = courses.Single(c => c.Title ==
"Microeconomics" ).CourseID,
                    Grade = Grade.C
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Alexander").ID,
                    CourseID = courses.Single(c => c.Title ==
"Macroeconomics" ).CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                        StudentID = students.Single(s => s.LastName ==
"Alonso").ID,
                    CourseID = courses.Single(c => c.Title == "Calculus"
).CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                        StudentID = students.Single(s => s.LastName ==
"Alonso").ID,
```

```
                    CourseID = courses.Single(c => c.Title == "Trigonometry"
).CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Alonso").ID,
                    CourseID = courses.Single(c => c.Title == "Composition"
).CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Anand").ID,
                    CourseID = courses.Single(c => c.Title == "Chemistry"
).CourseID
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Anand").ID,
                    CourseID = courses.Single(c => c.Title ==
"Microeconomics").CourseID,
                    Grade = Grade.B
                    },
                new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Barzdukas").ID,
                    CourseID = courses.Single(c => c.Title ==
"Chemistry").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName == "Li").ID,
                    CourseID = courses.Single(c => c.Title ==
"Composition").CourseID,
                    Grade = Grade.B
                    },
                    new Enrollment {
                    StudentID = students.Single(s => s.LastName ==
"Justice").ID,
                    CourseID = courses.Single(c => c.Title ==
"Literature").CourseID,
                    Grade = Grade.B
                    }
            };

            foreach (Enrollment e in enrollments)
            {
                var enrollmentInDataBase = context.Enrollments.Where(
                    s =>
                            s.Student.ID == e.StudentID &&
                            s.Course.CourseID ==
e.CourseID).SingleOrDefault();
                if (enrollmentInDataBase == null)
                {
```

```
                    context.Enrollments.Add(e);
                }
            }
            context.SaveChanges();
        }
    }
}
```

As you saw in the first tutorial, most of this code simply creates new entity objects and loads sample data into properties as required for testing. Notice how the many-to-many relationships are handled: the code creates relationships by creating entities in the `Enrollments` and `CourseAssignment` join entity sets.

Add a migration

Save your changes and build the project. Then open the command window in the project folder and enter the `migrations add` command (don't do the update-database command yet):

.NET CLI

```
dotnet ef migrations add ComplexDataModel
```

You get a warning about possible data loss.

text

```
An operation was scaffolded that may result in the loss of data. Please
review the migration for accuracy.
Done. To undo this action, use 'ef migrations remove'
```

If you tried to run the `database update` command at this point (don't do it yet), you would get the following error:

> The ALTER TABLE statement conflicted with the FOREIGN KEY constraint "FK_dbo.Course_dbo.Department_DepartmentID". The conflict occurred in database "ContosoUniversity", table "dbo.Department", column 'DepartmentID'.

Sometimes when you execute migrations with existing data, you need to insert stub data into the database to satisfy foreign key constraints. The generated code in the `Up` method adds a non-nullable `DepartmentID` foreign key to the `Course` table. If there are already rows in the Course table when the code runs, the `AddColumn` operation fails

because SQL Server doesn't know what value to put in the column that can't be null. For this tutorial you'll run the migration on a new database, but in a production application you'd have to make the migration handle existing data, so the following directions show an example of how to do that.

To make this migration work with existing data you have to change the code to give the new column a default value, and create a stub department named "Temp" to act as the default department. As a result, existing Course rows will all be related to the "Temp" department after the `Up` method runs.

- Open the `{timestamp}_ComplexDataModel.cs` file.
- Comment out the line of code that adds the DepartmentID column to the Course table.

```
C#

migrationBuilder.AlterColumn<string>(
    name: "Title",
    table: "Course",
    maxLength: 50,
    nullable: true,
    oldClrType: typeof(string),
    oldNullable: true);

//migrationBuilder.AddColumn<int>(
//    name: "DepartmentID",
//    table: "Course",
//    nullable: false,
//    defaultValue: 0);
```

- Add the following highlighted code after the code that creates the Department table:

```
C#

migrationBuilder.CreateTable(
    name: "Department",
    columns: table => new
    {
        DepartmentID = table.Column<int>(nullable: false)
            .Annotation("SqlServer:ValueGenerationStrategy",
SqlServerValueGenerationStrategy.IdentityColumn),
        Budget = table.Column<decimal>(type: "money", nullable: false),
        InstructorID = table.Column<int>(nullable: true),
        Name = table.Column<string>(maxLength: 50, nullable: true),
        StartDate = table.Column<DateTime>(nullable: false)
    },
    constraints: table =>
```

```
    {
        table.PrimaryKey("PK_Department", x => x.DepartmentID);
        table.ForeignKey(
            name: "FK_Department_Instructor_InstructorID",
            column: x => x.InstructorID,
            principalTable: "Instructor",
            principalColumn: "ID",
            onDelete: ReferentialAction.Restrict);
    });

migrationBuilder.Sql("INSERT INTO dbo.Department (Name, Budget,
StartDate) VALUES ('Temp', 0.00, GETDATE())");
// Default value for FK points to department created above, with
// defaultValue changed to 1 in following AddColumn statement.

migrationBuilder.AddColumn<int>(
    name: "DepartmentID",
    table: "Course",
    nullable: false,
    defaultValue: 1);
```

In a production application, you would write code or scripts to add Department rows and relate Course rows to the new Department rows. You would then no longer need the "Temp" department or the default value on the `Course.DepartmentID` column.

Save your changes and build the project.

Change the connection string

You now have new code in the `DbInitializer` class that adds seed data for the new entities to an empty database. To make EF create a new empty database, change the name of the database in the connection string in `appsettings.json` to ContosoUniversity3 or some other name that you haven't used on the computer you're using.

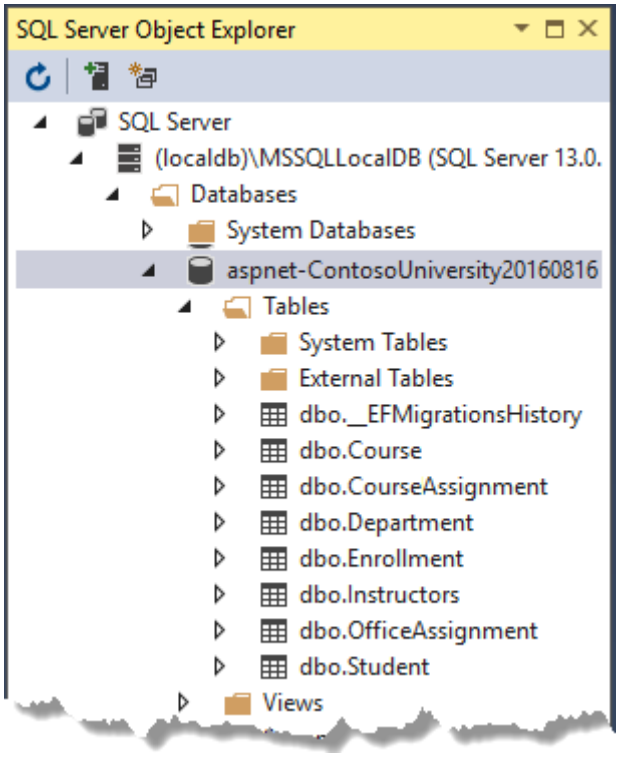
JSON

```
{
  "ConnectionStrings": {
    "DefaultConnection": "Server=
(localdb)\\mssqllocaldb;Database=ContosoUniversity3;Trusted_Connection=True;
MultipleActiveResultSets=true"
  },
```

Save your change to `appsettings.json`.

> **Note**
>
> As an alternative to changing the database name, you can delete the database. Use **SQL Server Object Explorer** (SSOX) or the `database drop` CLI command:
>
> .NET CLI
>
> ```
> dotnet ef database drop
> ```

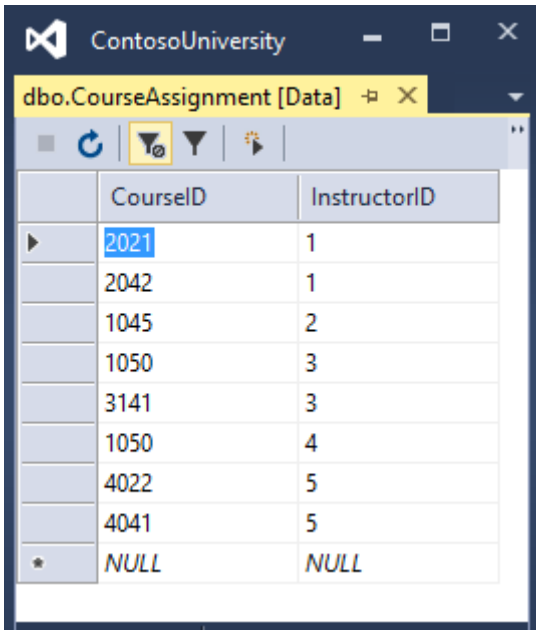
Update the database



After you have changed the database name or deleted the database, run the `database update` command in the command window to execute the migrations.

.NET CLI

```
dotnet ef database update
```



Run the app to cause the `DbInitializer.Initialize` method to run and populate the new database.

Open the database in SSOX as you did earlier, and expand the **Tables** node to see that all of the tables have been created. (If you still have SSOX open from the earlier time, click the **Refresh** button.)

Run the app to trigger the initializer code that seeds the database.

Right-click the **CourseAssignment** table and select **View Data** to verify that it has data in it.

Get the code

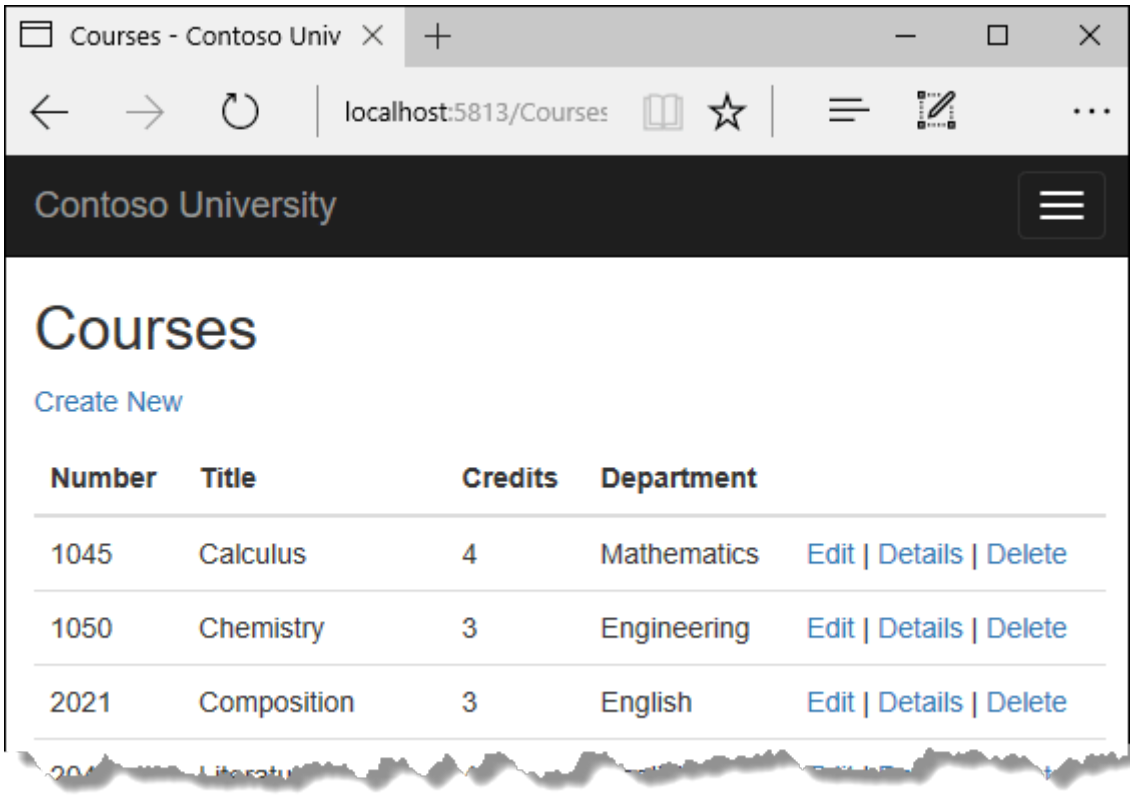
Download or view the completed application.

Next steps

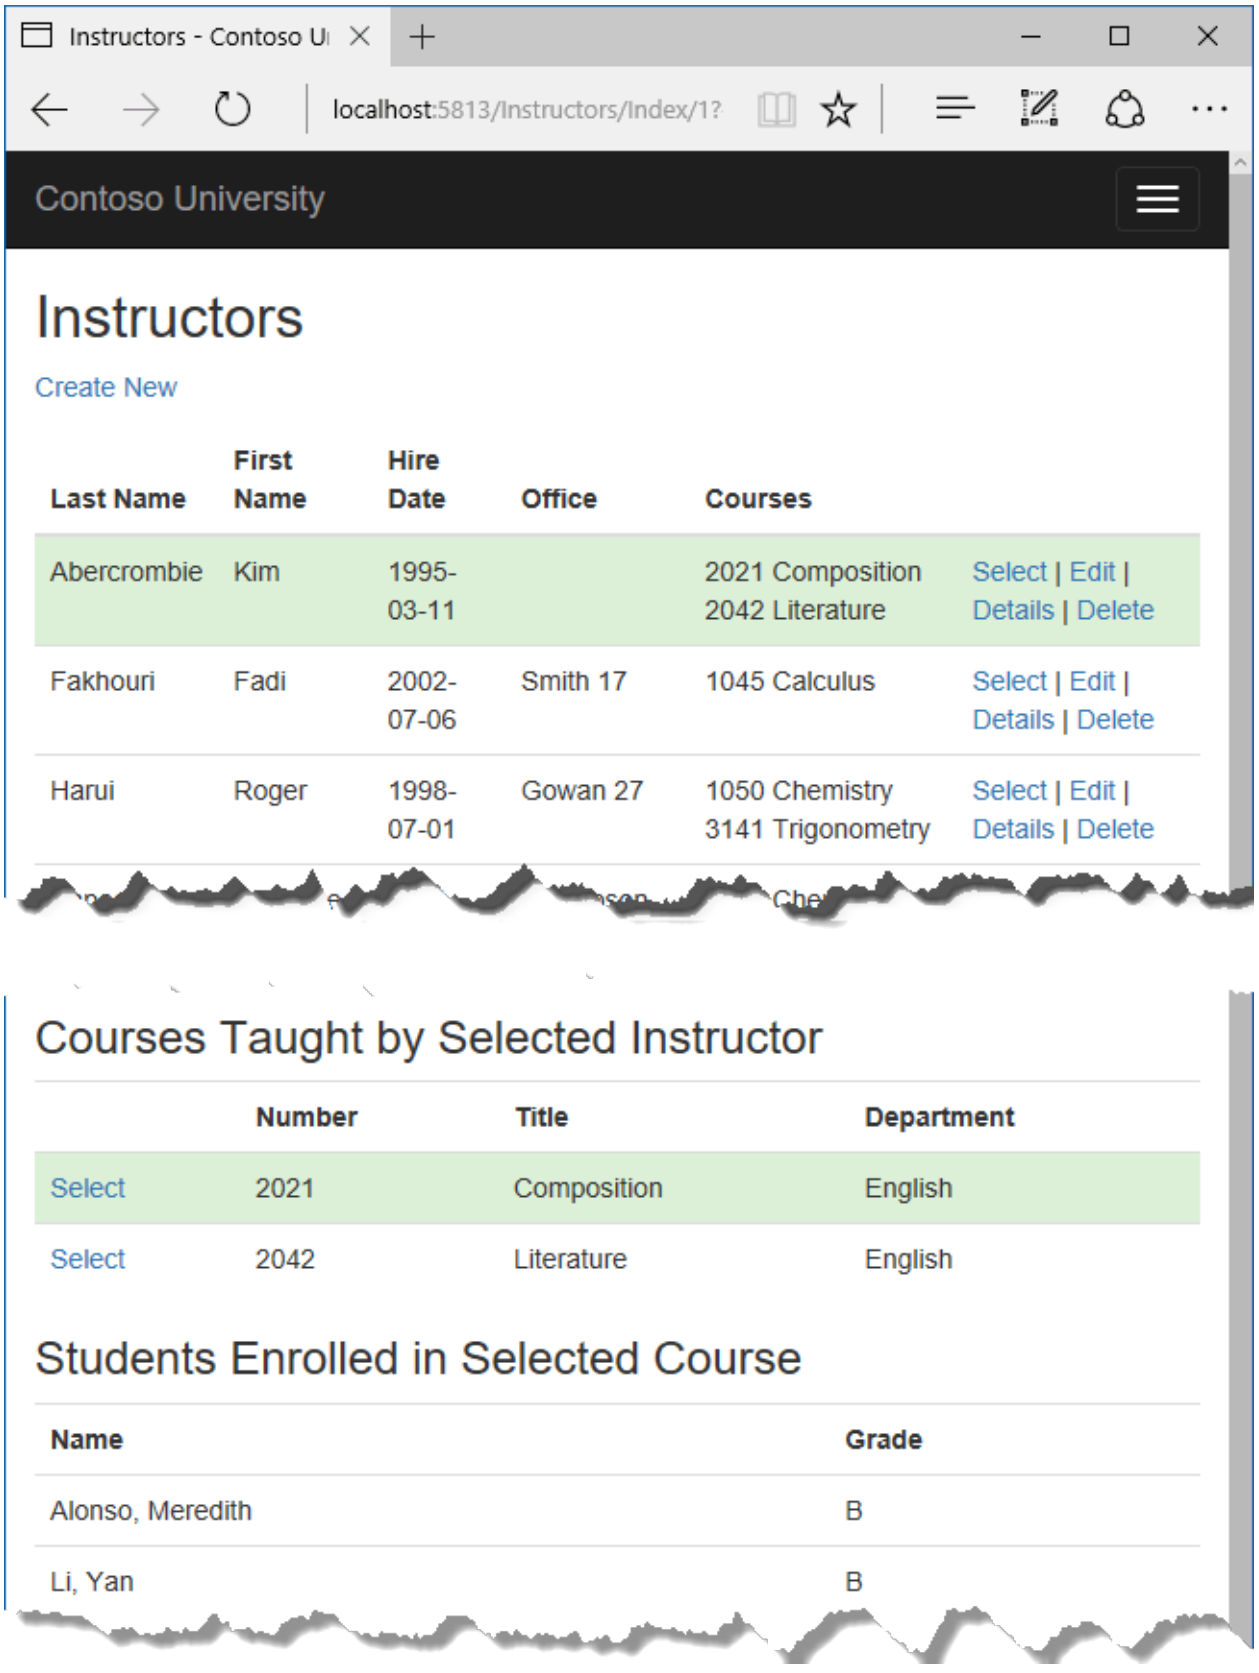
In this tutorial, you:

- ✓ Customized the Data model
- ✓ Made changes to Student entity
- ✓ Created Instructor entity
- ✓ Created OfficeAssignment entity
- ✓ Modified Course entity
- ✓ Created Department entity
- ✓ Modified Enrollment entity
- ✓ Updated the database context
- ✓ Seeded database with test data
- ✓ Added a migration
- ✓ Changed the connection string
- ✓ Updated the database

Advance to the next tutorial to learn more about how to access related data.



Next: Access related data



Tutorial: Read related data - ASP.NET MVC with EF Core

Article • 04/10/2024

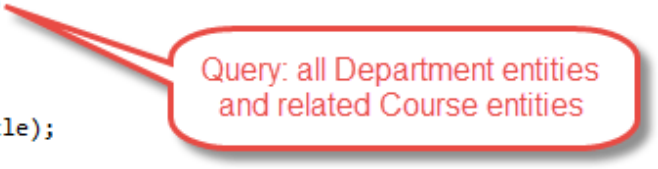
In the previous tutorial, you completed the School data model. In this tutorial, you'll read and display related data -- that is, data that the Entity Framework loads into navigation properties.

The following illustrations show the pages that you'll work with.

In this tutorial, you:

- ✓ Learn how to load related data
- ✓ Create a Courses page
- ✓ Create an Instructors page
- ✓ Learn about explicit loading

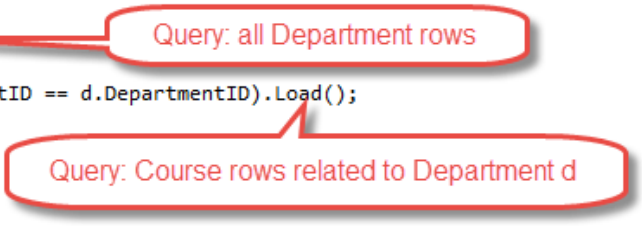
Prerequisites



- Create a complex data model

Learn how to load related data

There are several ways that Object-Relational Mapping (ORM) software such as Entity Framework can load related data into the navigation properties of an entity:



- Eager loading: When the entity is read, related data is retrieved along with it. This typically results in a single join query that retrieves all of the data that's needed. You specify eager loading in Entity Framework Core by using the `Include` and `ThenInclude` methods.

```
var departments = _context.Departments.Include(d => d.Courses);
foreach (Department d in departments)
{
    foreach(Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

  You can retrieve some of the data in separate queries, and EF "fixes up" the navigation properties. That is, EF automatically adds the separately retrieved entities where they belong in navigation properties of previously retrieved entities. For the query that retrieves related data, you can use the `Load` method instead of a method that returns a list or object, such as `ToList` or `Single`.

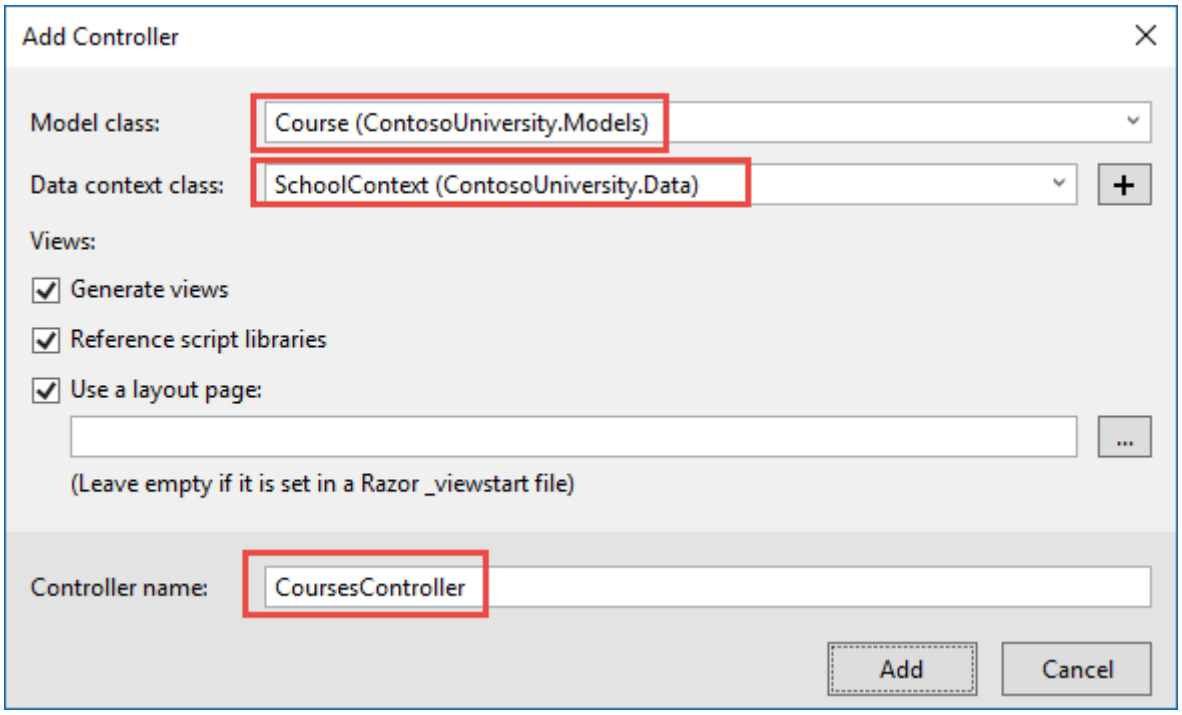
```
var departments = _context.Departments;
foreach (Department d in departments)
{
    _context.Courses.Where(c => c.DepartmentID == d.DepartmentID).Load();
    foreach (Course c in d.Courses)
    {
        courseList.Add(d.Name + c.Title);
    }
}
```

- Explicit loading: When the entity is first read, related data isn't retrieved. You write code that retrieves the related data if it's needed. As in the case of eager loading with separate queries, explicit loading results in multiple queries sent to the database. The difference is that with explicit loading, the code specifies the navigation properties to be loaded. In Entity Framework Core 1.1 you can use the `Load` method to do explicit loading. For example:

- Lazy loading: When the entity is first read, related data isn't retrieved. However, the first time you attempt to access a navigation property, the data required for that navigation property is automatically retrieved. A query is sent to the database each time you try to get data from a navigation property for the first time. Entity Framework Core 1.0 doesn't support lazy loading.

Performance considerations

If you know you need related data for every entity retrieved, eager loading often offers the best performance, because a single query sent to the database is typically more efficient than separate queries for each entity retrieved. For example, suppose that each department has ten related courses. Eager loading of all related data would result in just a single (join) query and a single round trip to the database. A separate query for courses for each department would result in eleven round trips to the database. The extra round trips to the database are especially detrimental to performance when latency is high.



On the other hand, in some scenarios separate queries is more efficient. Eager loading of all related data in one query might cause a very complex join to be generated, which SQL Server can't process efficiently. Or if you need to access an entity's navigation properties only for a subset of a set of the entities you're processing, separate queries might perform better because eager loading of everything up front would retrieve more data than you need. If performance is critical, it's best to test performance both ways in order to make the best choice.

Create a Courses page

The `Course` entity includes a navigation property that contains the `Department` entity of the department that the course is assigned to. To display the name of the assigned department in a list of courses, you need to get the `Name` property from the `Department` entity that's in the `Course.Department` navigation property.

Create a controller named `CoursesController` for the `Course` entity type, using the same options for the **MVC Controller with views, using Entity Framework** scaffolder that you

did earlier for the `StudentsController`, as shown in the following illustration:

Open `CoursesController.cs` and examine the `Index` method. The automatic scaffolding has specified eager loading for the `Department` navigation property by using the `Include` method.

Replace the `Index` method with the following code that uses a more appropriate name for the `IQueryable` that returns Course entities (`courses` instead of `schoolContext`):

C#

```
public async Task<IActionResult> Index()
{
    var courses = _context.Courses
        .Include(c => c.Department)
        .AsNoTracking();
    return View(await courses.ToListAsync());
}
```

Open `Views/Courses/Index.cshtml` and replace the template code with the following code. The changes are highlighted:

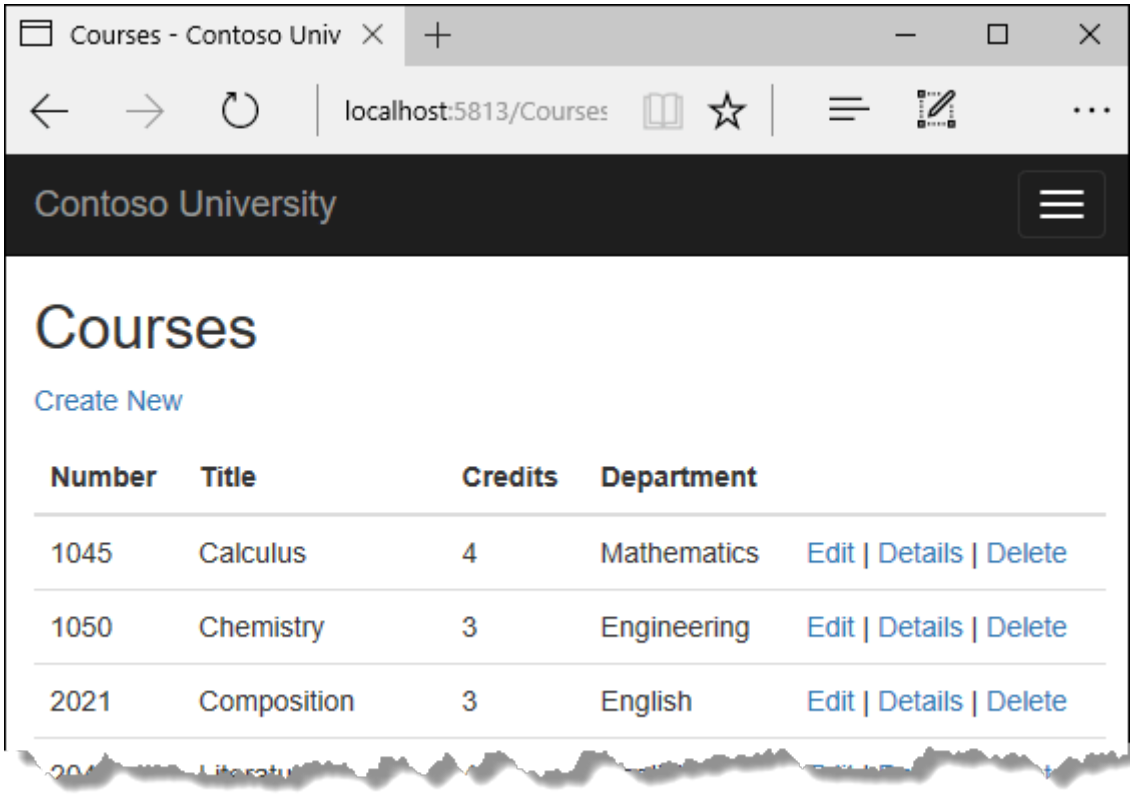
CSHTML

```
@model IEnumerable<ContosoUniversity.Models.Course>

@{
    ViewData["Title"] = "Courses";
}
```

```
<h2>Courses</h2>

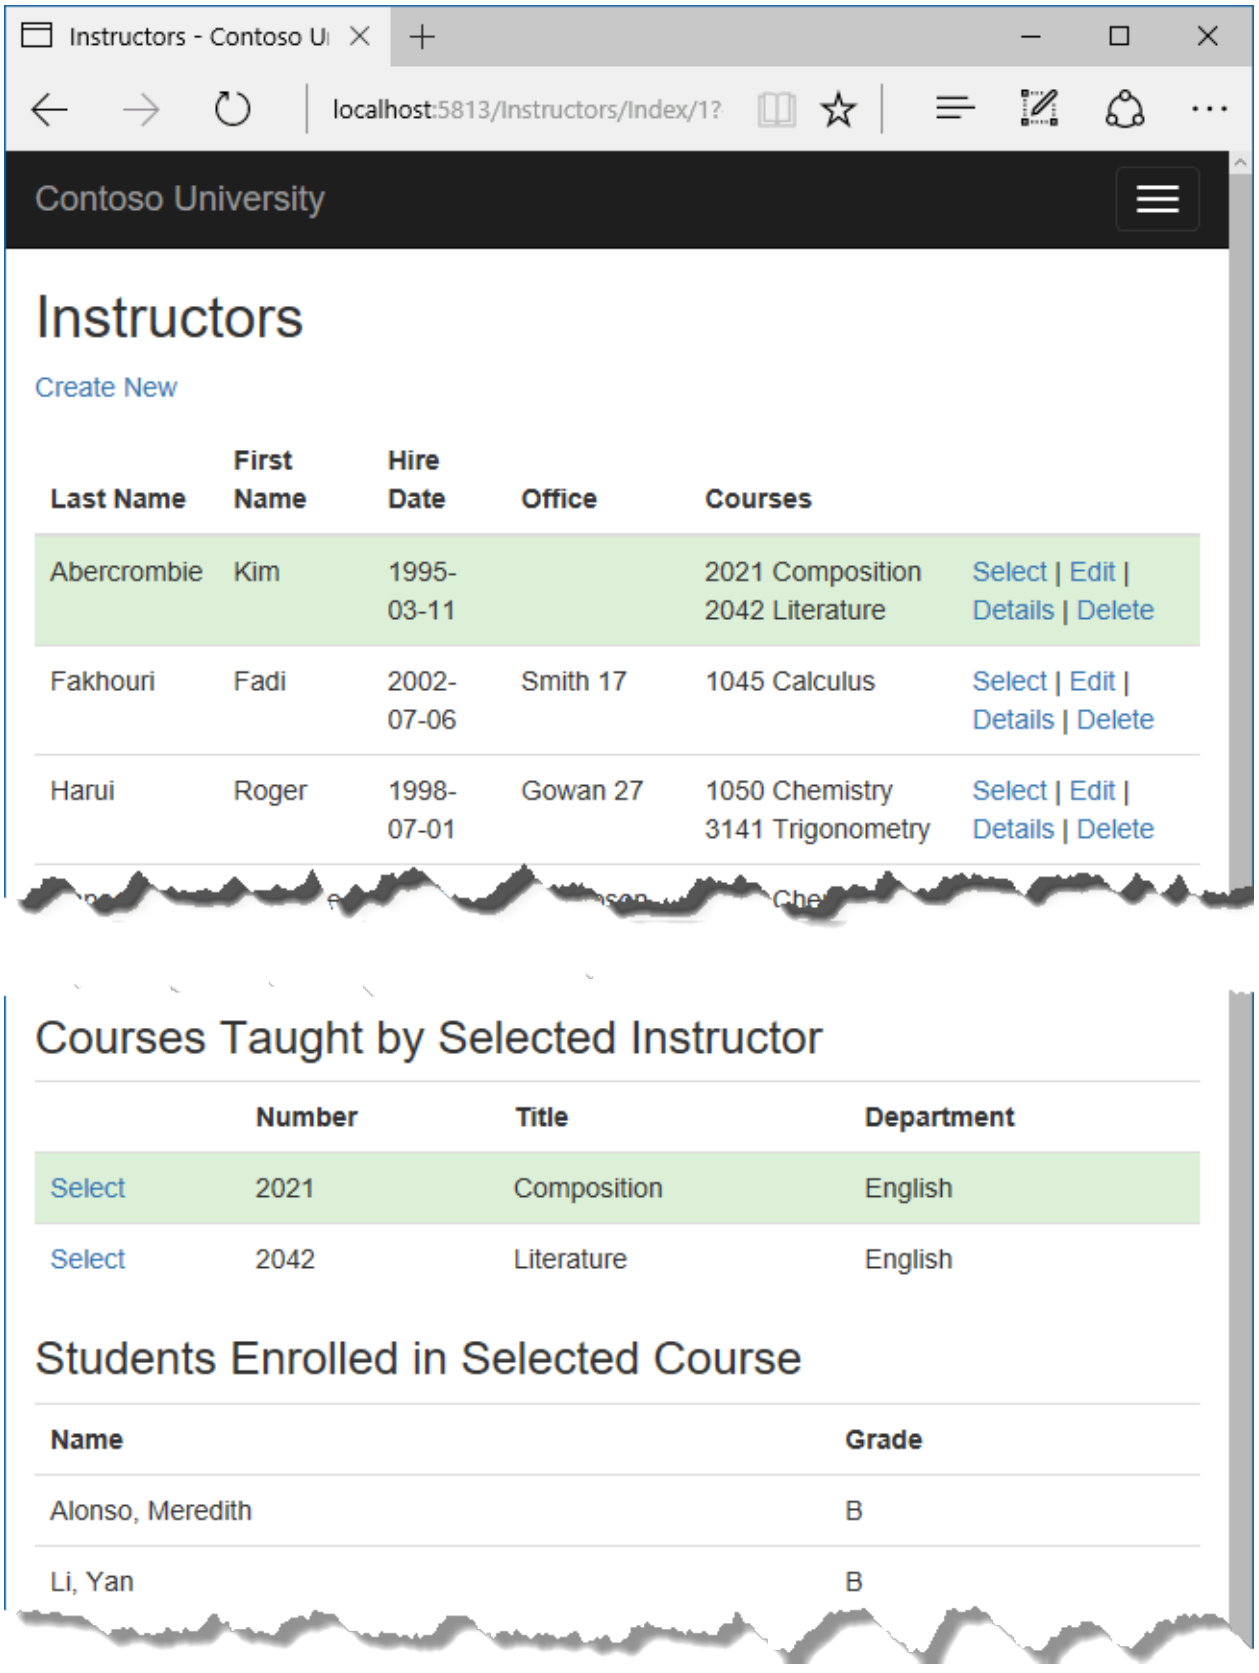
<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.CourseID)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Title)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Credits)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Department)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.CourseID)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Title)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Credits)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Department.Name)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-
id="@item.CourseID">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.CourseID">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.CourseID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```



You've made the following changes to the scaffolded code:

- Changed the heading from **Index** to **Courses**.
- Added a **Number** column that shows the `CourseID` property value. By default, primary keys aren't scaffolded because normally they're meaningless to end users. However, in this case the primary key is meaningful and you want to show it.
- Changed the **Department** column to display the department name. The code displays the `Name` property of the `Department` entity that's loaded into the `Department` navigation property:

```
HTML



@Html.DisplayFor(modelItem => item.Department.Name)
```

Run the app and select the **Courses** tab to see the list with department names.

Create an Instructors page

In this section, you'll create a controller and view for the `Instructor` entity in order to display the Instructors page:

This page reads and displays related data in the following ways:

- The list of instructors displays related data from the `OfficeAssignment` entity. The `Instructor` and `OfficeAssignment` entities are in a one-to-zero-or-one relationship. You'll use eager loading for the `OfficeAssignment` entities. As explained earlier, eager loading is typically more efficient when you need the

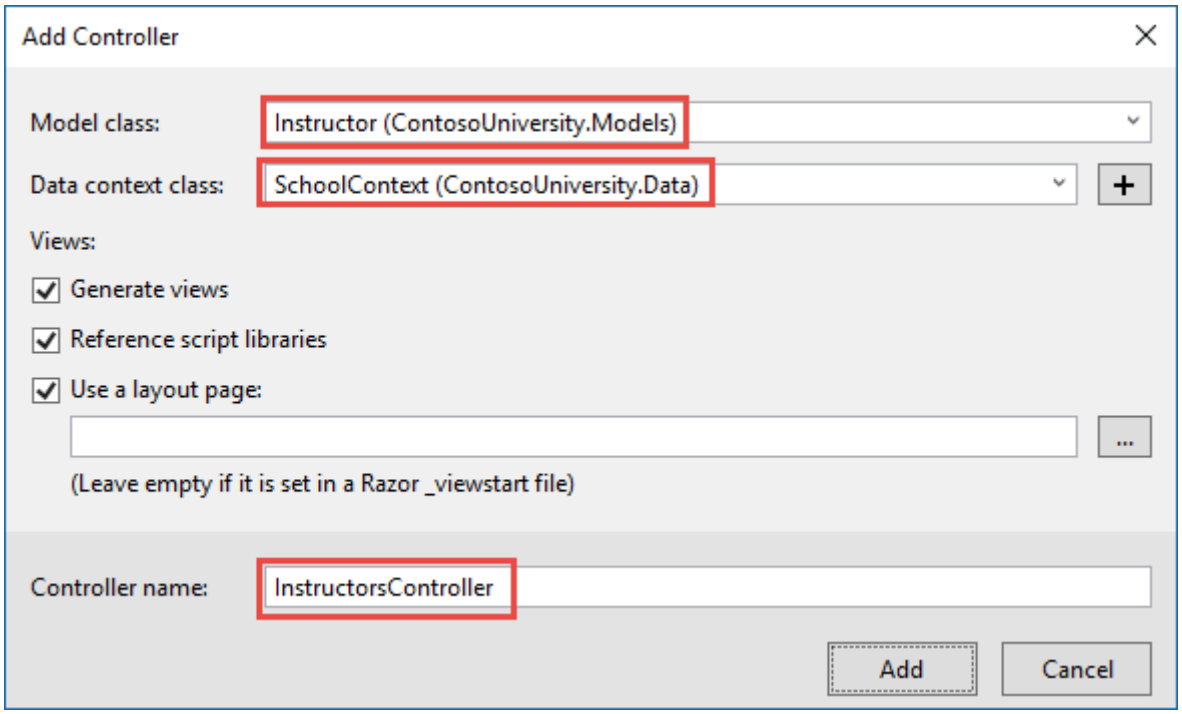
related data for all retrieved rows of the primary table. In this case, you want to display office assignments for all displayed instructors.

- When the user selects an instructor, related `Course` entities are displayed. The `Instructor` and `Course` entities are in a many-to-many relationship. You'll use eager loading for the `Course` entities and their related `Department` entities. In this case, separate queries might be more efficient because you need courses only for the selected instructor. However, this example shows how to use eager loading for navigation properties within entities that are themselves in navigation properties.
- When the user selects a course, related data from the `Enrollments` entity set is displayed. The `Course` and `Enrollment` entities are in a one-to-many relationship. You'll use separate queries for `Enrollment` entities and their related `Student` entities.

Create a view model for the Instructor Index view

The Instructors page shows data from three different tables. Therefore, you'll create a view model that includes three properties, each holding the data for one of the tables.

In the *SchoolViewModels* folder, create `InstructorIndexData.cs` and replace the existing code with the following code:



C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class InstructorIndexData
    {
        public IEnumerable<Instructor> Instructors { get; set; }
        public IEnumerable<Course> Courses { get; set; }
        public IEnumerable<Enrollment> Enrollments { get; set; }
    }
}
```

Create the Instructor controller and views

Create an Instructors controller with EF read/write actions as shown in the following illustration:

Open `InstructorsController.cs` and add a using statement for the ViewModels namespace:

C#

```
using ContosoUniversity.Models.SchoolViewModels;
```

Replace the Index method with the following code to do eager loading of related data and put it in the view model.

C#

```
public async Task<IActionResult> Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();
    viewModel.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Enrollments)
                    .ThenInclude(i => i.Student)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
          .AsNoTracking()
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        ViewData["InstructorID"] = id.Value;
        Instructor instructor = viewModel.Instructors.Where(
```

```
            i => i.ID == id.Value).Single();
        viewModel.Courses = instructor.CourseAssignments.Select(s =>
s.Course);
    }

    if (courseID != null)
    {
        ViewData["CourseID"] = courseID.Value;
        viewModel.Enrollments = viewModel.Courses.Where(
            x => x.CourseID == courseID).Single().Enrollments;
    }

    return View(viewModel);
}
```

The method accepts optional route data (`id`) and a query string parameter (`courseID`) that provide the ID values of the selected instructor and selected course. The parameters are provided by the **Select** hyperlinks on the page.

The code begins by creating an instance of the view model and putting in it the list of instructors. The code specifies eager loading for the `Instructor.OfficeAssignment` and the `Instructor.CourseAssignments` navigation properties. Within the `CourseAssignments` property, the `Course` property is loaded, and within that, the `Enrollments` and `Department` properties are loaded, and within each `Enrollment` entity the `Student` property is loaded.

C#

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

Since the view always requires the `OfficeAssignment` entity, it's more efficient to fetch that in the same query. Course entities are required when an instructor is selected in the web page, so a single query is better than multiple queries only if the page is displayed more often with a course selected than without.

The code repeats `CourseAssignments` and `Course` because you need two properties from `Course`. The first string of `ThenInclude` calls gets `CourseAssignment.Course`, `Course.Enrollments`, and `Enrollment.Student`.

You can read more about including multiple levels of related data here.

C#

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

At that point in the code, another `ThenInclude` would be for navigation properties of `Student`, which you don't need. But calling `Include` starts over with `Instructor` properties, so you have to go through the chain again, this time specifying `Course.Department` instead of `Course.Enrollments`.

C#

```
viewModel.Instructors = await _context.Instructors
      .Include(i => i.OfficeAssignment)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Enrollments)
                .ThenInclude(i => i.Student)
      .Include(i => i.CourseAssignments)
        .ThenInclude(i => i.Course)
            .ThenInclude(i => i.Department)
      .AsNoTracking()
      .OrderBy(i => i.LastName)
      .ToListAsync();
```

The following code executes when an instructor was selected. The selected instructor is retrieved from the list of instructors in the view model. The view model's `Courses` property is then loaded with the `Course` entities from that instructor's `CourseAssignments` navigation property.

C#

```
if (id != null)
{
    ViewData["InstructorID"] = id.Value;
    Instructor instructor = viewModel.Instructors.Where(
        i => i.ID == id.Value).Single();
    viewModel.Courses = instructor.CourseAssignments.Select(s => s.Course);
}
```

The `Where` method returns a collection, but in this case the criteria passed to that method result in only a single Instructor entity being returned. The `Single` method converts the collection into a single `Instructor` entity, which gives you access to that entity's `CourseAssignments` property. The `CourseAssignments` property contains `CourseAssignment` entities, from which you want only the related `Course` entities.

You use the `Single` method on a collection when you know the collection will have only one item. The `Single` method throws an exception if the collection passed to it's empty or if there's more than one item. An alternative is `SingleOrDefault`, which returns a default value (null in this case) if the collection is empty. However, in this case that would still result in an exception (from trying to find a `Courses` property on a null reference), and the exception message would less clearly indicate the cause of the problem. When you call the `Single` method, you can also pass in the Where condition instead of calling the `Where` method separately:

C#

```
.Single(i => i.ID == id.Value)
```

Instead of:

C#

```
.Where(i => i.ID == id.Value).Single()
```

Next, if a course was selected, the selected course is retrieved from the list of courses in the view model. Then the view model's `Enrollments` property is loaded with the Enrollment entities from that course's `Enrollments` navigation property.

C#

```
if (courseID != null)
{
    ViewData["CourseID"] = courseID.Value;
    viewModel.Enrollments = viewModel.Courses.Where(
```

```
        x => x.CourseID == courseID).Single().Enrollments;
}
```

Tracking vs no-tracking

No-tracking queries are useful when the results are used in a read-only scenario. They're generally quicker to execute because there's no need to set up the change tracking information. If the entities retrieved from the database don't need to be updated, then a no-tracking query is likely to perform better than a tracking query.

In some cases a tracking query is more efficient than a no-tracking query. For more information, see Tracking vs. No-Tracking Queries.

Modify the Instructor Index view

In `Views/Instructors/Index.cshtml`, replace the template code with the following code. The changes are highlighted.

CSHTML

```
@model ContosoUniversity.Models.SchoolViewModels.InstructorIndexData

@{
    ViewData["Title"] = "Instructors";
}

<h2>Instructors</h2>

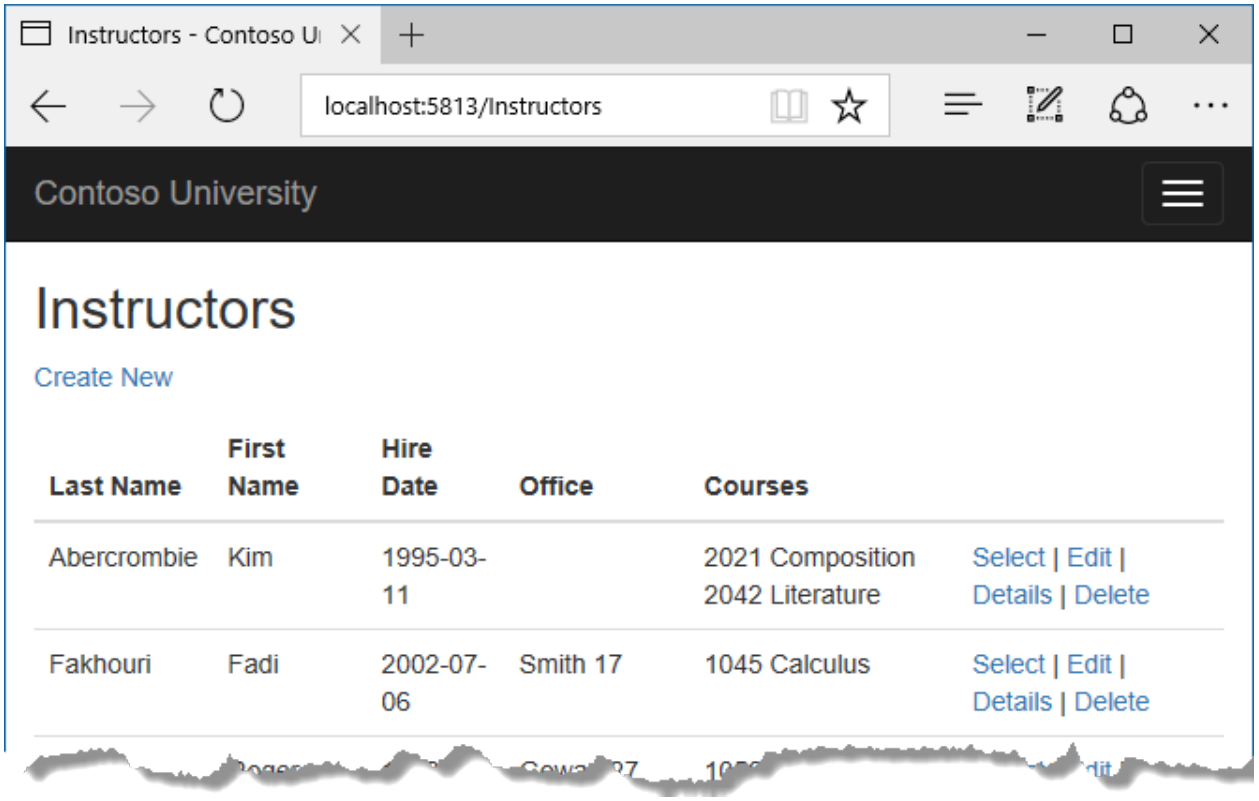
<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>Last Name</th>
            <th>First Name</th>
            <th>Hire Date</th>
            <th>Office</th>
            <th>Courses</th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model.Instructors)
        {
```

```
            string selectedRow = "";
            if (item.ID == (int?)ViewData["InstructorID"])
            {
                selectedRow = "table-success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.DisplayFor(modelItem => item.LastName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.FirstMidName)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.HireDate)
                </td>
                <td>
                    @if (item.OfficeAssignment != null)
                    {
                        @item.OfficeAssignment.Location
                    }
                </td>
                <td>
                    @foreach (var course in item.CourseAssignments)
                    {
                        @course.Course.CourseID @course.Course.Title <br />
                    }
                </td>
                <td>
                    <a asp-action="Index" asp-route-id="@item.ID">Select</a>
|
                    <a asp-action="Edit" asp-route-id="@item.ID">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.ID">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.ID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

You've made the following changes to the existing code:

- Changed the model class to `InstructorIndexData`.
- Changed the page title from **Index** to **Instructors**.
- Added an **Office** column that displays `item.OfficeAssignment.Location` only if `item.OfficeAssignment` isn't null. (Because this is a one-to-zero-or-one relationship, there might not be a related OfficeAssignment entity.)

CSHTML



```
@if (item.OfficeAssignment != null)
{
    @item.OfficeAssignment.Location
}
```

- Added a **Courses** column that displays courses taught by each instructor. For more information, see the Explicit line transition section of the Razor syntax article.
- Added code that conditionally adds a Bootstrap CSS class to the `tr` element of the selected instructor. This class sets a background color for the selected row.
- Added a new hyperlink labeled **Select** immediately before the other links in each row, which causes the selected instructor's ID to be sent to the `Index` method.

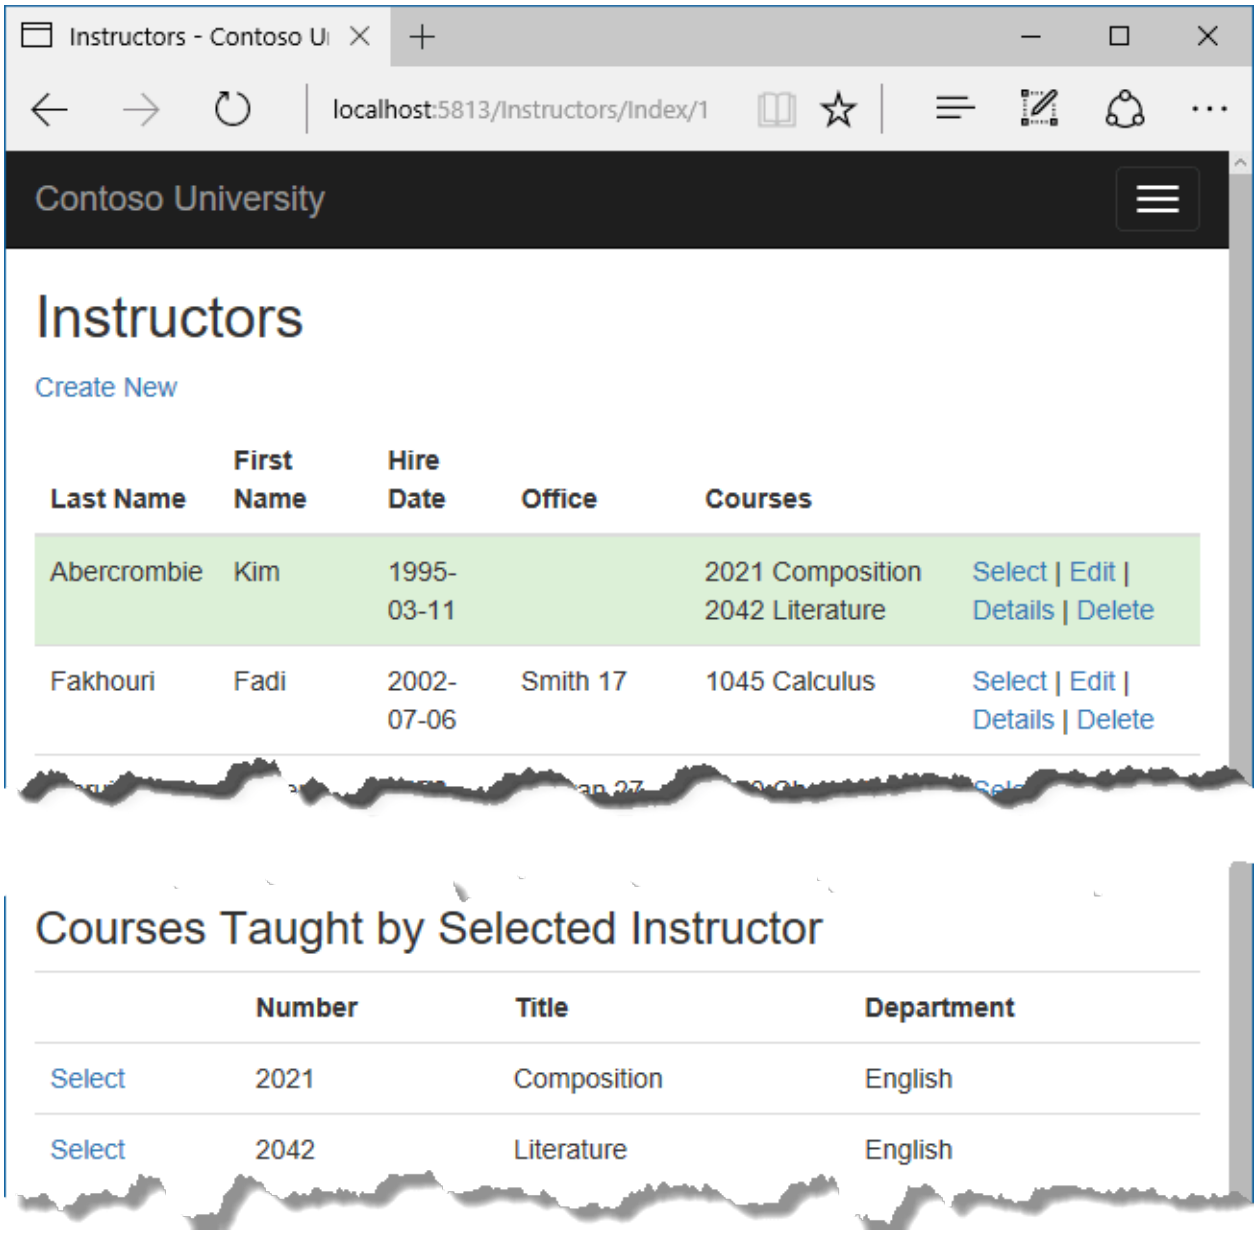
CSHTML

```
<a asp-action="Index" asp-route-id="@item.ID">Select</a> |
```

Run the app and select the **Instructors** tab. The page displays the Location property of related OfficeAssignment entities and an empty table cell when there's no related OfficeAssignment entity.

In the `Views/Instructors/Index.cshtml` file, after the closing table element (at the end of the file), add the following code. This code displays a list of courses related to an instructor when an instructor is selected.

CSHTML



```
@if (Model.Courses != null)
{
    <h3>Courses Taught by Selected Instructor</h3>
    <table class="table">
        <tr>
            <th></th>
            <th>Number</th>
            <th>Title</th>
            <th>Department</th>
        </tr>

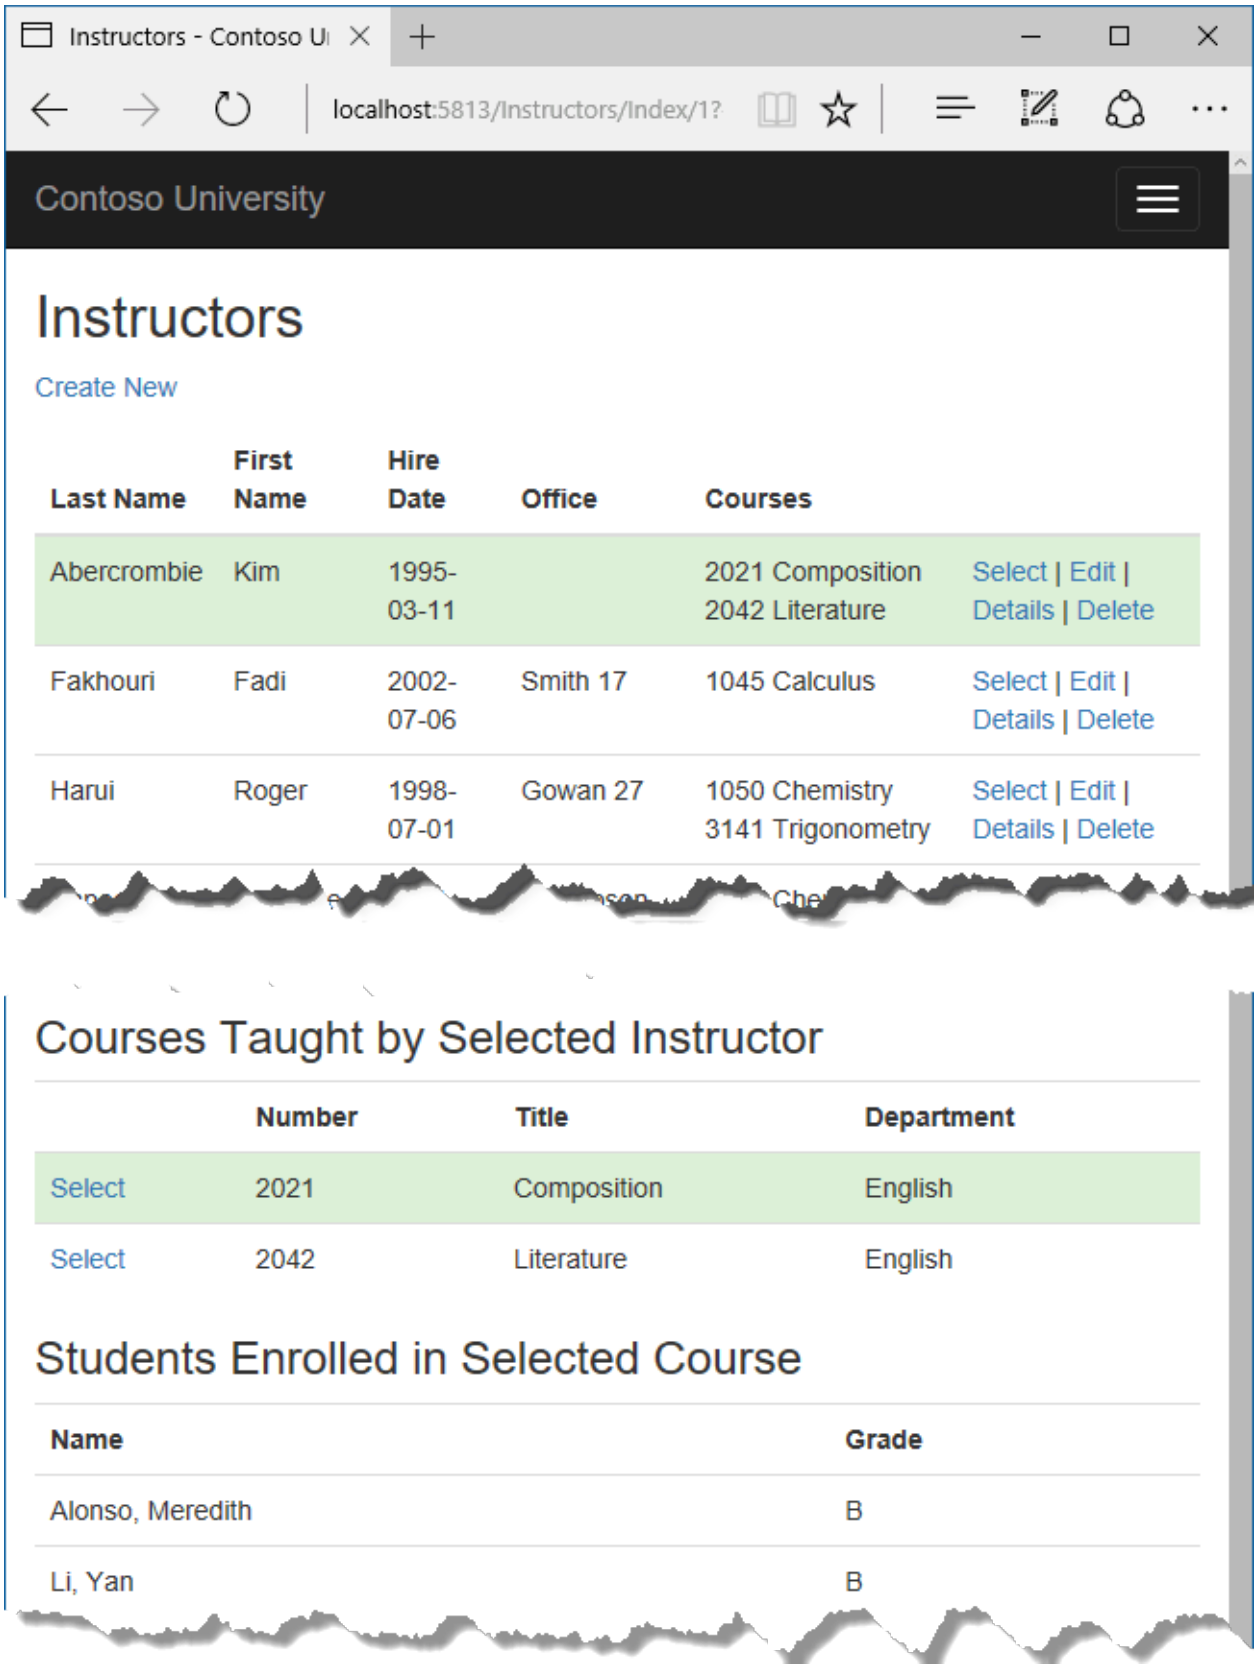
        @foreach (var item in Model.Courses)
        {
            string selectedRow = "";
            if (item.CourseID == (int?)ViewData["CourseID"])
            {
                selectedRow = "success";
            }
            <tr class="@selectedRow">
                <td>
                    @Html.ActionLink("Select", "Index", new { courseID =
item.CourseID })
                </td>
                <td>
                    @item.CourseID
                </td>
                <td>
                    @item.Title
                </td>
                <td>
                    @item.Department.Name
                </td>
            </tr>
        }

    </table>
}
```

This code reads the `Courses` property of the view model to display a list of courses. It also provides a **Select** hyperlink that sends the ID of the selected course to the `Index` action method.

Refresh the page and select an instructor. Now you see a grid that displays courses assigned to the selected instructor, and for each course you see the name of the assigned department.

After the code block you just added, add the following code. This displays a list of the students who are enrolled in a course when that course is selected.



CSHTML

```
@if (Model.Enrollments != null)
{
    <h3>
        Students Enrolled in Selected Course
    </h3>
    <table class="table">
        <tr>
            <th>Name</th>
            <th>Grade</th>
        </tr>
        @foreach (var item in Model.Enrollments)
        {
            <tr>
                <td>
                    @item.Student.FullName
```

```
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Grade)
                </td>
            </tr>
        }
    </table>
}
```

This code reads the `Enrollments` property of the view model in order to display a list of students enrolled in the course.

Refresh the page again and select an instructor. Then select a course to see the list of enrolled students and their grades.

About explicit loading

When you retrieved the list of instructors in `InstructorsController.cs`, you specified eager loading for the `CourseAssignments` navigation property.

Suppose you expected users to only rarely want to see enrollments in a selected instructor and course. In that case, you might want to load the enrollment data only if

it's requested. To see an example of how to do explicit loading, replace the `Index` method with the following code, which removes eager loading for `Enrollments` and loads that property explicitly. The code changes are highlighted.

C#

```
public async Task<IActionResult> Index(int? id, int? courseID)
{
    var viewModel = new InstructorIndexData();
    viewModel.Instructors = await _context.Instructors
          .Include(i => i.OfficeAssignment)
          .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
                .ThenInclude(i => i.Department)
          .OrderBy(i => i.LastName)
          .ToListAsync();

    if (id != null)
    {
        ViewData["InstructorID"] = id.Value;
        Instructor instructor = viewModel.Instructors.Where(
            i => i.ID == id.Value).Single();
        viewModel.Courses = instructor.CourseAssignments.Select(s =>
s.Course);
    }

    if (courseID != null)
    {
        ViewData["CourseID"] = courseID.Value;
        var selectedCourse = viewModel.Courses.Where(x => x.CourseID ==
courseID).Single();
        await _context.Entry(selectedCourse).Collection(x =>
x.Enrollments).LoadAsync();
        foreach (Enrollment enrollment in selectedCourse.Enrollments)
        {
            await _context.Entry(enrollment).Reference(x =>
x.Student).LoadAsync();
        }
        viewModel.Enrollments = selectedCourse.Enrollments;
    }

    return View(viewModel);
}
```

The new code drops the `ThenInclude` method calls for enrollment data from the code that retrieves instructor entities. It also drops `AsNoTracking`. If an instructor and course are selected, the highlighted code retrieves `Enrollment` entities for the selected course, and `Student` entities for each `Enrollment`.

Run the app, go to the Instructors Index page now and you'll see no difference in what's displayed on the page, although you've changed how the data is retrieved.

Get the code

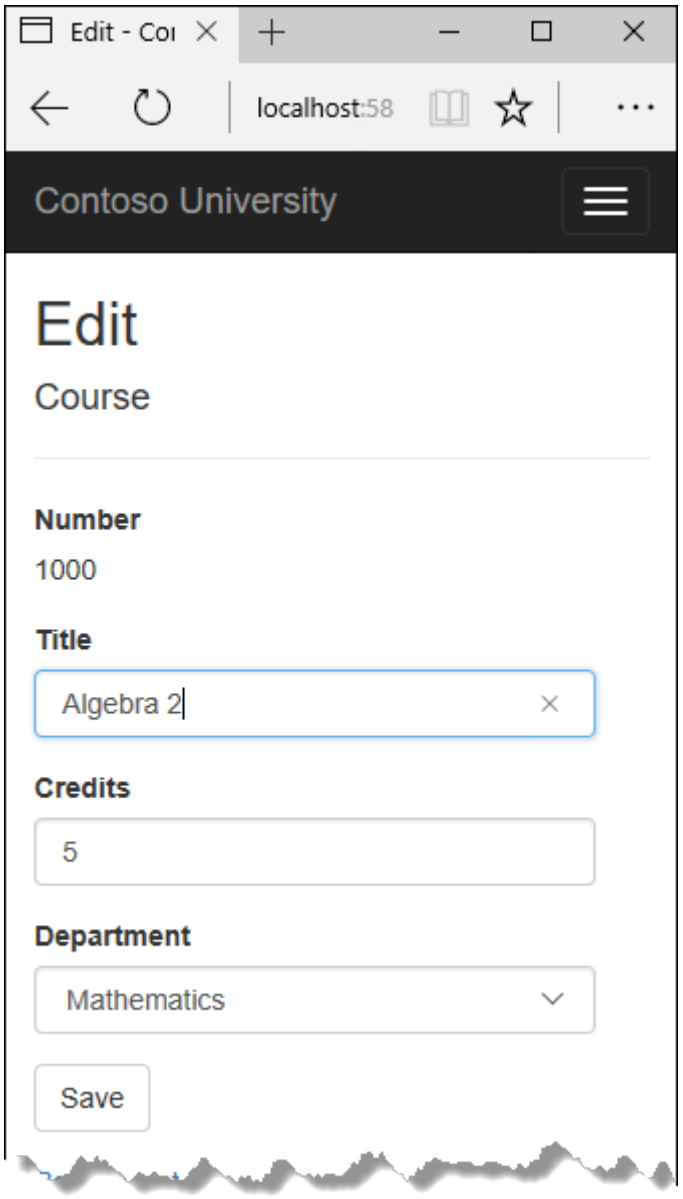
Download or view the completed application.

Next steps

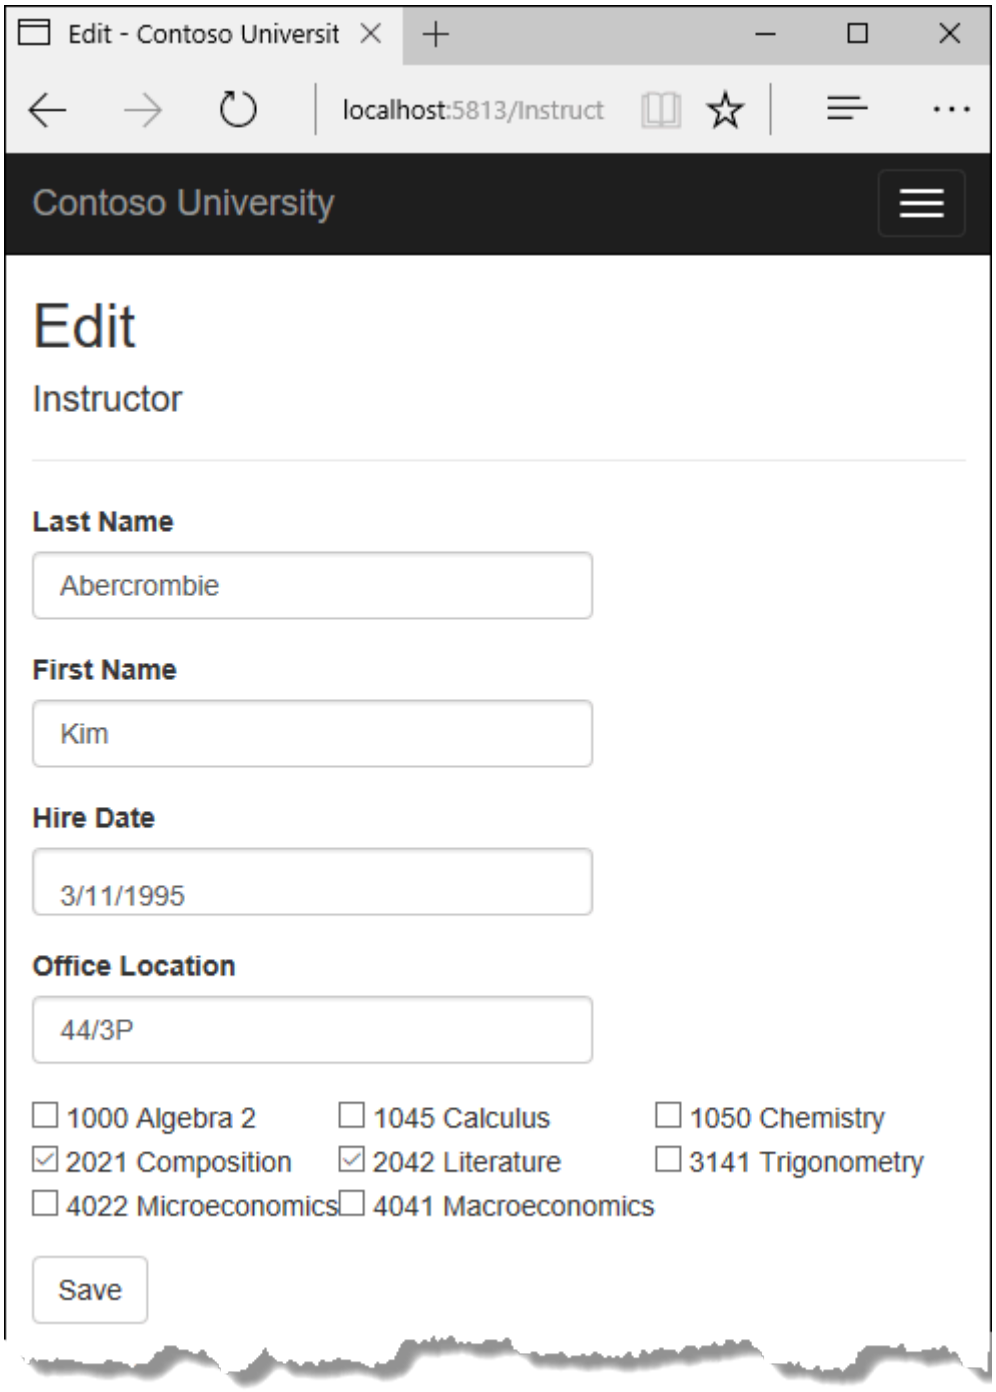
In this tutorial, you:

- ✓ Learned how to load related data
- ✓ Created a Courses page
- ✓ Created an Instructors page
- ✓ Learned about explicit loading

Advance to the next tutorial to learn how to update related data.



Update related data



Tutorial: Update related data - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorial you displayed related data; in this tutorial you'll update related data by updating foreign key fields and navigation properties.

The following illustrations show some of the pages that you'll work with.

In this tutorial, you:

- ✓ Customize Courses pages
- ✓ Add Instructors Edit page
- ✓ Add courses to Edit page
- ✓ Update Delete page
- ✓ Add office location and courses to Create page

Prerequisites

- Read related data

Customize Courses pages

When a new `Course` entity is created, it must have a relationship to an existing department. To facilitate this, the scaffolded code includes controller methods and Create and Edit views that include a drop-down list for selecting the department. The drop-down list sets the `Course.DepartmentID` foreign key property, and that's all the Entity Framework needs in order to load the `Department` navigation property with the appropriate `Department` entity. You'll use the scaffolded code, but change it slightly to add error handling and sort the drop-down list.

In `CoursesController.cs`, delete the four Create and Edit methods and replace them with the following code:

C#

```
public IActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}
```

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult>
Create([Bind("CourseID,Credits,DepartmentID,Title")] Course course)
{
    if (ModelState.IsValid)
    {
        _context.Add(course);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

C#

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }
```

```
    var course = await _context.Courses
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

C#

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var courseToUpdate = await _context.Courses
        .FirstOrDefaultAsync(c => c.CourseID == id);

    if (await TryUpdateModelAsync<Course>(courseToUpdate,
        "",
        c => c.Credits, c => c.DepartmentID, c => c.Title))
    {
        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
        return RedirectToAction(nameof(Index));
    }
    PopulateDepartmentsDropDownList(courseToUpdate.DepartmentID);
    return View(courseToUpdate);
}
```

After the `Edit` HttpPost method, create a new method that loads department info for the drop-down list.

C#

```
private void PopulateDepartmentsDropDownList(object selectedDepartment =
null)
{
    var departmentsQuery = from d in _context.Departments
                           orderby d.Name
                           select d;
    ViewBag.DepartmentID = new SelectList(departmentsQuery.AsNoTracking(),
"DepartmentID", "Name", selectedDepartment);
}
```

The `PopulateDepartmentsDropDownList` method gets a list of all departments sorted by name, creates a `SelectList` collection for a drop-down list, and passes the collection to the view in `ViewBag`. The method accepts the optional `selectedDepartment` parameter that allows the calling code to specify the item that will be selected when the drop-down list is rendered. The view will pass the name "DepartmentID" to the `<select>` tag helper, and the helper then knows to look in the `ViewBag` object for a `SelectList` named "DepartmentID".

The HttpGet `Create` method calls the `PopulateDepartmentsDropDownList` method without setting the selected item, because for a new course the department isn't established yet:

C#

```
public IActionResult Create()
{
    PopulateDepartmentsDropDownList();
    return View();
}
```

The HttpGet `Edit` method sets the selected item, based on the ID of the department that's already assigned to the course being edited:

C#

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
```

```
    }
    PopulateDepartmentsDropDownList(course.DepartmentID);
    return View(course);
}
```

The HttpPost methods for both `Create` and `Edit` also include code that sets the selected item when they redisplay the page after an error. This ensures that when the page is redisplayed to show the error message, whatever department was selected stays selected.

Add .AsNoTracking to Details and Delete methods

To optimize performance of the Course Details and Delete pages, add `AsNoTracking` calls in the `Details` and HttpGet `Delete` methods.

C#

```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
    if (course == null)
    {
        return NotFound();
    }

    return View(course);
}
```

C#

```
public async Task<IActionResult> Delete(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var course = await _context.Courses
        .Include(c => c.Department)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.CourseID == id);
```

```
    if (course == null)
    {
        return NotFound();
    }

    return View(course);
}
```

Modify the Course views

In `Views/Courses/Create.cshtml`, add a "Select Department" option to the **Department** drop-down list, change the caption from **DepartmentID** to **Department**, and add a validation message.

CSHTML

```
<div class="form-group">
    <label asp-for="Department" class="control-label"></label>
    <select asp-for="DepartmentID" class="form-control" asp-
items="ViewBag.DepartmentID">
        <option value="">-- Select Department --</option>
    </select>
    <span asp-validation-for="DepartmentID" class="text-danger" />
</div>
```

In `Views/Courses/Edit.cshtml`, make the same change for the Department field that you just did in `Create.cshtml`.

Also in `Views/Courses/Edit.cshtml`, add a course number field before the **Title** field. Because the course number is the primary key, it's displayed, but it can't be changed.

CSHTML

```
<div class="form-group">
    <label asp-for="CourseID" class="control-label"></label>
    <div>@Html.DisplayFor(model => model.CourseID)</div>
</div>
```

There's already a hidden field (`<input type="hidden">`) for the course number in the Edit view. Adding a `<label>` tag helper doesn't eliminate the need for the hidden field because it doesn't cause the course number to be included in the posted data when the user clicks **Save** on the **Edit** page.

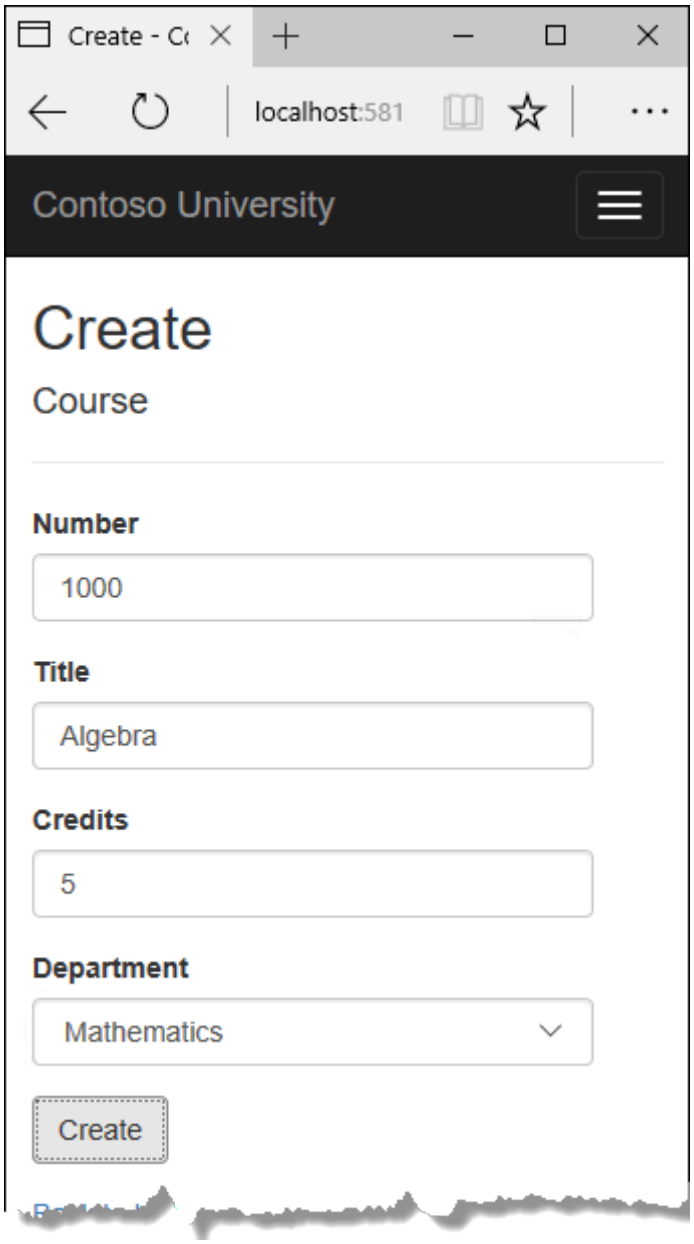
In `Views/Courses/Delete.cshtml`, add a course number field at the top and change department ID to department name.

CSHTML

```
@model ContosoUniversity.Models.Course

@{
    ViewData["Title"] = "Delete";
}

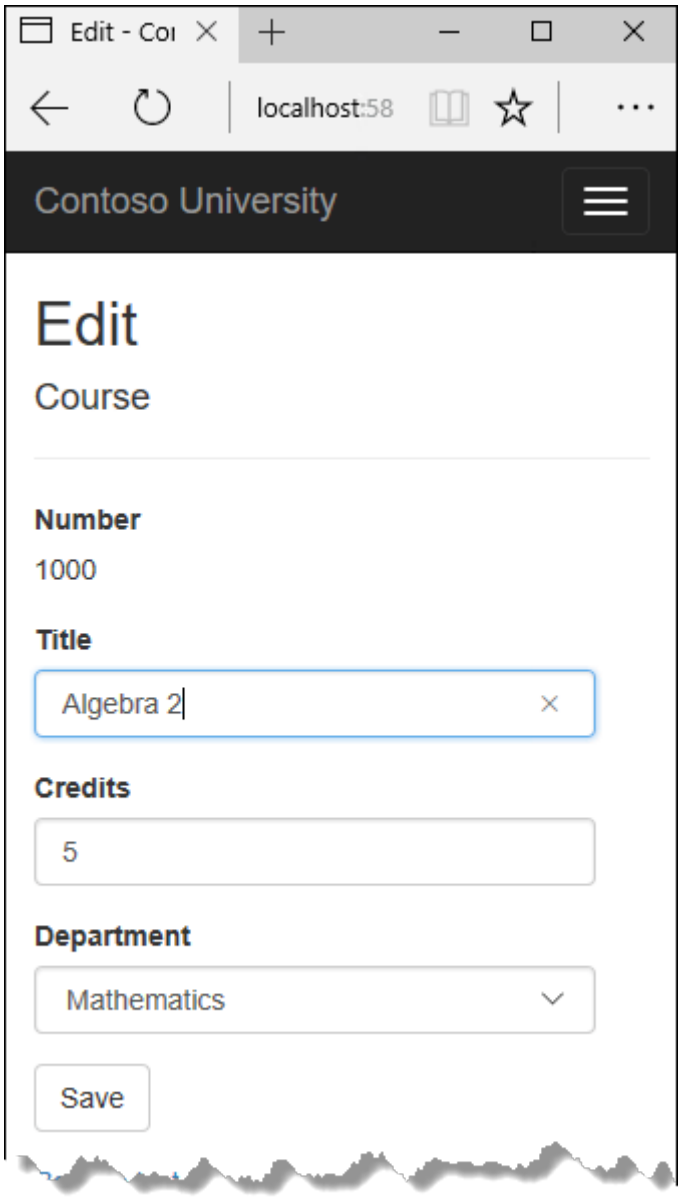
<h2>Delete</h2>



<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Course</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.CourseID)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.CourseID)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Title)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Title)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Credits)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Credits)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Department)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Department.Name)
        </dd>
    </dl>

    <form asp-action="Delete">
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            <a asp-action="Index">Back to List</a>
        </div>
    </form>
</div>
```

In `Views/Courses/Details.cshtml`, make the same change that you just did for `Delete.cshtml`.



Test the Course pages

Run the app, select the **Courses** tab, click **Create New**, and enter data for a new course:

Click **Create**. The Courses Index page is displayed with the new course added to the list. The department name in the Index page list comes from the navigation property, showing that the relationship was established correctly.

Click **Edit** on a course in the Courses Index page.

Change data on the page and click **Save**. The Courses Index page is displayed with the updated course data.

Add Instructors Edit page

When you edit an instructor record, you want to be able to update the instructor's office assignment. The `Instructor` entity has a one-to-zero-or-one relationship with the `OfficeAssignment` entity, which means your code has to handle the following situations:

- If the user clears the office assignment and it originally had a value, delete the `OfficeAssignment` entity.
- If the user enters an office assignment value and it originally was empty, create a new `OfficeAssignment` entity.
- If the user changes the value of an office assignment, change the value in an existing `OfficeAssignment` entity.

Update the Instructors controller

In `InstructorsController.cs`, change the code in the HttpGet `Edit` method so that it loads the Instructor entity's `OfficeAssignment` navigation property and calls `AsNoTracking`:

C#

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructor = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (instructor == null)
    {
        return NotFound();
    }
    return View(instructor);
}
```

Replace the HttpPost `Edit` method with the following code to handle office assignment updates:

C#

```
[HttpPost, ActionName("Edit")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> EditPost(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructorToUpdate = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .FirstOrDefaultAsync(s => s.ID == id);

    if (await TryUpdateModelAsync<Instructor>(
        instructorToUpdate,
        "",
        i => i.FirstMidName, i => i.LastName, i => i.HireDate, i =>
i.OfficeAssignment))
    {
```

```
        if
(String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Location))
        {
            instructorToUpdate.OfficeAssignment = null;
        }
        try
        {
            await _context.SaveChangesAsync();
        }
        catch (DbUpdateException /* ex */)
        {
            //Log the error (uncomment ex variable name and write a log.)
            ModelState.AddModelError("", "Unable to save changes. " +
                "Try again, and if the problem persists, " +
                "see your system administrator.");
        }
        return RedirectToAction(nameof(Index));
    }
    return View(instructorToUpdate);
}
```

The code does the following:

- Changes the method name to `EditPost` because the signature is now the same as the HttpGet `Edit` method (the `ActionName` attribute specifies that the `/Edit/` URL is still used).
- Gets the current `Instructor` entity from the database using eager loading for the `OfficeAssignment` navigation property. This is the same as what you did in the HttpGet `Edit` method.
- Updates the retrieved `Instructor` entity with values from the model binder. The `TryUpdateModel` overload enables you to declare the properties you want to include. This prevents over-posting, as explained in the second tutorial.

  C#

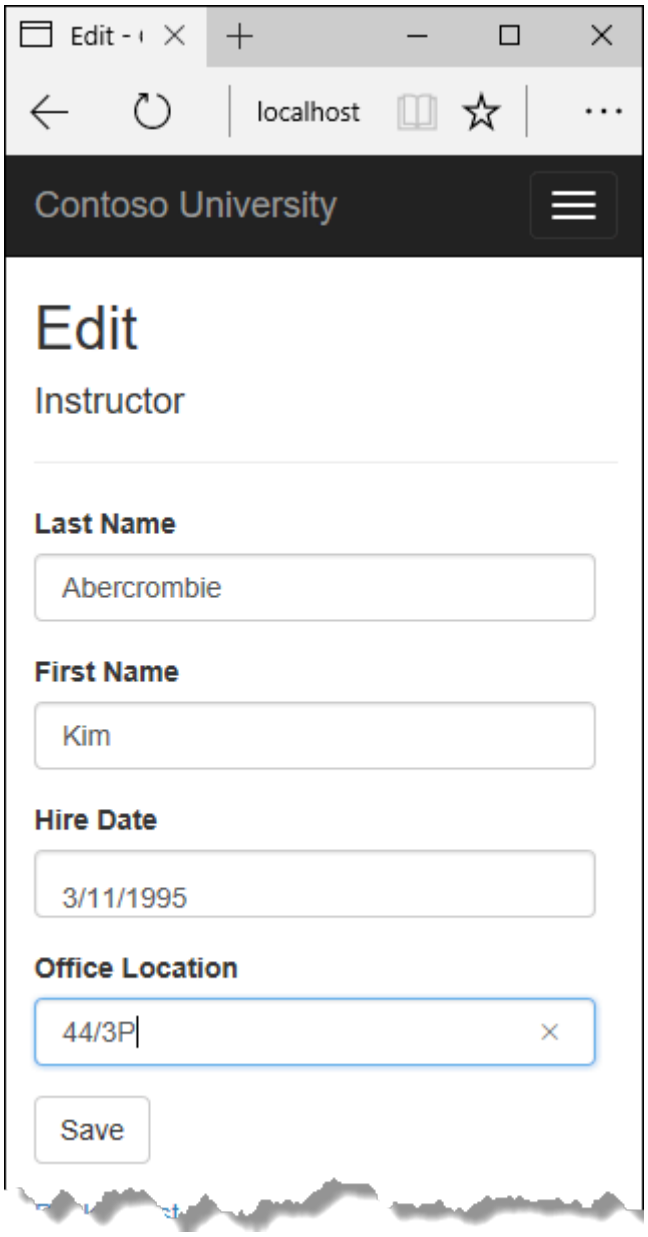
  ```
  if (await TryUpdateModelAsync<Instructor>(
      instructorToUpdate,
      "",
      i => i.FirstMidName, i => i.LastName, i => i.HireDate, i =>
  i.OfficeAssignment))
  ```

- If the office location is blank, sets the `Instructor.OfficeAssignment` property to null so that the related row in the `OfficeAssignment` table will be deleted.

  C#

```
if
(String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Locatio
n))
{
    instructorToUpdate.OfficeAssignment = null;
}
```

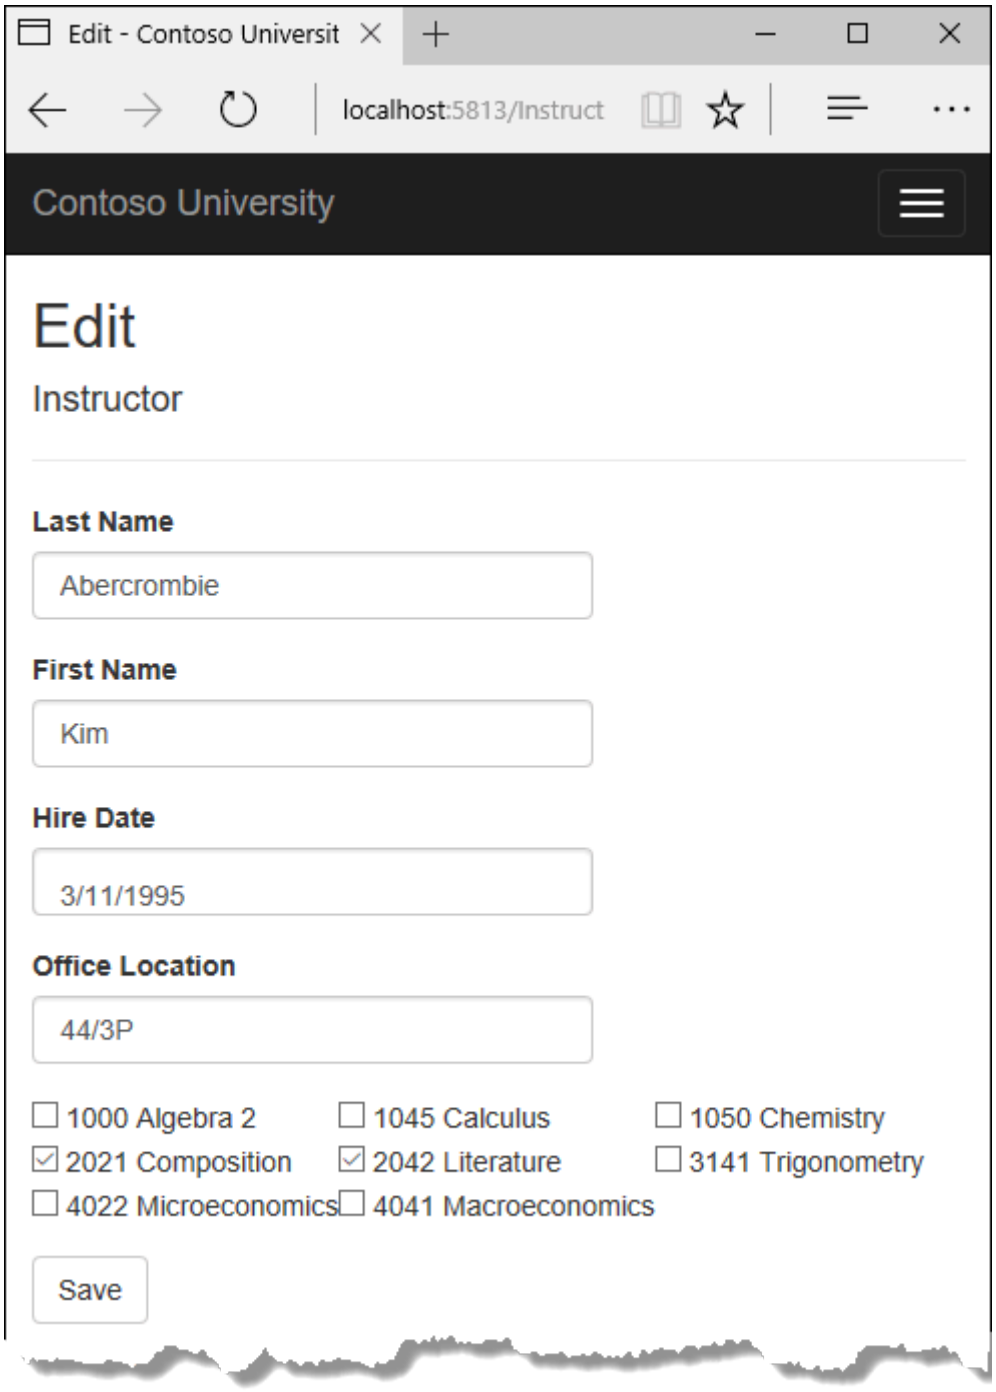
- Saves the changes to the database.



Update the Instructor Edit view

In `Views/Instructors/Edit.cshtml`, add a new field for editing the office location, at the end before the **Save** button:

CSHTML



```
<div class="form-group">
    <label asp-for="OfficeAssignment.Location" class="control-label">
</label>
    <input asp-for="OfficeAssignment.Location" class="form-control" />
    <span asp-validation-for="OfficeAssignment.Location" class="text-danger"
/>
</div>
```

Run the app, select the **Instructors** tab, and then click **Edit** on an instructor. Change the **Office Location** and click **Save**.

Add courses to Edit page

Instructors may teach any number of courses. Now you'll enhance the Instructor Edit page by adding the ability to change course assignments using a group of checkboxes, as shown in the following screen shot:

The relationship between the `Course` and `Instructor` entities is many-to-many. To add and remove relationships, you add and remove entities to and from the `CourseAssignments` join entity set.

The UI that enables you to change which courses an instructor is assigned to is a group of checkboxes. A checkbox for every course in the database is displayed, and the ones that the instructor is currently assigned to are selected. The user can select or clear checkboxes to change course assignments. If the number of courses were much greater, you would probably want to use a different method of presenting the data in the view, but you'd use the same method of manipulating a join entity to create or delete relationships.

Update the Instructors controller

To provide data to the view for the list of checkboxes, you'll use a view model class.

Create `AssignedCourseData.cs` in the *SchoolViewModels* folder and replace the existing code with the following code:

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;

namespace ContosoUniversity.Models.SchoolViewModels
{
    public class AssignedCourseData
    {
        public int CourseID { get; set; }
        public string Title { get; set; }
        public bool Assigned { get; set; }
    }
}
```

In `InstructorsController.cs`, replace the HttpGet `Edit` method with the following code. The changes are highlighted.

C#

```
public async Task<IActionResult> Edit(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructor = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.CourseAssignments).ThenInclude(i => i.Course)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.ID == id);
    if (instructor == null)
    {
        return NotFound();
    }
    PopulateAssignedCourseData(instructor);
    return View(instructor);
}

private void PopulateAssignedCourseData(Instructor instructor)
{
```

```
    var allCourses = _context.Courses;
    var instructorCourses = new HashSet<int>
(instructor.CourseAssignments.Select(c => c.CourseID));
    var viewModel = new List<AssignedCourseData>();
    foreach (var course in allCourses)
    {
        viewModel.Add(new AssignedCourseData
        {
            CourseID = course.CourseID,
            Title = course.Title,
            Assigned = instructorCourses.Contains(course.CourseID)
        });
    }
    ViewData["Courses"] = viewModel;
}
```

The code adds eager loading for the `Courses` navigation property and calls the new `PopulateAssignedCourseData` method to provide information for the checkbox array using the `AssignedCourseData` view model class.

The code in the `PopulateAssignedCourseData` method reads through all `Course` entities in order to load a list of courses using the view model class. For each course, the code checks whether the course exists in the instructor's `Courses` navigation property. To create efficient lookup when checking whether a course is assigned to the instructor, the courses assigned to the instructor are put into a `HashSet` collection. The `Assigned` property is set to true for courses the instructor is assigned to. The view will use this property to determine which checkboxes must be displayed as selected. Finally, the list is passed to the view in `ViewData`.

Next, add the code that's executed when the user clicks **Save**. Replace the `EditPost` method with the following code, and add a new method that updates the `Courses` navigation property of the Instructor entity.

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int? id, string[] selectedCourses)
{
    if (id == null)
    {
        return NotFound();
    }

    var instructorToUpdate = await _context.Instructors
        .Include(i => i.OfficeAssignment)
        .Include(i => i.CourseAssignments)
            .ThenInclude(i => i.Course)
```

```
            .FirstOrDefaultAsync(m => m.ID == id);

        if (await TryUpdateModelAsync<Instructor>(
            instructorToUpdate,
            "",
            i => i.FirstMidName, i => i.LastName, i => i.HireDate, i =>
i.OfficeAssignment))
        {
            if
(String.IsNullOrWhiteSpace(instructorToUpdate.OfficeAssignment?.Location))
            {
                instructorToUpdate.OfficeAssignment = null;
            }
            UpdateInstructorCourses(selectedCourses, instructorToUpdate);
            try
            {
                await _context.SaveChangesAsync();
            }
            catch (DbUpdateException /* ex */)
            {
                //Log the error (uncomment ex variable name and write a log.)
                ModelState.AddModelError("", "Unable to save changes. " +
                    "Try again, and if the problem persists, " +
                    "see your system administrator.");
            }
            return RedirectToAction(nameof(Index));
        }
        UpdateInstructorCourses(selectedCourses, instructorToUpdate);
        PopulateAssignedCourseData(instructorToUpdate);
        return View(instructorToUpdate);
    }
```

C#

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor
instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c =>
c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new
CourseAssignment { InstructorID = instructorToUpdate.ID, CourseID =
course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove =
instructorToUpdate.CourseAssignments.FirstOrDefault(i => i.CourseID ==
course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

The method signature is now different from the HttpGet `Edit` method, so the method name changes from `EditPost` back to `Edit`.

Since the view doesn't have a collection of Course entities, the model binder can't automatically update the `CourseAssignments` navigation property. Instead of using the model binder to update the `CourseAssignments` navigation property, you do that in the new `UpdateInstructorCourses` method. Therefore, you need to exclude the `CourseAssignments` property from model binding. This doesn't require any change to the code that calls `TryUpdateModel` because you're using the overload that requires explicit approval and `CourseAssignments` isn't in the include list.

If no checkboxes were selected, the code in `UpdateInstructorCourses` initializes the `CourseAssignments` navigation property with an empty collection and returns:

C#

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor
instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c =>
c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new
CourseAssignment { InstructorID = instructorToUpdate.ID, CourseID =
course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove =
instructorToUpdate.CourseAssignments.FirstOrDefault(i => i.CourseID ==
course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

The code then loops through all courses in the database and checks each course against the ones currently assigned to the instructor versus the ones that were selected in the view. To facilitate efficient lookups, the latter two collections are stored in `HashSet` objects.

If the checkbox for a course was selected but the course isn't in the `Instructor.CourseAssignments` navigation property, the course is added to the collection

in the navigation property.

C#

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor
instructorToUpdate)
{
    if (selectedCourses == null)
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c =>
c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new
CourseAssignment { InstructorID = instructorToUpdate.ID, CourseID =
course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove =
instructorToUpdate.CourseAssignments.FirstOrDefault(i => i.CourseID ==
course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

If the checkbox for a course wasn't selected, but the course is in the `Instructor.CourseAssignments` navigation property, the course is removed from the navigation property.

C#

```
private void UpdateInstructorCourses(string[] selectedCourses, Instructor
instructorToUpdate)
{
    if (selectedCourses == null)
```

```
    {
        instructorToUpdate.CourseAssignments = new List<CourseAssignment>();
        return;
    }

    var selectedCoursesHS = new HashSet<string>(selectedCourses);
    var instructorCourses = new HashSet<int>
        (instructorToUpdate.CourseAssignments.Select(c =>
c.Course.CourseID));
    foreach (var course in _context.Courses)
    {
        if (selectedCoursesHS.Contains(course.CourseID.ToString()))
        {
            if (!instructorCourses.Contains(course.CourseID))
            {
                instructorToUpdate.CourseAssignments.Add(new
CourseAssignment { InstructorID = instructorToUpdate.ID, CourseID =
course.CourseID });
            }
        }
        else
        {

            if (instructorCourses.Contains(course.CourseID))
            {
                CourseAssignment courseToRemove =
instructorToUpdate.CourseAssignments.FirstOrDefault(i => i.CourseID ==
course.CourseID);
                _context.Remove(courseToRemove);
            }
        }
    }
}
```

Update the Instructor views

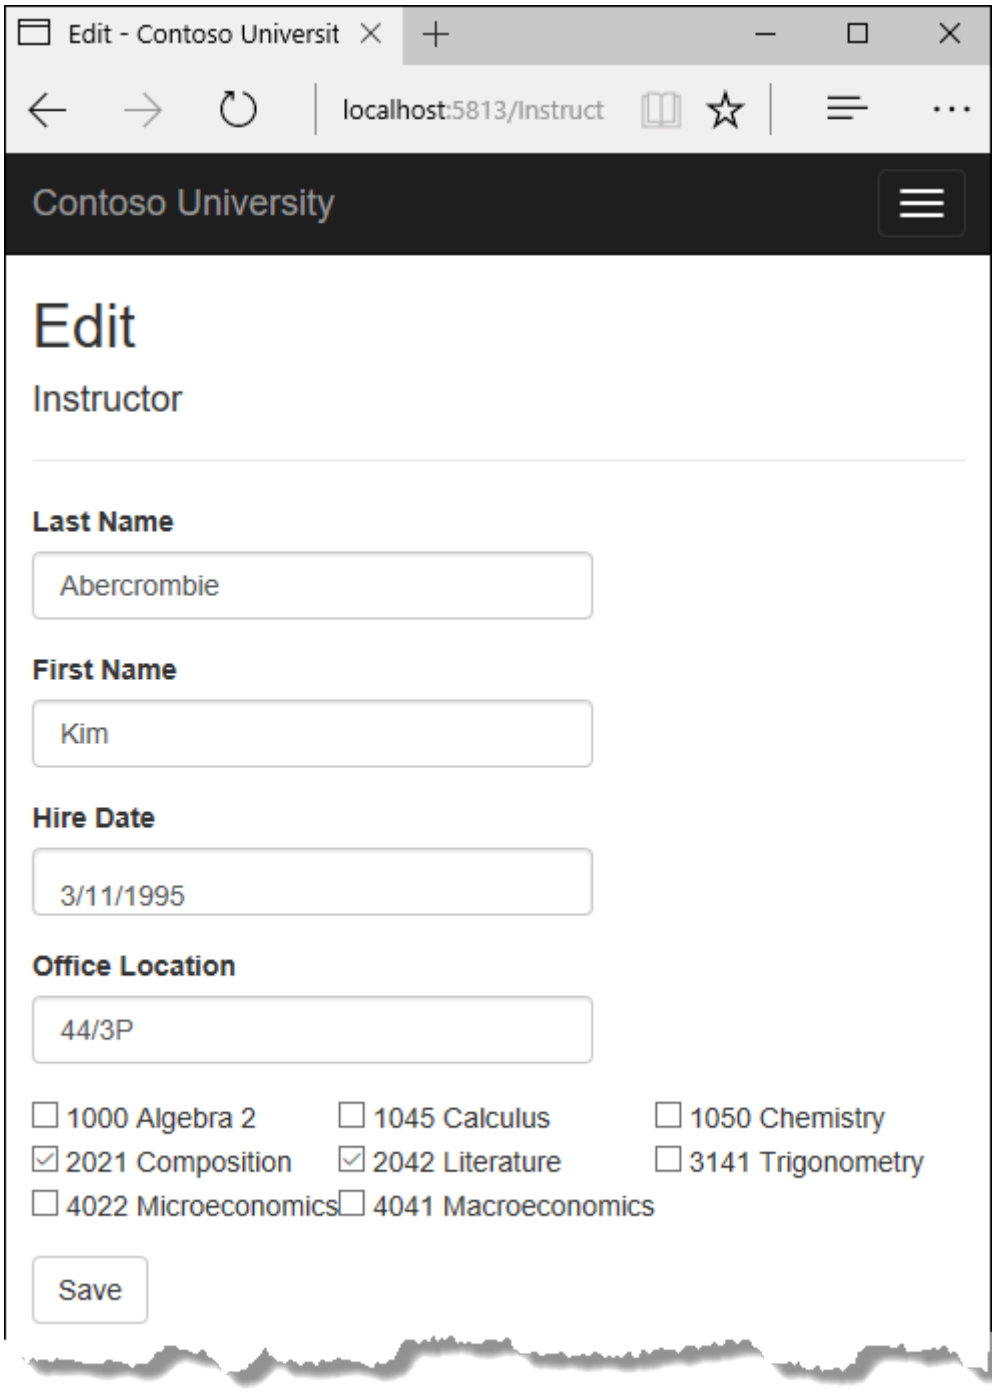
In `Views/Instructors/Edit.cshtml`, add a **Courses** field with an array of checkboxes by adding the following code immediately after the `div` elements for the **Office** field and before the `div` element for the **Save** button.

> ⓘ Note
>
> When you paste the code in Visual Studio, line breaks might be changed in a way that breaks the code. If the code looks different after pasting, press Ctrl+Z one time to undo the automatic formatting. This will fix the line breaks so that they look like what you see here. The indentation doesn't have to be perfect, but the `@:</tr><tr>`, `@:<td>`, `@:</td>`, and `@:</tr>` lines must each be on a single line as shown or you'll get a runtime error. With the block of new code selected, press Tab three

times to line up the new code with the existing code. This problem is fixed in Visual Studio 2019.

CSHTML

```
<div class="form-group">
    <div class="col-md-offset-2 col-md-10">
        <table>
            <tr>
                @{
                    int cnt = 0;



List<ContosoUniversity.Models.SchoolViewModels.AssignedCourseData> courses =
ViewBag.Courses;

                    foreach (var course in courses)
                    {
                        if (cnt++ % 3 == 0)
                        {
                            @:</tr><tr>
                        }
                        @:<td>
                            <input type="checkbox"
                                   name="selectedCourses"
                                   value="@course.CourseID"
                                   @(Html.Raw(course.Assigned ?
"checked=\"checked\"" : "")) />
                                   @course.CourseID @:  @course.Title
                        @:</td>
                    }
                    @:</tr>
                }
        </table>
    </div>
</div>
```

This code creates an HTML table that has three columns. In each column is a checkbox followed by a caption that consists of the course number and title. The checkboxes all have the same name ("selectedCourses"), which informs the model binder that they're to be treated as a group. The value attribute of each checkbox is set to the value of `CourseID`. When the page is posted, the model binder passes an array to the controller that consists of the `CourseID` values for only the checkboxes which are selected.

When the checkboxes are initially rendered, those that are for courses assigned to the instructor have checked attributes, which selects them (displays them checked).

Run the app, select the **Instructors** tab, and click **Edit** on an instructor to see the **Edit** page.

Change some course assignments and click Save. The changes you make are reflected on the Index page.

> ⓘ **Note**
>
> The approach taken here to edit instructor course data works well when there's a limited number of courses. For collections that are much larger, a different UI and a different updating method would be required.

Update Delete page

In `InstructorsController.cs`, delete the `DeleteConfirmed` method and insert the following code in its place.

```
C#

[HttpPost, ActionName("Delete")]
[ValidateAntiForgeryToken]
public async Task<IActionResult> DeleteConfirmed(int id)
{
    Instructor instructor = await _context.Instructors
        .Include(i => i.CourseAssignments)
        .SingleAsync(i => i.ID == id);

    var departments = await _context.Departments
        .Where(d => d.InstructorID == id)
        .ToListAsync();
    departments.ForEach(d => d.InstructorID = null);

    _context.Instructors.Remove(instructor);

    await _context.SaveChangesAsync();
    return RedirectToAction(nameof(Index));
}
```

This code makes the following changes:

- Does eager loading for the `CourseAssignments` navigation property. You have to include this or EF won't know about related `CourseAssignment` entities and won't delete them. To avoid needing to read them here you could configure cascade delete in the database.
- If the instructor to be deleted is assigned as administrator of any departments, removes the instructor assignment from those departments.

Add office location and courses to Create page

In `InstructorsController.cs`, delete the HttpGet and HttpPost `Create` methods, and then add the following code in their place:

```
C#

public IActionResult Create()
{
    var instructor = new Instructor();
    instructor.CourseAssignments = new List<CourseAssignment>();
    PopulateAssignedCourseData(instructor);
    return View();
}
```

```
// POST: Instructors/Create
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult>
Create([Bind("FirstMidName,HireDate,LastName,OfficeAssignment")] Instructor
instructor, string[] selectedCourses)
{
    if (selectedCourses != null)
    {
        instructor.CourseAssignments = new List<CourseAssignment>();
        foreach (var course in selectedCourses)
        {
            var courseToAdd = new CourseAssignment { InstructorID =
instructor.ID, CourseID = int.Parse(course) };
            instructor.CourseAssignments.Add(courseToAdd);
        }
    }
    if (ModelState.IsValid)
    {
        _context.Add(instructor);
        await _context.SaveChangesAsync();
        return RedirectToAction(nameof(Index));
    }
    PopulateAssignedCourseData(instructor);
    return View(instructor);
}
```

This code is similar to what you saw for the `Edit` methods except that initially no courses are selected. The HttpGet `Create` method calls the `PopulateAssignedCourseData` method not because there might be courses selected but in order to provide an empty collection for the `foreach` loop in the view (otherwise the view code would throw a null reference exception).

The HttpPost `Create` method adds each selected course to the `CourseAssignments` navigation property before it checks for validation errors and adds the new instructor to the database. Courses are added even if there are model errors so that when there are model errors (for an example, the user keyed an invalid date), and the page is redisplayed with an error message, any course selections that were made are automatically restored.

Notice that in order to be able to add courses to the `CourseAssignments` navigation property you have to initialize the property as an empty collection:

C#

```
instructor.CourseAssignments = new List<CourseAssignment>();
```

As an alternative to doing this in controller code, you could do it in the `Instructor` model by changing the property getter to automatically create the collection if it doesn't exist, as shown in the following example:

C#

```
private ICollection<CourseAssignment> _courseAssignments;
public ICollection<CourseAssignment> CourseAssignments
{
    get
    {
        return _courseAssignments ?? (_courseAssignments = new
List<CourseAssignment>());
    }
    set
    {
        _courseAssignments = value;
    }
}
```

If you modify the `CourseAssignments` property in this way, you can remove the explicit property initialization code in the controller.

In `Views/Instructor/Create.cshtml`, add an office location text box and checkboxes for courses before the Submit button. As in the case of the Edit page, fix the formatting if Visual Studio reformats the code when you paste it.

CSHTML

```
<div class="form-group">
    <label asp-for="OfficeAssignment.Location" class="control-label">
</label>
    <input asp-for="OfficeAssignment.Location" class="form-control" />
    <span asp-validation-for="OfficeAssignment.Location" class="text-danger"
/>
</div>

<div class="form-group">
    <div class="col-md-offset-2 col-md-10">
        <table>
            <tr>
                @{
                    int cnt = 0;

List<ContosoUniversity.Models.SchoolViewModels.AssignedCourseData> courses =
ViewBag.Courses;

                    foreach (var course in courses)
                    {
                        if (cnt++ % 3 == 0)
```

```
                        {
                            @:</tr><tr>
                        }
                        @:<td>
                            <input type="checkbox"
                                   name="selectedCourses"
                                   value="@course.CourseID"
                                   @(Html.Raw(course.Assigned ?
"checked=\"checked\"" : "")) />
                                   @course.CourseID @:  @course.Title
                            @:</td>
                    }
                    @:</tr>
                }
        </table>
    </div>
</div>
```

Test by running the app and creating an instructor.

Handling Transactions

As explained in the CRUD tutorial, the Entity Framework implicitly implements transactions. For scenarios where you need more control -- for example, if you want to include operations done outside of Entity Framework in a transaction -- see Transactions.

Get the code

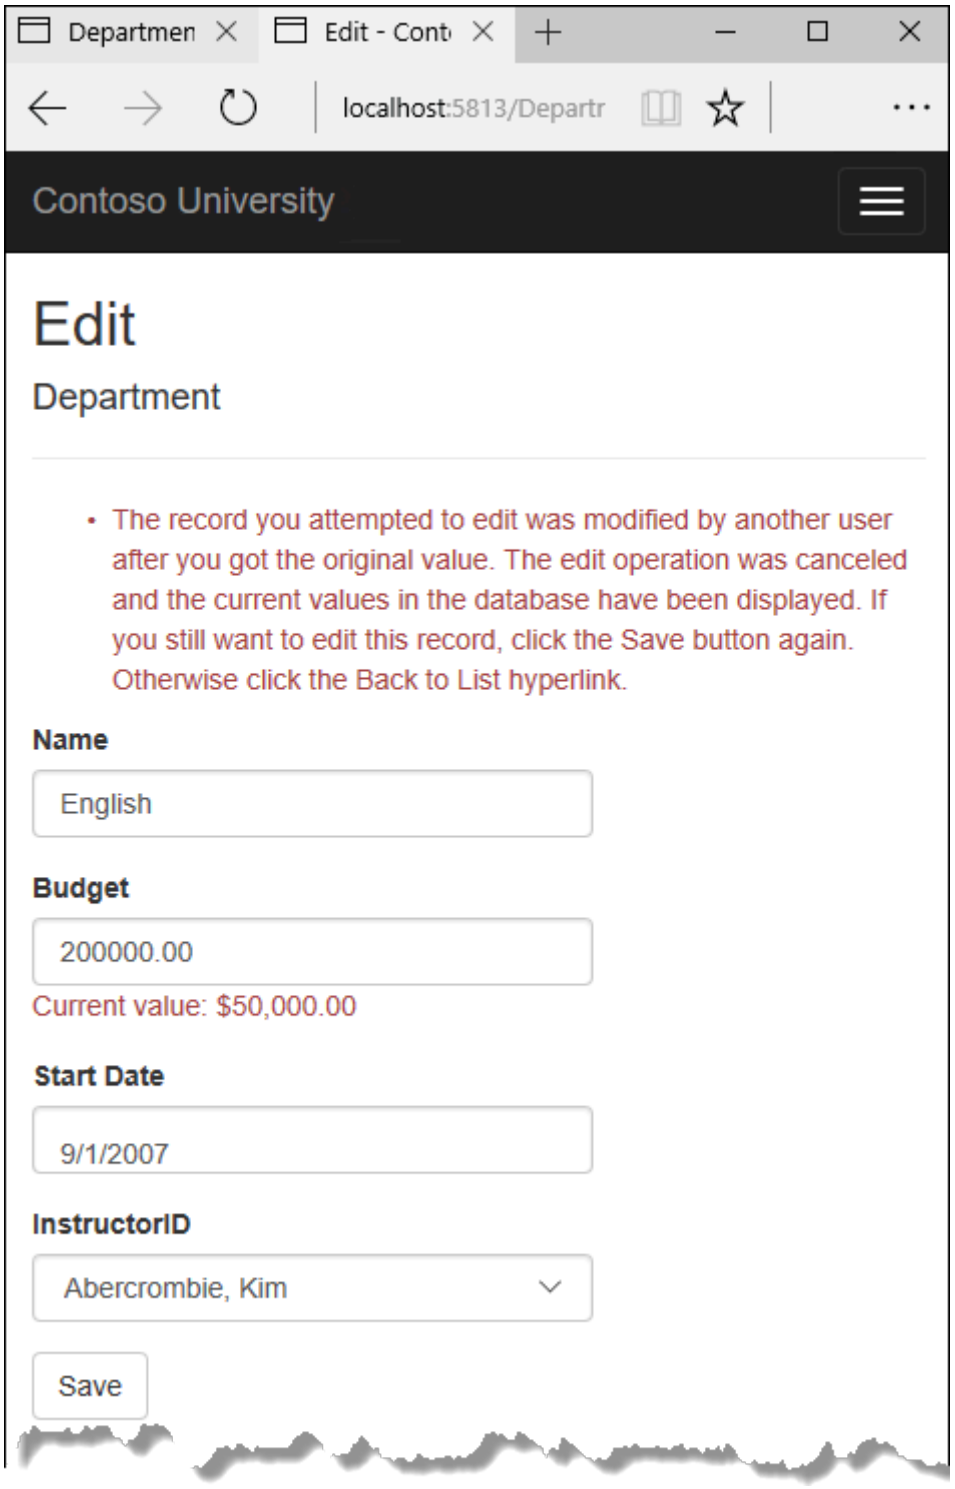
Download or view the completed application.

Next steps

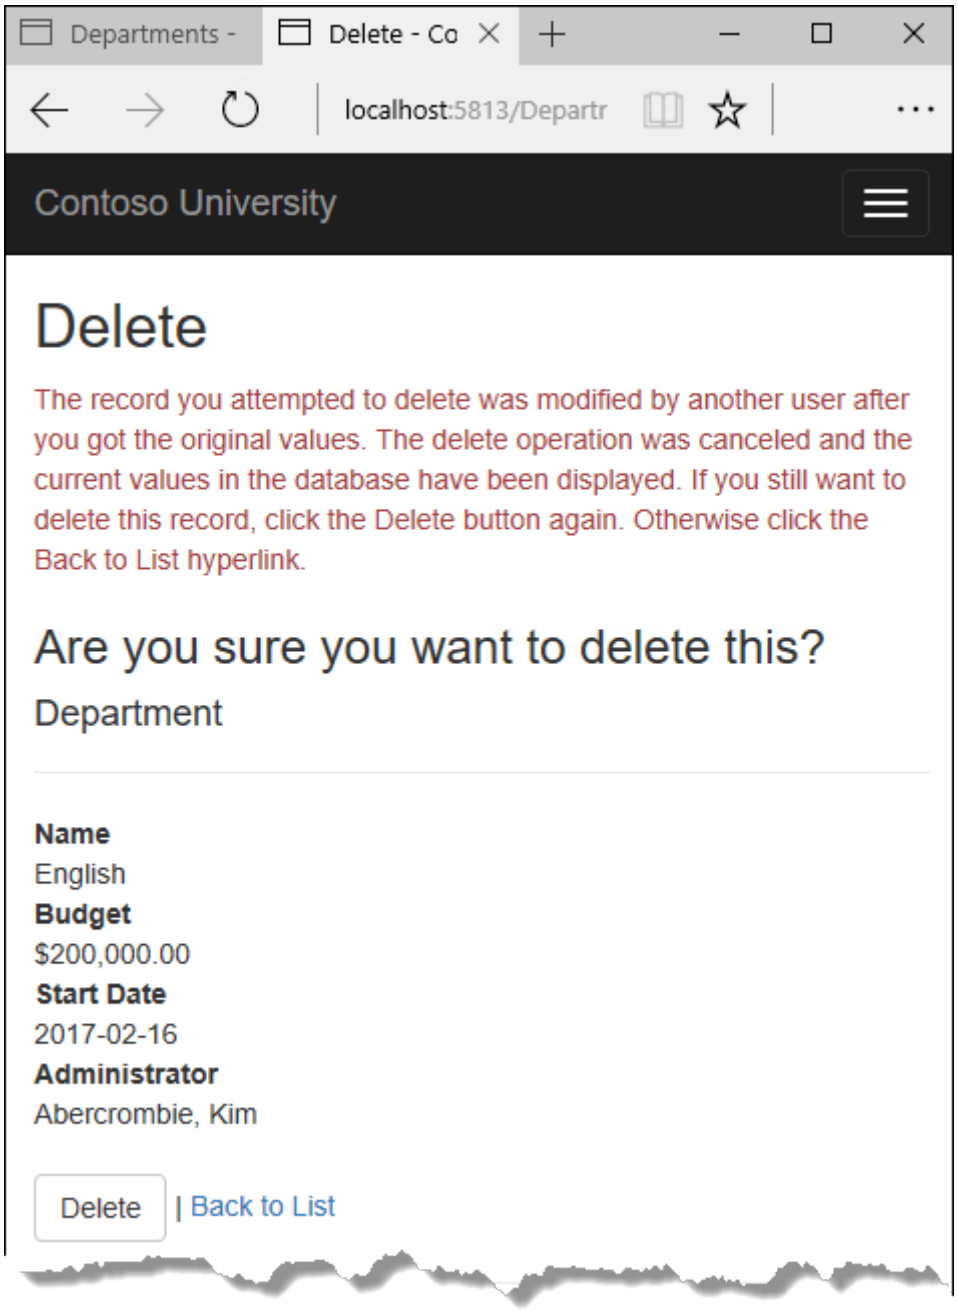
In this tutorial, you:

- ✓ Customized Courses pages
- ✓ Added Instructors Edit page
- ✓ Added courses to Edit page
- ✓ Updated Delete page
- ✓ Added office location and courses to Create page

Advance to the next tutorial to learn how to handle concurrency conflicts.



Handle concurrency conflicts



Tutorial: Handle concurrency - ASP.NET MVC with EF Core

Article • 07/09/2024

In earlier tutorials, you learned how to update data. This tutorial shows how to handle conflicts when multiple users update the same entity at the same time.

You'll create web pages that work with the `Department` entity and handle concurrency errors. The following illustrations show the Edit and Delete pages, including some messages that are displayed if a concurrency conflict occurs.

Departmen
Edit - Cont
localhost:5813/Departr
Contoso University
Edit
Department
The record you attempted to edit was modified by another user after you got the original value. The edit operation was canceled and the current values in the database have been displayed. If you still want to edit this record, click the Save button again. Otherwise click the Back to List hyperlink.
Name
English

Abercrombie, Kim
Save

In this tutorial, you:

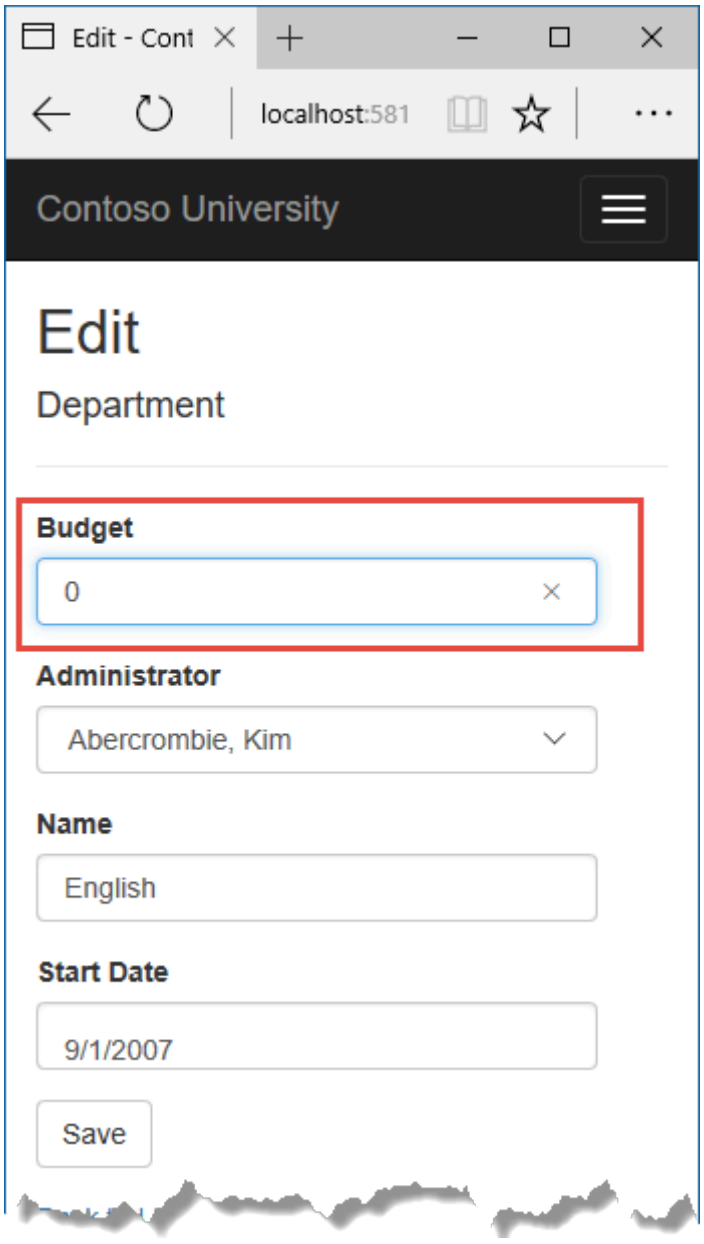
- ✓ Learn about concurrency conflicts
- ✓ Add a tracking property
- ✓ Create Departments controller and views
- ✓ Update Index view
- ✓ Update Edit methods
- ✓ Update Edit view
- ✓ Test concurrency conflicts
- ✓ Update the Delete page
- ✓ Update Details and Create views

Prerequisites

- Update related data

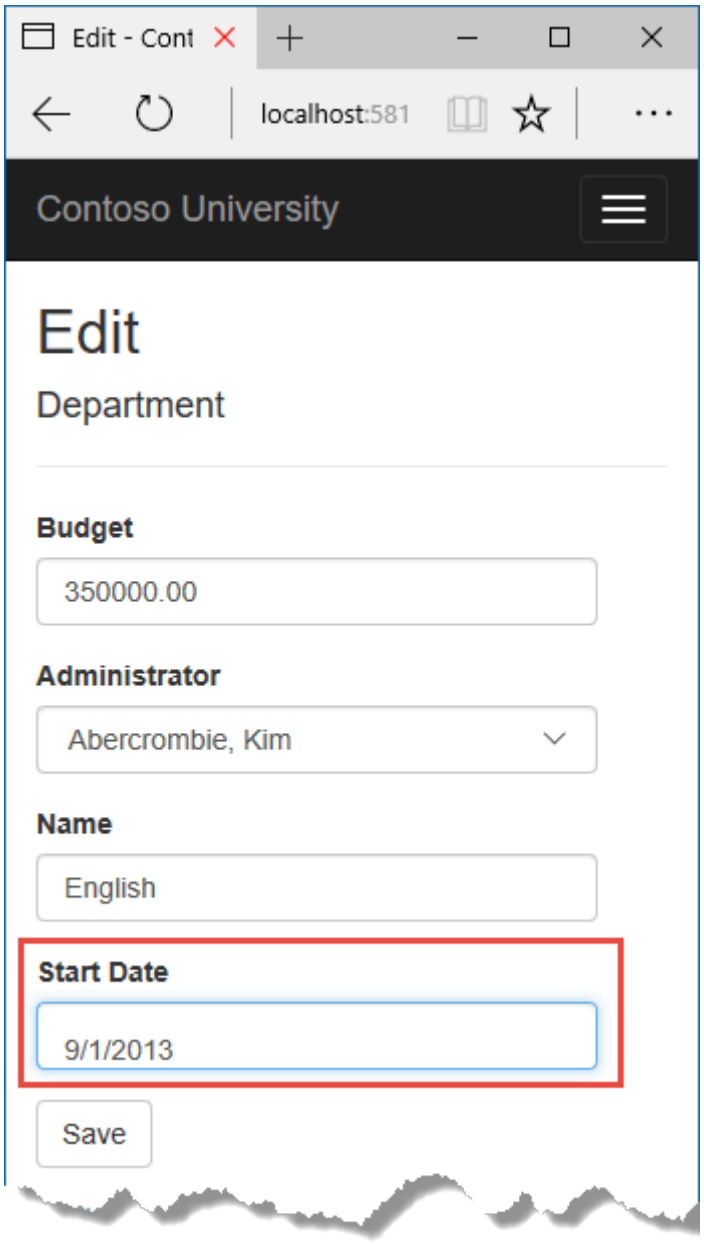
Concurrency conflicts

A concurrency conflict occurs when one user displays an entity's data in order to edit it, and then another user updates the same entity's data before the first user's change is written to the database. If you don't enable the detection of such conflicts, whoever updates the database last overwrites the other user's changes. In many applications, this risk is acceptable: if there are few users, or few updates, or if isn't really critical if some changes are overwritten, the cost of programming for concurrency might outweigh the benefit. In that case, you don't have to configure the application to handle concurrency conflicts.



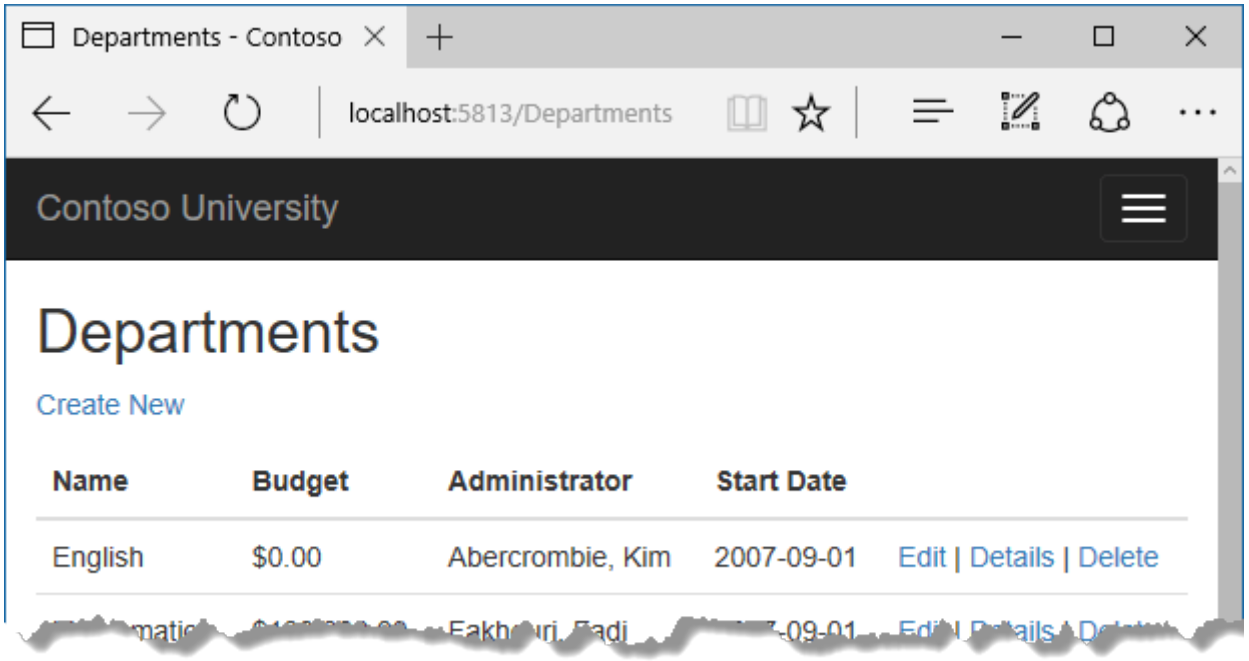
Pessimistic concurrency (locking)

If your application does need to prevent accidental data loss in concurrency scenarios, one way to do that is to use database locks. This is called pessimistic concurrency. For example, before you read a row from a database, you request a lock for read-only or for update access. If you lock a row for update access, no other users are allowed to lock the row either for read-only or update access, because they would get a copy of data that's in the process of being changed. If you lock a row for read-only access, others can also lock it for read-only access but not for update.



Managing locks has disadvantages. It can be complex to program. It requires significant database management resources, and it can cause performance problems as the number of users of an application increases. For these reasons, not all database management systems support pessimistic concurrency. Entity Framework Core provides no built-in support for it, and this tutorial doesn't show you how to implement it.

Optimistic Concurrency



The alternative to pessimistic concurrency is optimistic concurrency. Optimistic concurrency means allowing concurrency conflicts to happen, and then reacting appropriately if they do. For example, Jane visits the Department Edit page and changes the Budget amount for the English department from $350,000.00 to $0.00.

Before Jane clicks **Save**, John visits the same page and changes the Start Date field from 9/1/2007 to 9/1/2013.

Jane clicks **Save** first and sees her change when the browser returns to the Index page.

Then John clicks **Save** on an Edit page that still shows a budget of $350,000.00. What happens next is determined by how you handle concurrency conflicts.

Some of the options include the following:

- You can keep track of which property a user has modified and update only the corresponding columns in the database.

  In the example scenario, no data would be lost, because different properties were updated by the two users. The next time someone browses the English department, they will see both Jane's and John's changes -- a start date of 9/1/2013 and a budget of zero dollars. This method of updating can reduce the number of conflicts that could result in data loss, but it can't avoid data loss if competing changes are made to the same property of an entity. Whether the Entity Framework works this way depends on how you implement your update code. It's often not practical in a web application, because it can require that you maintain large amounts of state in order to keep track of all original property values for an entity as well as new values. Maintaining large amounts of state can affect application performance because it either requires server resources or must be included in the web page itself (for example, in hidden fields) or in a cookie.

- You can let John's change overwrite Jane's change.

  The next time someone browses the English department, they will see 9/1/2013 and the restored $350,000.00 value. This is called a *Client Wins* or *Last in Wins* scenario. (All values from the client take precedence over what's in the data store.) As noted in the introduction to this section, if you don't do any coding for concurrency handling, this will happen automatically.

- You can prevent John's change from being updated in the database.

  Typically, you would display an error message, show him the current state of the data, and allow him to reapply his changes if he still wants to make them. This is called a *Store Wins* scenario. (The data-store values take precedence over the values submitted by the client.) You'll implement the Store Wins scenario in this tutorial. This method ensures that no changes are overwritten without a user being alerted to what's happening.

Detecting concurrency conflicts

You can resolve conflicts by handling `DbConcurrencyException` exceptions that the Entity Framework throws. In order to know when to throw these exceptions, the Entity Framework must be able to detect conflicts. Therefore, you must configure the database

and the data model appropriately. Some options for enabling conflict detection include the following:

- In the database table, include a tracking column that can be used to determine when a row has been changed. You can then configure the Entity Framework to include that column in the Where clause of SQL Update or Delete commands.

  The data type of the tracking column is typically `rowversion`. The `rowversion` value is a sequential number that's incremented each time the row is updated. In an Update or Delete command, the Where clause includes the original value of the tracking column (the original row version) . If the row being updated has been changed by another user, the value in the `rowversion` column is different than the original value, so the Update or Delete statement can't find the row to update because of the Where clause. When the Entity Framework finds that no rows have been updated by the Update or Delete command (that is, when the number of affected rows is zero), it interprets that as a concurrency conflict.

- Configure the Entity Framework to include the original values of every column in the table in the Where clause of Update and Delete commands.

  As in the first option, if anything in the row has changed since the row was first read, the Where clause won't return a row to update, which the Entity Framework interprets as a concurrency conflict. For database tables that have many columns, this approach can result in very large Where clauses, and can require that you maintain large amounts of state. As noted earlier, maintaining large amounts of state can affect application performance. Therefore this approach is generally not recommended, and it isn't the method used in this tutorial.

  If you do want to implement this approach to concurrency, you have to mark all non-primary-key properties in the entity you want to track concurrency for by adding the `ConcurrencyCheck` attribute to them. That change enables the Entity Framework to include all columns in the SQL Where clause of Update and Delete statements.

In the remainder of this tutorial you'll add a `rowversion` tracking property to the Department entity, create a controller and views, and test to verify that everything works correctly.

Add a tracking property

In `Models/Department.cs`, add a tracking property named RowVersion:

```
```

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Department
    {
        public int DepartmentID { get; set; }

        [StringLength(50, MinimumLength = 3)]
        public string Name { get; set; }

        [DataType(DataType.Currency)]
        [Column(TypeName = "money")]
        public decimal Budget { get; set; }

        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Start Date")]
        public DateTime StartDate { get; set; }

        public int? InstructorID { get; set; }

        [Timestamp]
        public byte[] RowVersion { get; set; }

        public Instructor Administrator { get; set; }
        public ICollection<Course> Courses { get; set; }
    }
}
```

The `Timestamp` attribute specifies that this column will be included in the Where clause of Update and Delete commands sent to the database. The attribute is called `Timestamp` because previous versions of SQL Server used a SQL `timestamp` data type before the SQL `rowversion` replaced it. The .NET type for `rowversion` is a byte array.

If you prefer to use the fluent API, you can use the `IsRowVersion()` method (in `Data/SchoolContext.cs`) to specify the tracking property, as shown in the following example:

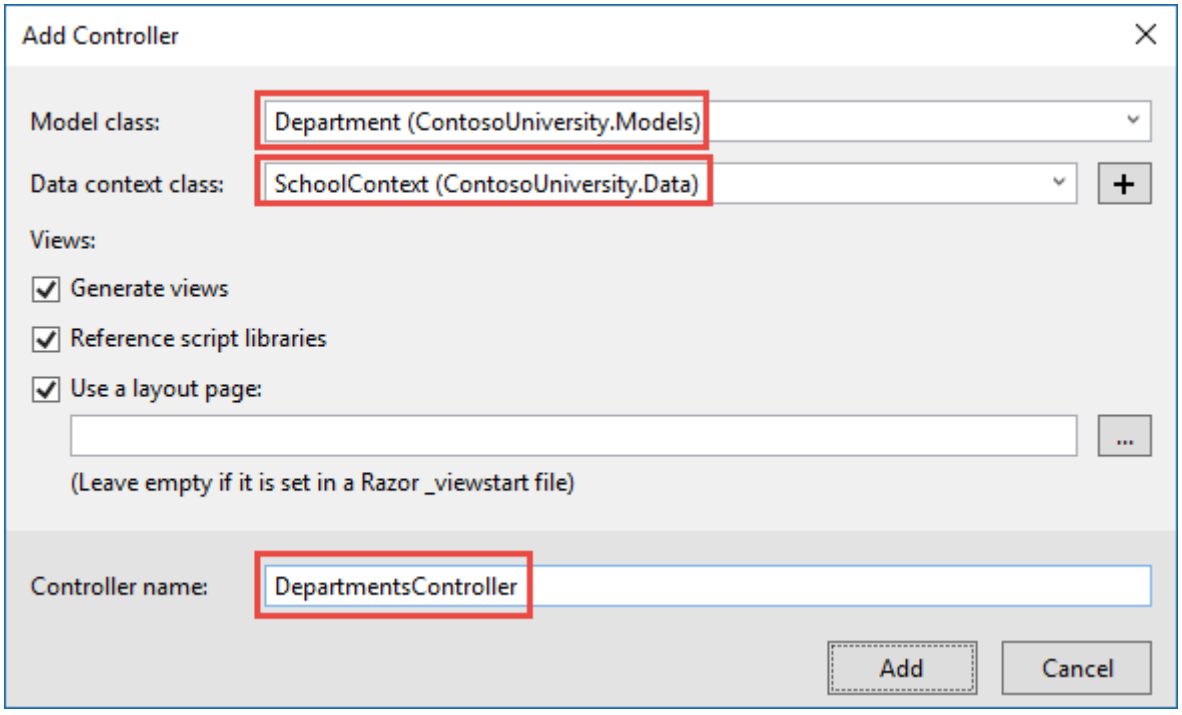
C#

```
modelBuilder.Entity<Department>()
    .Property(p => p.RowVersion).IsRowVersion();
```

By adding a property you changed the database model, so you need to do another migration.

Save your changes and build the project, and then enter the following commands in the command window:

.NET CLI



```
dotnet ef migrations add RowVersion
```

.NET CLI

```
dotnet ef database update
```

Create Departments controller and views

Scaffold a Departments controller and views as you did earlier for Students, Courses, and Instructors.

In the `DepartmentsController.cs` file, change all four occurrences of "FirstMidName" to "FullName" so that the department administrator drop-down lists will contain the full name of the instructor rather than just the last name.

C#

```
ViewData["InstructorID"] = new SelectList(_context.Instructors, "ID",
"FullName", department.InstructorID);
```

Update Index view

The scaffolding engine created a `RowVersion` column in the Index view, but that field shouldn't be displayed.

Replace the code in `Views/Departments/Index.cshtml` with the following code.

CSHTML

```
@model IEnumerable<ContosoUniversity.Models.Department>

@{
    ViewData["Title"] = "Departments";
}

<h2>Departments</h2>

<p>
    <a asp-action="Create">Create New</a>
</p>
<table class="table">
    <thead>
        <tr>
            <th>
                @Html.DisplayNameFor(model => model.Name)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Budget)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.StartDate)
            </th>
            <th>
                @Html.DisplayNameFor(model => model.Administrator)
            </th>
            <th></th>
        </tr>
    </thead>
    <tbody>
        @foreach (var item in Model)
        {
            <tr>
                <td>
                    @Html.DisplayFor(modelItem => item.Name)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.Budget)
                </td>
                <td>
                    @Html.DisplayFor(modelItem => item.StartDate)
                </td>
                <td>
```

```
                    @Html.DisplayFor(modelItem =>
item.Administrator.FullName)
                </td>
                <td>
                    <a asp-action="Edit" asp-route-
id="@item.DepartmentID">Edit</a> |
                    <a asp-action="Details" asp-route-
id="@item.DepartmentID">Details</a> |
                    <a asp-action="Delete" asp-route-
id="@item.DepartmentID">Delete</a>
                </td>
            </tr>
        }
    </tbody>
</table>
```

This changes the heading to "Departments", deletes the `RowVersion` column, and shows full name instead of first name for the administrator.

Update Edit methods

In both the HttpGet `Edit` method and the `Details` method, add `AsNoTracking`. In the HttpGet `Edit` method, add eager loading for the Administrator.

C#

```
var department = await _context.Departments
    .Include(i => i.Administrator)
    .AsNoTracking()
    .FirstOrDefaultAsync(m => m.DepartmentID == id);
```

Replace the existing code for the HttpPost `Edit` method with the following code:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Edit(int? id, byte[] rowVersion)
{
    if (id == null)
    {
        return NotFound();
    }

    var departmentToUpdate = await _context.Departments.Include(i =>
i.Administrator).FirstOrDefaultAsync(m => m.DepartmentID == id);

    if (departmentToUpdate == null)
    {
```

```
        Department deletedDepartment = new Department();
        await TryUpdateModelAsync(deletedDepartment);
        ModelState.AddModelError(string.Empty,
            "Unable to save changes. The department was deleted by another
user.");
        ViewData["InstructorID"] = new SelectList(_context.Instructors,
"ID", "FullName", deletedDepartment.InstructorID);
        return View(deletedDepartment);
    }

    _context.Entry(departmentToUpdate).Property("RowVersion").OriginalValue
= rowVersion;

    if (await TryUpdateModelAsync<Department>(
        departmentToUpdate,
        "",
        s => s.Name, s => s.StartDate, s => s.Budget, s => s.InstructorID))
    {
        try
        {
            await _context.SaveChangesAsync();
            return RedirectToAction(nameof(Index));
        }
        catch (DbUpdateConcurrencyException ex)
        {
            var exceptionEntry = ex.Entries.Single();
            var clientValues = (Department)exceptionEntry.Entity;
            var databaseEntry = exceptionEntry.GetDatabaseValues();
            if (databaseEntry == null)
            {
                ModelState.AddModelError(string.Empty,
                    "Unable to save changes. The department was deleted by
another user.");
            }
            else
            {
                var databaseValues = (Department)databaseEntry.ToObject();

                if (databaseValues.Name != clientValues.Name)
                {
                    ModelState.AddModelError("Name", $"Current value:
{databaseValues.Name}");
                }
                if (databaseValues.Budget != clientValues.Budget)
                {
                    ModelState.AddModelError("Budget", $"Current value:
{databaseValues.Budget:c}");
                }
                if (databaseValues.StartDate != clientValues.StartDate)
                {
                    ModelState.AddModelError("StartDate", $"Current value:
{databaseValues.StartDate:d}");
                }
                if (databaseValues.InstructorID !=
clientValues.InstructorID)
```

```
                {
                    Instructor databaseInstructor = await
_context.Instructors.FirstOrDefaultAsync(i => i.ID ==
databaseValues.InstructorID);
                    ModelState.AddModelError("InstructorID", $"Current
value: {databaseInstructor?.FullName}");
                }

                ModelState.AddModelError(string.Empty, "The record you
attempted to edit "
                        + "was modified by another user after you got the
original value. The "
                        + "edit operation was canceled and the current
values in the database "
                        + "have been displayed. If you still want to edit
this record, click "
                        + "the Save button again. Otherwise click the Back
to List hyperlink.");
                departmentToUpdate.RowVersion =
(byte[])databaseValues.RowVersion;
                ModelState.Remove("RowVersion");
            }
        }
    }
    ViewData["InstructorID"] = new SelectList(_context.Instructors, "ID",
"FullName", departmentToUpdate.InstructorID);
    return View(departmentToUpdate);
}
```

The code begins by trying to read the department to be updated. If the `FirstOrDefaultAsync` method returns null, the department was deleted by another user. In that case the code uses the posted form values to create a `Department` entity so that the Edit page can be redisplayed with an error message. As an alternative, you wouldn't have to re-create the `Department` entity if you display only an error message without redisplaying the department fields.

The view stores the original `RowVersion` value in a hidden field, and this method receives that value in the `rowVersion` parameter. Before you call `SaveChanges`, you have to put that original `RowVersion` property value in the `OriginalValues` collection for the entity.

C#

```
_context.Entry(departmentToUpdate).Property("RowVersion").OriginalValue =
rowVersion;
```

Then when the Entity Framework creates a SQL UPDATE command, that command will include a WHERE clause that looks for a row that has the original `RowVersion` value. If no

rows are affected by the UPDATE command (no rows have the original `RowVersion` value), the Entity Framework throws a `DbUpdateConcurrencyException` exception.

The code in the catch block for that exception gets the affected Department entity that has the updated values from the `Entries` property on the exception object.

C#

```
var exceptionEntry = ex.Entries.Single();
```

The `Entries` collection will have just one `EntityEntry` object. You can use that object to get the new values entered by the user and the current database values.

C#

```
var clientValues = (Department)exceptionEntry.Entity;
var databaseEntry = exceptionEntry.GetDatabaseValues();
```

The code adds a custom error message for each column that has database values different from what the user entered on the Edit page (only one field is shown here for brevity).

C#

```
var databaseValues = (Department)databaseEntry.ToObject();

if (databaseValues.Name != clientValues.Name)
{
    ModelState.AddModelError("Name", $"Current value:
{databaseValues.Name}");
```

Finally, the code sets the `RowVersion` value of the `departmentToUpdate` to the new value retrieved from the database. This new `RowVersion` value will be stored in the hidden field when the Edit page is redisplayed, and the next time the user clicks **Save**, only concurrency errors that happen since the redisplay of the Edit page will be caught.

C#

```
departmentToUpdate.RowVersion = (byte[])databaseValues.RowVersion;
ModelState.Remove("RowVersion");
```

The `ModelState.Remove` statement is required because `ModelState` has the old `RowVersion` value. In the view, the `ModelState` value for a field takes precedence over the model property values when both are present.

Update Edit view

In `Views/Departments/Edit.cshtml`, make the following changes:

- Add a hidden field to save the `RowVersion` property value, immediately following the hidden field for the `DepartmentID` property.
- Add a "Select Administrator" option to the drop-down list.

CSHTML

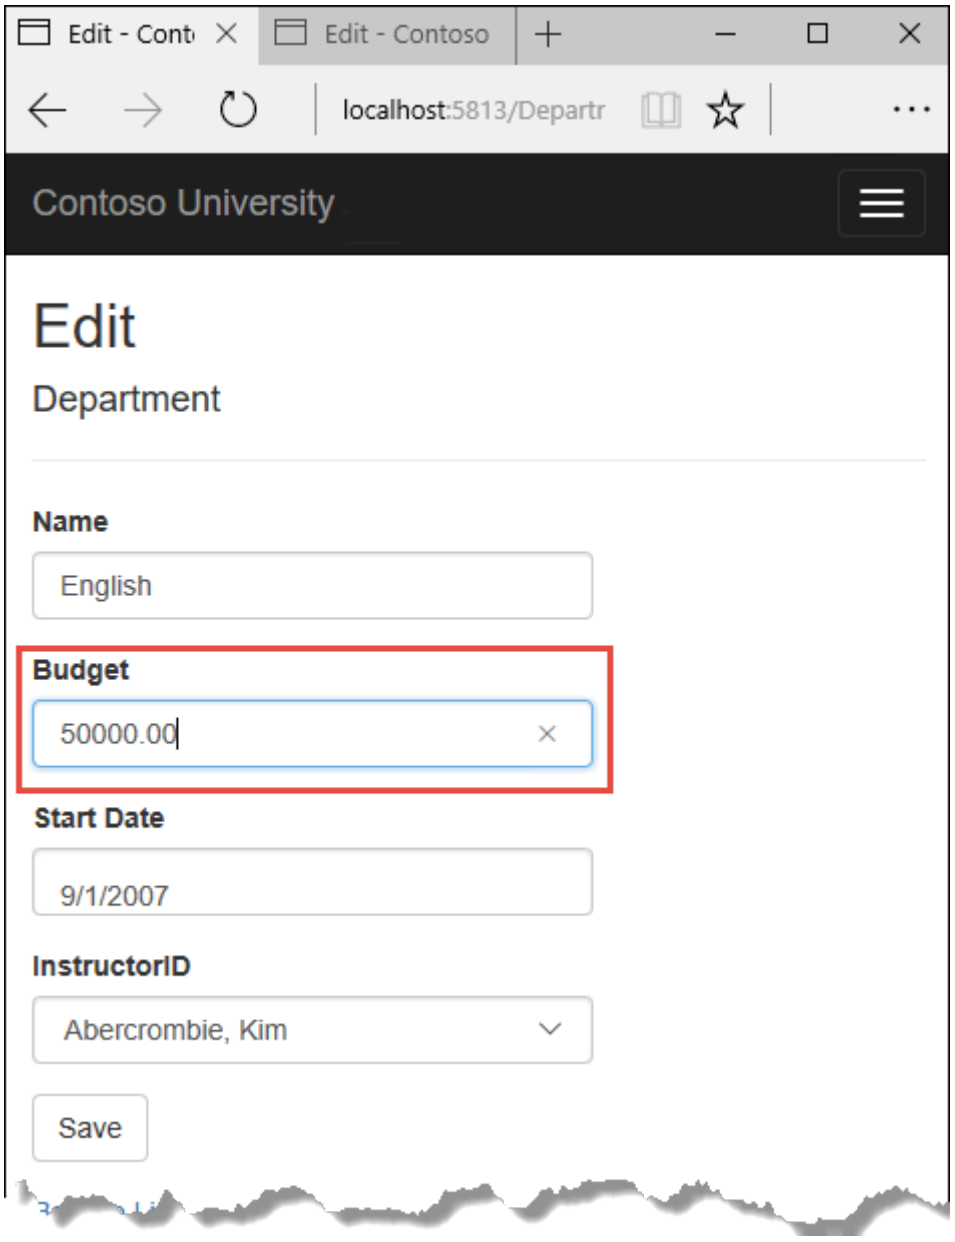
```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Edit";
}

<h2>Edit</h2>

<h4>Department</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Edit">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="DepartmentID" />
            <input type="hidden" asp-for="RowVersion" />
            <div class="form-group">
                <label asp-for="Name" class="control-label"></label>
                <input asp-for="Name" class="form-control" />
                <span asp-validation-for="Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Budget" class="control-label"></label>
                <input asp-for="Budget" class="form-control" />
                <span asp-validation-for="Budget" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="StartDate" class="control-label"></label>
                <input asp-for="StartDate" class="form-control" />
                <span asp-validation-for="StartDate" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="InstructorID" class="control-label"></label>
                <select asp-for="InstructorID" class="form-control" asp-
items="ViewBag.InstructorID">
                    <option value="">-- Select Administrator --</option>
                </select>
                <span asp-validation-for="InstructorID" class="text-danger">
```

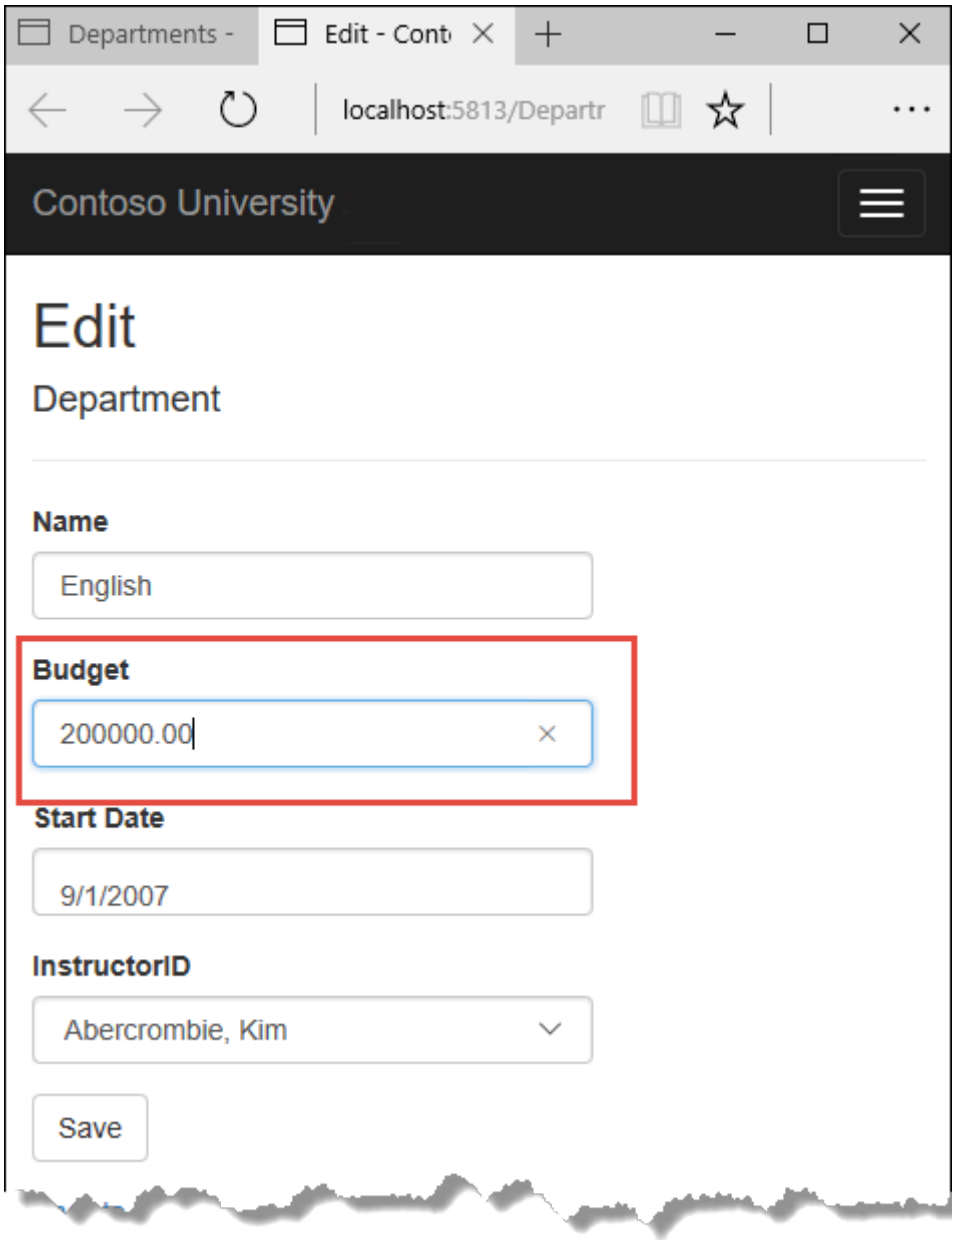
```
</span>
            </div>
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-default" />
            </div>
        </form>
    </div>
</div>



<div>
    <a asp-action="Index">Back to List</a>
</div>

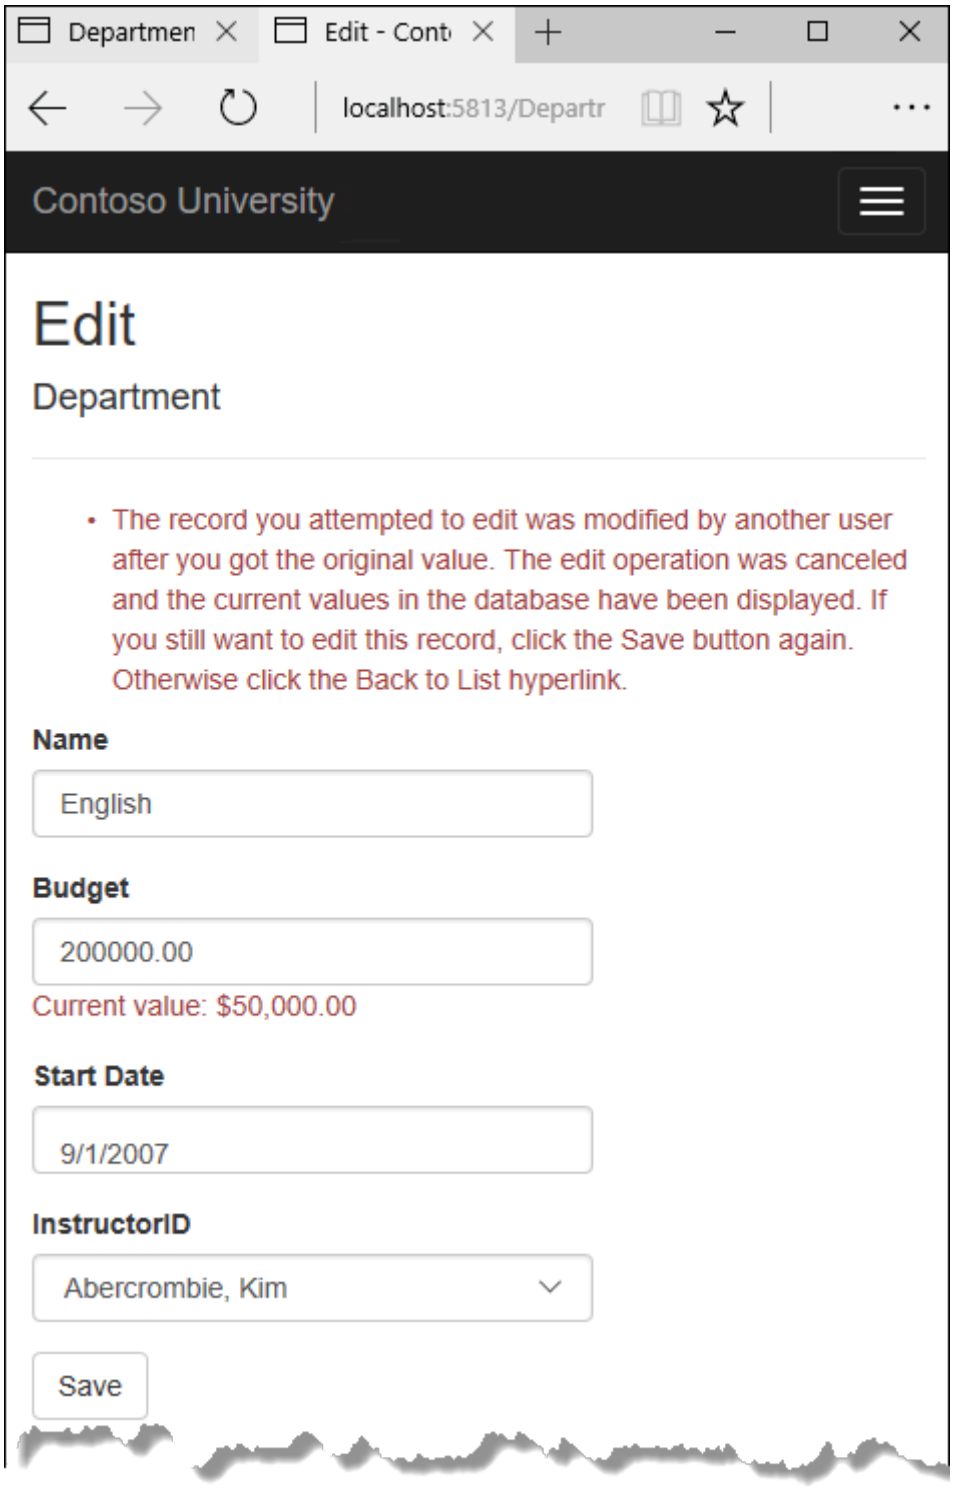
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Test concurrency conflicts



Run the app and go to the Departments Index page. Right-click the **Edit** hyperlink for the English department and select **Open in new tab**, then click the **Edit** hyperlink for the English department. The two browser tabs now display the same information.

Change a field in the first browser tab and click **Save**.



The browser shows the Index page with the changed value.

Change a field in the second browser tab.

Click **Save**. You see an error message:

Click **Save** again. The value you entered in the second browser tab is saved. You see the saved values when the Index page appears.

Update the Delete page

For the Delete page, the Entity Framework detects concurrency conflicts caused by someone else editing the department in a similar manner. When the HttpGet `Delete` method displays the confirmation view, the view includes the original `RowVersion` value in a hidden field. That value is then available to the HttpPost `Delete` method that's called when the user confirms the deletion. When the Entity Framework creates the SQL

DELETE command, it includes a WHERE clause with the original `RowVersion` value. If the command results in zero rows affected (meaning the row was changed after the Delete confirmation page was displayed), a concurrency exception is thrown, and the HttpGet `Delete` method is called with an error flag set to true in order to redisplay the confirmation page with an error message. It's also possible that zero rows were affected because the row was deleted by another user, so in that case no error message is displayed.

Update the Delete methods in the Departments controller

In `DepartmentsController.cs`, replace the HttpGet `Delete` method with the following code:

C#

```
public async Task<IActionResult> Delete(int? id, bool? concurrencyError)
{
    if (id == null)
    {
        return NotFound();
    }

    var department = await _context.Departments
        .Include(d => d.Administrator)
        .AsNoTracking()
        .FirstOrDefaultAsync(m => m.DepartmentID == id);
    if (department == null)
    {
        if (concurrencyError.GetValueOrDefault())
        {
            return RedirectToAction(nameof(Index));
        }
        return NotFound();
    }

    if (concurrencyError.GetValueOrDefault())
    {
        ViewData["ConcurrencyErrorMessage"] = "The record you attempted to
delete "
            + "was modified by another user after you got the original
values. "
            + "The delete operation was canceled and the current values in
the "
            + "database have been displayed. If you still want to delete
this "
            + "record, click the Delete button again. Otherwise "
            + "click the Back to List hyperlink.";
    }
```

```
    return View(department);
}
```

The method accepts an optional parameter that indicates whether the page is being redisplayed after a concurrency error. If this flag is true and the department specified no longer exists, it was deleted by another user. In that case, the code redirects to the Index page. If this flag is true and the department does exist, it was changed by another user. In that case, the code sends an error message to the view using `ViewData`.

Replace the code in the HttpPost `Delete` method (named `DeleteConfirmed`) with the following code:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
public async Task<IActionResult> Delete(Department department)
{
    try
    {
        if (await _context.Departments.AnyAsync(m => m.DepartmentID ==
department.DepartmentID))
        {
            _context.Departments.Remove(department);
            await _context.SaveChangesAsync();
        }
        return RedirectToAction(nameof(Index));
    }
    catch (DbUpdateConcurrencyException /* ex */)
    {
        //Log the error (uncomment ex variable name and write a log.)
        return RedirectToAction(nameof(Delete), new { concurrencyError =
true, id = department.DepartmentID });
    }
}
```

In the scaffolded code that you just replaced, this method accepted only a record ID:

C#

```
public async Task<IActionResult> DeleteConfirmed(int id)
```

You've changed this parameter to a `Department` entity instance created by the model binder. This gives EF access to the RowVers`ion property value in addition to the record key.

C#

```
public async Task<IActionResult> Delete(Department department)
```

You have also changed the action method name from `DeleteConfirmed` to `Delete`. The scaffolded code used the name `DeleteConfirmed` to give the HttpPost method a unique signature. (The CLR requires overloaded methods to have different method parameters.) Now that the signatures are unique, you can stick with the MVC convention and use the same name for the HttpPost and HttpGet delete methods.

If the department is already deleted, the `AnyAsync` method returns false and the application just goes back to the Index method.

If a concurrency error is caught, the code redisplays the Delete confirmation page and provides a flag that indicates it should display a concurrency error message.

Update the Delete view

In `Views/Departments/Delete.cshtml`, replace the scaffolded code with the following code that adds an error message field and hidden fields for the DepartmentID and RowVersion properties. The changes are highlighted.

CSHTML

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Delete";
}

<h2>Delete</h2>

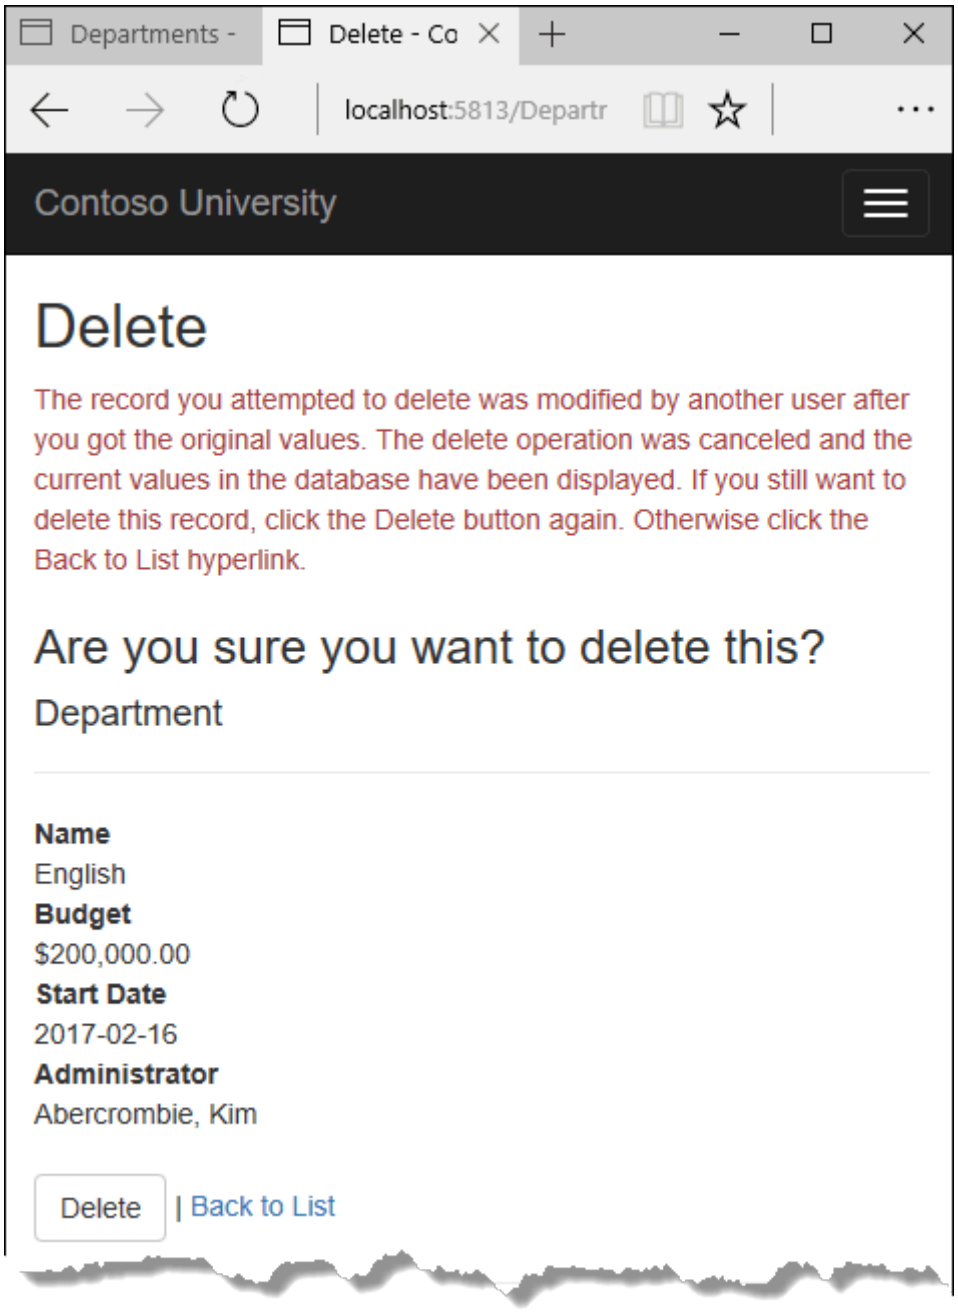
<p class="text-danger">@ViewData["ConcurrencyErrorMessage"]</p>

<h3>Are you sure you want to delete this?</h3>
<div>
    <h4>Department</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Name)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Name)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Budget)
        </dt>
        <dd class="col-sm-10">
```

```
            @Html.DisplayFor(model => model.Budget)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.StartDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.StartDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Administrator)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Administrator.FullName)
        </dd>
    </dl>

    <form asp-action="Delete">
        <input type="hidden" asp-for="DepartmentID" />
        <input type="hidden" asp-for="RowVersion" />
        <div class="form-actions no-color">
            <input type="submit" value="Delete" class="btn btn-default" /> |
            <a asp-action="Index">Back to List</a>
        </div>
    </form>
</div>
```

This makes the following changes:



- Adds an error message between the `h2` and `h3` headings.
- Replaces FirstMidName with FullName in the **Administrator** field.
- Removes the RowVersion field.
- Adds a hidden field for the `RowVersion` property.

Run the app and go to the Departments Index page. Right-click the **Delete** hyperlink for the English department and select **Open in new tab**, then in the first tab click the **Edit** hyperlink for the English department.

In the first window, change one of the values, and click **Save**:

In the second tab, click **Delete**. You see the concurrency error message, and the Department values are refreshed with what's currently in the database.

If you click **Delete** again, you're redirected to the Index page, which shows that the department has been deleted.

Update Details and Create views

You can optionally clean up scaffolded code in the Details and Create views.

Replace the code in `Views/Departments/Details.cshtml` to delete the RowVersion column and show the full name of the Administrator.

CSHTML

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Details";
```

```
}

<h2>Details</h2>

<div>
    <h4>Department</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Name)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Name)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Budget)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Budget)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.StartDate)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.StartDate)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Administrator)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Administrator.FullName)
        </dd>
    </dl>
</div>
<div>
    <a asp-action="Edit" asp-route-id="@Model.DepartmentID">Edit</a> |
    <a asp-action="Index">Back to List</a>
</div>
```

Replace the code in `Views/Departments/Create.cshtml` to add a Select option to the drop-down list.

CSHTML

```
@model ContosoUniversity.Models.Department

@{
    ViewData["Title"] = "Create";
}

<h2>Create</h2>

<h4>Department</h4>
```

```
<hr />
<div class="row">
    <div class="col-md-4">
        <form asp-action="Create">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <div class="form-group">
                <label asp-for="Name" class="control-label"></label>
                <input asp-for="Name" class="form-control" />
                <span asp-validation-for="Name" class="text-danger"></span>
            </div>
            <div class="form-group">
                <label asp-for="Budget" class="control-label"></label>
                <input asp-for="Budget" class="form-control" />
                <span asp-validation-for="Budget" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="StartDate" class="control-label"></label>
                <input asp-for="StartDate" class="form-control" />
                <span asp-validation-for="StartDate" class="text-danger">
</span>
            </div>
            <div class="form-group">
                <label asp-for="InstructorID" class="control-label"></label>
                <select asp-for="InstructorID" class="form-control" asp-
items="ViewBag.InstructorID">
                    <option value="">-- Select Administrator --</option>
                </select>
            </div>
            <div class="form-group">
                <input type="submit" value="Create" class="btn btn-default"
/>
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-action="Index">Back to List</a>
</div>

@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Next steps

In this tutorial, you:

- ✓ Learned about concurrency conflicts
- ✓ Added a tracking property
- ✓ Created Departments controller and views
- ✓ Updated Index view
- ✓ Updated Edit methods
- ✓ Updated Edit view
- ✓ Tested concurrency conflicts
- ✓ Updated the Delete page
- ✓ Updated Details and Create views

Advance to the next tutorial to learn how to implement table-per-hierarchy inheritance for the Instructor and Student entities.

Next: Implement table-per-hierarchy inheritance

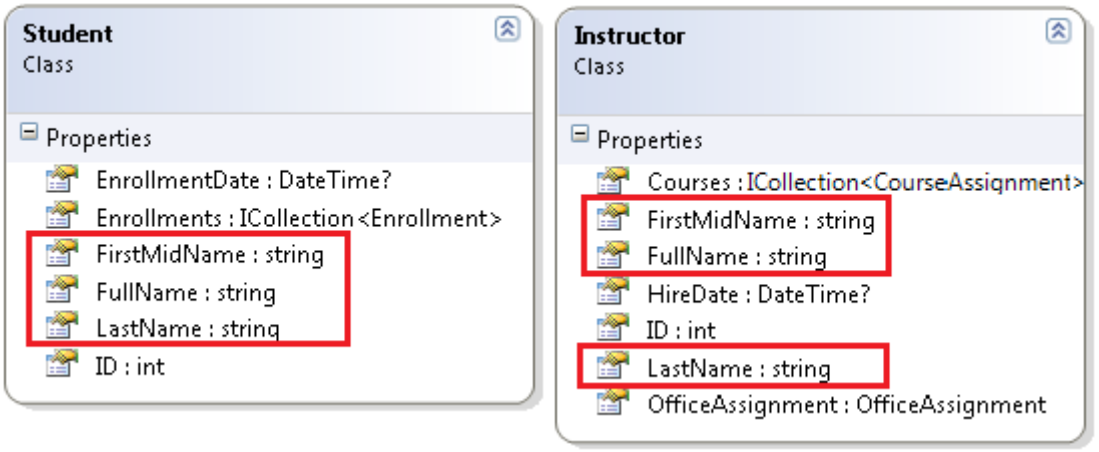
Tutorial: Implement inheritance - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorial, you handled concurrency exceptions. This tutorial will show you how to implement inheritance in the data model.

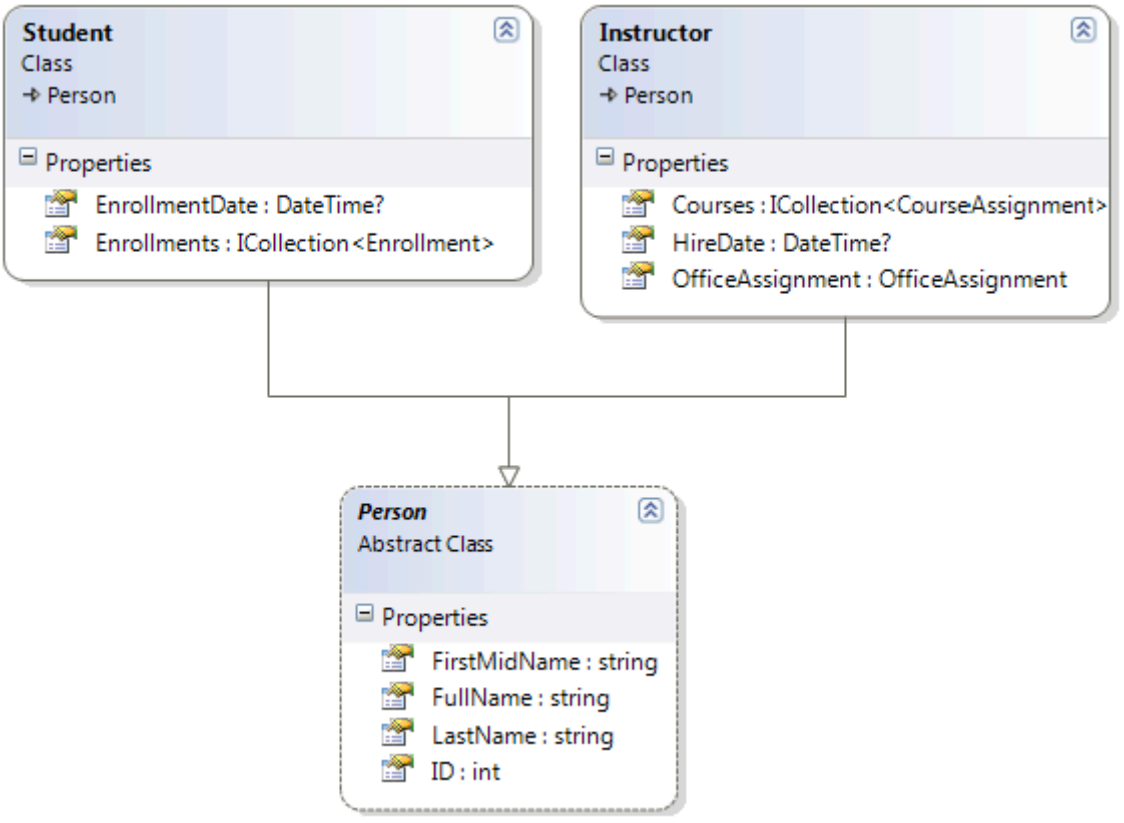
In object-oriented programming, you can use inheritance to facilitate code reuse. In this tutorial, you'll change the `Instructor` and `Student` classes so that they derive from a `Person` base class which contains properties such as `LastName` that are common to both instructors and students. You won't add or change any web pages, but you'll change some of the code and those changes will be automatically reflected in the database.

In this tutorial, you:



- ✓ Map inheritance to database
- ✓ Create the Person class
- ✓ Update Instructor and Student
- ✓ Add Person to the model
- ✓ Create and update migrations
- ✓ Test the implementation

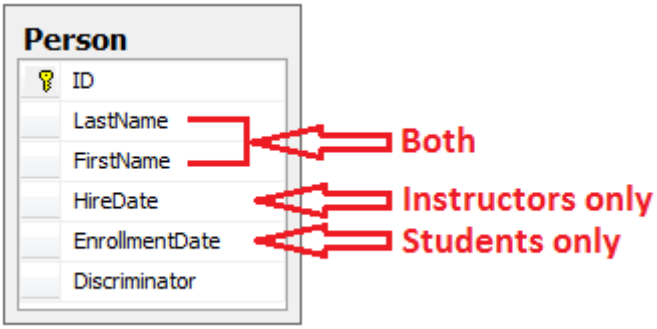
Prerequisites



- Handle Concurrency

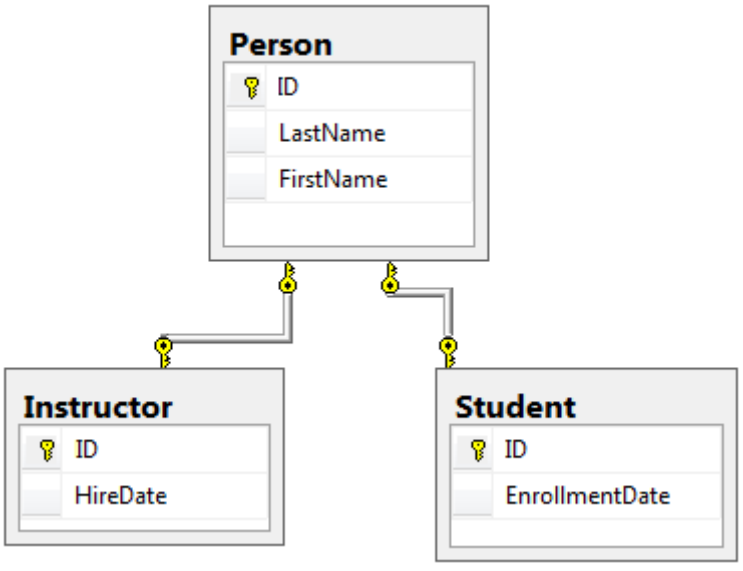
Map inheritance to database

The `Instructor` and `Student` classes in the School data model have several properties that are identical:



Suppose you want to eliminate the redundant code for the properties that are shared by the `Instructor` and `Student` entities. Or you want to write a service that can format names without caring whether the name came from an instructor or a student. You could create a `Person` base class that contains only those shared properties, then make the `Instructor` and `Student` classes inherit from that base class, as shown in the following illustration:

There are several ways this inheritance structure could be represented in the database. You could have a `Person` table that includes information about both students and instructors in a single table. Some of the columns could apply only to instructors (HireDate), some only to students (EnrollmentDate), some to both (LastName, FirstName). Typically, you'd have a discriminator column to indicate which type each row



represents. For example, the discriminator column might have "Instructor" for instructors and "Student" for students.

This pattern of generating an entity inheritance structure from a single database table is called *table-per-hierarchy (TPH)* inheritance.

An alternative is to make the database look more like the inheritance structure. For example, you could have only the name fields in the `Person` table and have separate `Instructor` and `Student` tables with the date fields.

> ⚠ **Warning**
>
> Table-Per-Type (TPT) is not supported by EF Core 3.x, however it is has been implemented in EF Core 5.0.

This pattern of making a database table for each entity class is called *table-per-type (TPT)* inheritance.

Yet another option is to map all non-abstract types to individual tables. All properties of a class, including inherited properties, map to columns of the corresponding table. This pattern is called *Table-per-Concrete Class (TPC)* inheritance. If you implemented TPC

inheritance for the `Person`, `Student`, and `Instructor` classes as shown earlier, the `Student` and `Instructor` tables would look no different after implementing inheritance than they did before.

TPC and TPH inheritance patterns generally deliver better performance than TPT inheritance patterns, because TPT patterns can result in complex join queries.

This tutorial demonstrates how to implement TPH inheritance. TPH is the only inheritance pattern that the Entity Framework Core supports. What you'll do is create a `Person` class, change the `Instructor` and `Student` classes to derive from `Person`, add the new class to the `DbContext`, and create a migration.

> **Tip**
>
> Consider saving a copy of the project before making the following changes. Then if you run into problems and need to start over, it will be easier to start from the saved project instead of reversing steps done for this tutorial or going back to the beginning of the whole series.

Create the Person class

In the Models folder, create Person.cs and replace the template code with the following code:

C#

```
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public abstract class Person
    {
        public int ID { get; set; }

        [Required]
        [StringLength(50)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required]
        [StringLength(50, ErrorMessage = "First name cannot be longer than
50 characters.")]
        [Column("FirstName")]
        [Display(Name = "First Name")]
        public string FirstMidName { get; set; }
```

```
        [Display(Name = "Full Name")]
        public string FullName
        {
            get
            {
                return LastName + ", " + FirstMidName;
            }
        }
    }
}
```

Update Instructor and Student

In `Instructor.cs`, derive the Instructor class from the Person class and remove the key and name fields. The code will look like the following example:

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
    public class Instructor : Person
    {
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Hire Date")]
        public DateTime HireDate { get; set; }

        public ICollection<CourseAssignment> CourseAssignments { get; set; }
        public OfficeAssignment OfficeAssignment { get; set; }
    }
}
```

Make the same changes in `Student.cs`.

C#

```
using System;
using System.Collections.Generic;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace ContosoUniversity.Models
{
```

```
    public class Student : Person
    {
        [DataType(DataType.Date)]
        [DisplayFormat(DataFormatString = "{0:yyyy-MM-dd}",
ApplyFormatInEditMode = true)]
        [Display(Name = "Enrollment Date")]
        public DateTime EnrollmentDate { get; set; }

        public ICollection<Enrollment> Enrollments { get; set; }
    }
}
```

Add Person to the model

Add the Person entity type to `SchoolContext.cs`. The new lines are highlighted.

C#

```
using ContosoUniversity.Models;
using Microsoft.EntityFrameworkCore;

namespace ContosoUniversity.Data
{
    public class SchoolContext : DbContext
    {
        public SchoolContext(DbContextOptions<SchoolContext> options) :
base(options)
        {
        }

        public DbSet<Course> Courses { get; set; }
        public DbSet<Enrollment> Enrollments { get; set; }
        public DbSet<Student> Students { get; set; }
        public DbSet<Department> Departments { get; set; }
        public DbSet<Instructor> Instructors { get; set; }
        public DbSet<OfficeAssignment> OfficeAssignments { get; set; }
        public DbSet<CourseAssignment> CourseAssignments { get; set; }
        public DbSet<Person> People { get; set; }

        protected override void OnModelCreating(ModelBuilder modelBuilder)
        {
            modelBuilder.Entity<Course>().ToTable("Course");
            modelBuilder.Entity<Enrollment>().ToTable("Enrollment");
            modelBuilder.Entity<Student>().ToTable("Student");
            modelBuilder.Entity<Department>().ToTable("Department");
            modelBuilder.Entity<Instructor>().ToTable("Instructor");
            modelBuilder.Entity<OfficeAssignment>
().ToTable("OfficeAssignment");
            modelBuilder.Entity<CourseAssignment>
().ToTable("CourseAssignment");
```

```
            modelBuilder.Entity<Person>().ToTable("Person");

            modelBuilder.Entity<CourseAssignment>()
                .HasKey(c => new { c.CourseID, c.InstructorID });
        }
    }
}
```

This is all that the Entity Framework needs in order to configure table-per-hierarchy inheritance. As you'll see, when the database is updated, it will have a Person table in place of the Student and Instructor tables.

Create and update migrations

Save your changes and build the project. Then open the command window in the project folder and enter the following command:

.NET CLI

```
dotnet ef migrations add Inheritance
```

Don't run the `database update` command yet. That command will result in lost data because it will drop the Instructor table and rename the Student table to Person. You need to provide custom code to preserve existing data.

Open `Migrations/<timestamp>_Inheritance.cs` and replace the `Up` method with the following code:

C#

```
protected override void Up(MigrationBuilder migrationBuilder)
{
    migrationBuilder.DropForeignKey(
        name: "FK_Enrollment_Student_StudentID",
        table: "Enrollment");

    migrationBuilder.DropIndex(name: "IX_Enrollment_StudentID", table:
"Enrollment");

    migrationBuilder.RenameTable(name: "Instructor", newName: "Person");
    migrationBuilder.AddColumn<DateTime>(name: "EnrollmentDate", table:
"Person", nullable: true);
    migrationBuilder.AddColumn<string>(name: "Discriminator", table:
"Person", nullable: false, maxLength: 128, defaultValue: "Instructor");
    migrationBuilder.AlterColumn<DateTime>(name: "HireDate", table:
"Person", nullable: true);
    migrationBuilder.AddColumn<int>(name: "OldId", table: "Person",
```

```
nullable: true);

    // Copy existing Student data into new Person table.
    migrationBuilder.Sql("INSERT INTO dbo.Person (LastName, FirstName,
HireDate, EnrollmentDate, Discriminator, OldId) SELECT LastName, FirstName,
null AS HireDate, EnrollmentDate, 'Student' AS Discriminator, ID AS OldId
FROM dbo.Student");
    // Fix up existing relationships to match new PK's.
    migrationBuilder.Sql("UPDATE dbo.Enrollment SET StudentId = (SELECT ID
FROM dbo.Person WHERE OldId = Enrollment.StudentId AND Discriminator =
'Student')");

    // Remove temporary key
    migrationBuilder.DropColumn(name: "OldID", table: "Person");

    migrationBuilder.DropTable(
        name: "Student");

    migrationBuilder.CreateIndex(
         name: "IX_Enrollment_StudentID",
         table: "Enrollment",
         column: "StudentID");

    migrationBuilder.AddForeignKey(
        name: "FK_Enrollment_Person_StudentID",
        table: "Enrollment",
        column: "StudentID",
        principalTable: "Person",
        principalColumn: "ID",
        onDelete: ReferentialAction.Cascade);
}
```

This code takes care of the following database update tasks:

- Removes foreign key constraints and indexes that point to the Student table.
- Renames the Instructor table as Person and makes changes needed for it to store Student data:
- Adds nullable EnrollmentDate for students.
- Adds Discriminator column to indicate whether a row is for a student or an instructor.
- Makes HireDate nullable since student rows won't have hire dates.
- Adds a temporary field that will be used to update foreign keys that point to students. When you copy students into the Person table they will get new primary key values.

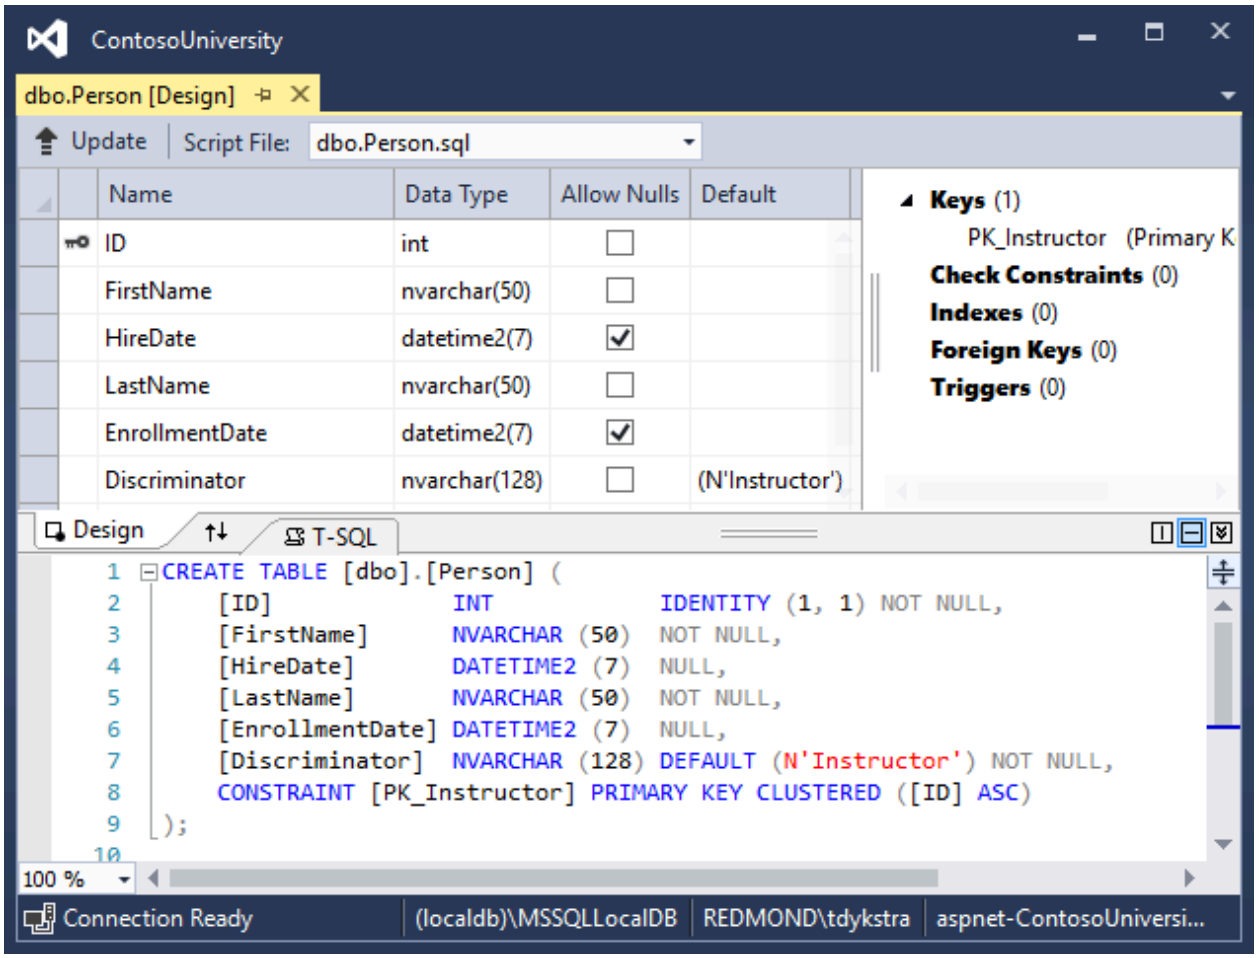
- Copies data from the Student table into the Person table. This causes students to get assigned new primary key values.
- Fixes foreign key values that point to students.
- Re-creates foreign key constraints and indexes, now pointing them to the Person table.

(If you had used GUID instead of integer as the primary key type, the student primary key values wouldn't have to change, and several of these steps could have been omitted.)

Run the `database update` command:

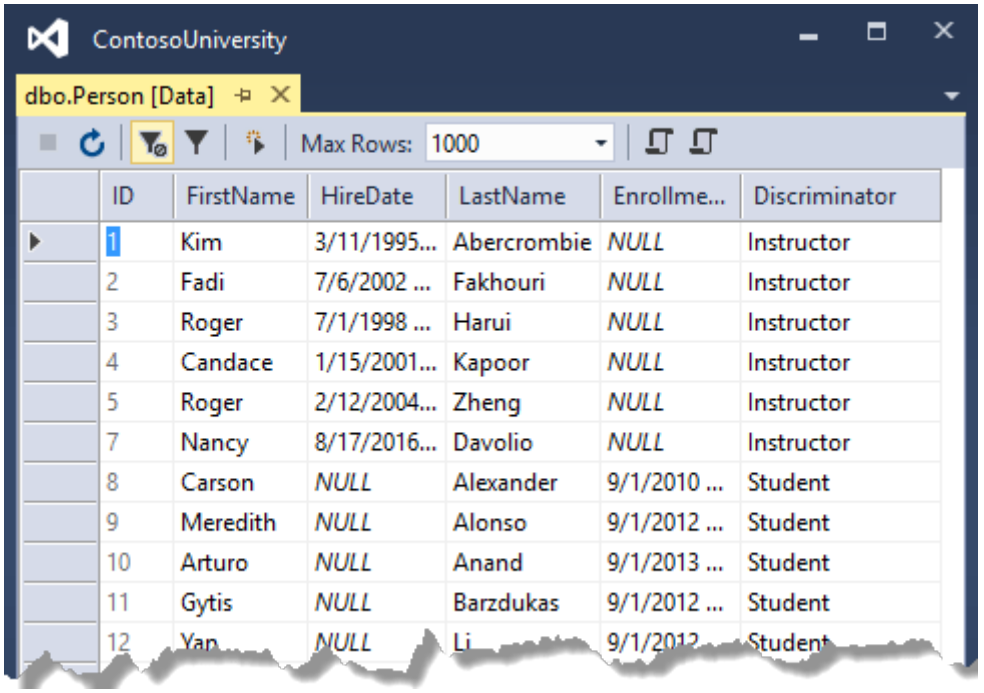
.NET CLI

```
dotnet ef database update
```



(In a production system you would make corresponding changes to the `Down` method in case you ever had to use that to go back to the previous database version. For this tutorial you won't be using the `Down` method.)

> **Note**
>
> It's possible to get other errors when making schema changes in a database that has existing data. If you get migration errors that you can't resolve, you can either change the database name in the connection string or delete the database. With a new database, there's no data to migrate, and the update-database command is more likely to complete without errors. To delete the database, use SSOX or run the `database drop` CLI command.



Test the implementation

Run the app and try various pages. Everything works the same as it did before.

In **SQL Server Object Explorer**, expand **Data Connections/SchoolContext** and then **Tables**, and you see that the Student and Instructor tables have been replaced by a Person table. Open the Person table designer and you see that it has all of the columns that used to be in the Student and Instructor tables.

Right-click the Person table, and then click **Show Table Data** to see the discriminator column.

Get the code

Download or view the completed application.

Next steps

In this tutorial, you:

- ✓ Mapped inheritance to database
- ✓ Created the Person class
- ✓ Updated Instructor and Student
- ✓ Added Person to the model
- ✓ Created and update migrations
- ✓ Tested the implementation

Advance to the next tutorial to learn how to handle a variety of relatively advanced Entity Framework scenarios.

Next: Advanced topics

Tutorial: Learn about advanced scenarios - ASP.NET MVC with EF Core

Article • 04/10/2024

In the previous tutorial, you implemented table-per-hierarchy inheritance. This tutorial introduces several topics that are useful to be aware of when you go beyond the basics of developing ASP.NET Core web applications that use Entity Framework Core.

In this tutorial, you:

- ✓ Perform raw SQL queries
- ✓ Call a query to return entities
- ✓ Call a query to return other types
- ✓ Call an update query
- ✓ Examine SQL queries
- ✓ Create an abstraction layer
- ✓ Learn about Automatic change detection
- ✓ Learn about EF Core source code and development plans
- ✓ Learn how to use dynamic LINQ to simplify code

Prerequisites

- Implement Inheritance

Perform raw SQL queries

One of the advantages of using the Entity Framework is that it avoids tying your code too closely to a particular method of storing data. It does this by generating SQL queries and commands for you, which also frees you from having to write them yourself. But there are exceptional scenarios when you need to run specific SQL queries that you have manually created. For these scenarios, the Entity Framework Code First API includes methods that enable you to pass SQL commands directly to the database. You have the following options in EF Core 1.0:

- Use the `DbSet.FromSql` method for queries that return entity types. The returned objects must be of the type expected by the `DbSet` object, and they're automatically tracked by the database context unless you turn tracking off.
- Use the `Database.ExecuteSqlCommand` for non-query commands.

If you need to run a query that returns types that aren't entities, you can use ADO.NET with the database connection provided by EF. The returned data isn't tracked by the database context, even if you use this method to retrieve entity types.

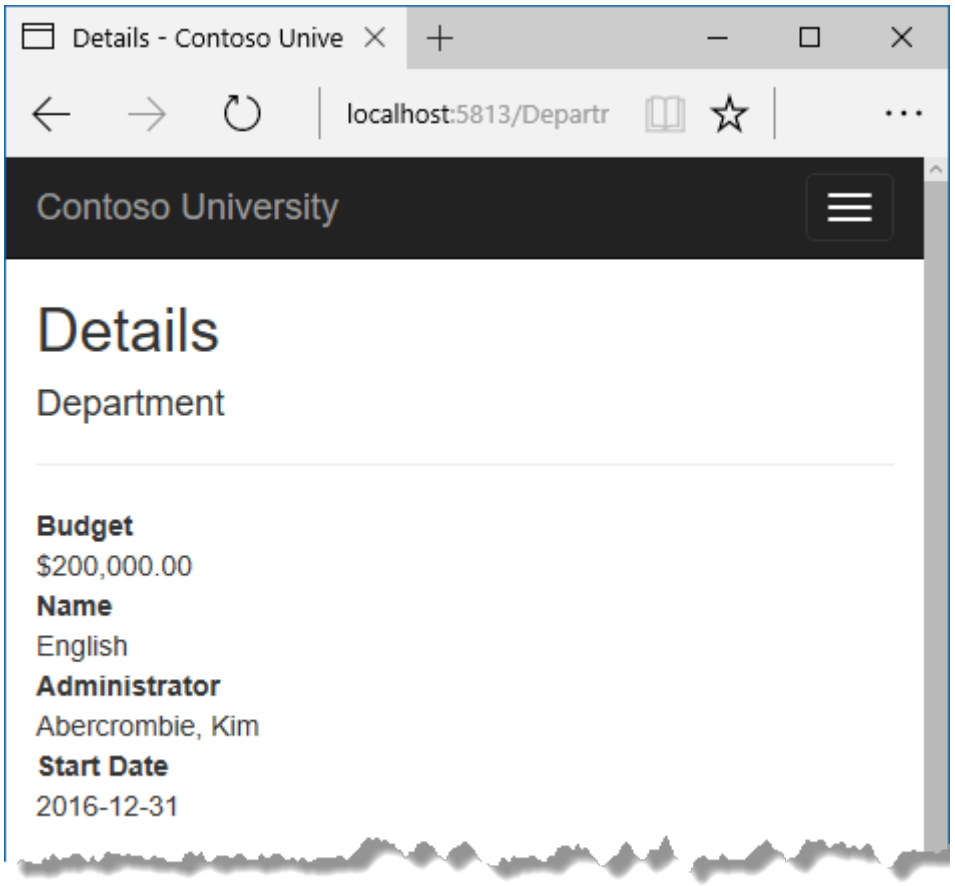
As is always true when you execute SQL commands in a web application, you must take precautions to protect your site against SQL injection attacks. One way to do that is to use parameterized queries to make sure that strings submitted by a web page can't be interpreted as SQL commands. In this tutorial you'll use parameterized queries when integrating user input into a query.

Call a query to return entities

The `DbSet<TEntity>` class provides a method that you can use to execute a query that returns an entity of type `TEntity`. To see how this works you'll change the code in the `Details` method of the Department controller.

In `DepartmentsController.cs`, in the `Details` method, replace the code that retrieves a department with a `FromSql` method call, as shown in the following highlighted code:

C#



```
public async Task<IActionResult> Details(int? id)
{
    if (id == null)
    {
        return NotFound();
    }

    string query = "SELECT * FROM Department WHERE DepartmentID = {0}";
    var department = await _context.Departments
        .FromSql(query, id)
        .Include(d => d.Administrator)
        .AsNoTracking()
        .FirstOrDefaultAsync();

    if (department == null)
    {
        return NotFound();
    }

    return View(department);
}
```

To verify that the new code works correctly, select the **Departments** tab and then **Details** for one of the departments.

Call a query to return other types

Earlier you created a student statistics grid for the About page that showed the number of students for each enrollment date. You got the data from the Students entity set (`_context.Students`) and used LINQ to project the results into a list of `EnrollmentDateGroup` view model objects. Suppose you want to write the SQL itself rather than using LINQ. To do that you need to run a SQL query that returns something other than entity objects. In EF Core 1.0, one way to do that is to write ADO.NET code and get the database connection from EF.

In `HomeController.cs`, replace the `About` method with the following code:

C#

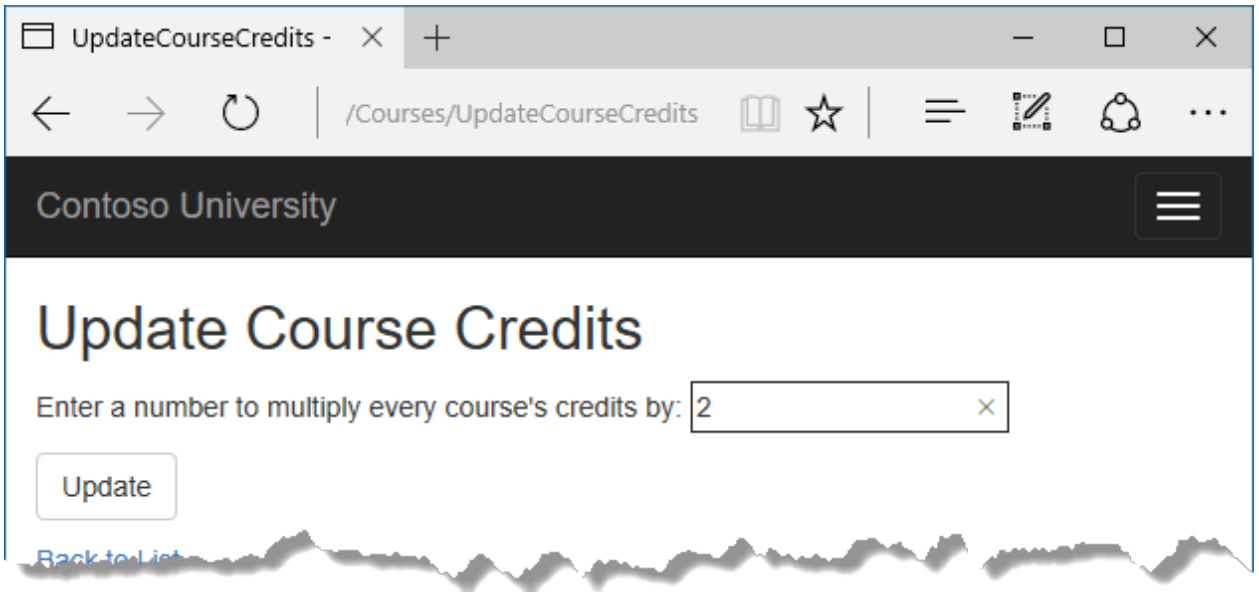
```
public async Task<ActionResult> About()
{
```

```
    List<EnrollmentDateGroup> groups = new List<EnrollmentDateGroup>();
    var conn = _context.Database.GetDbConnection();
    try
    {
        await conn.OpenAsync();
        using (var command = conn.CreateCommand())
        {
            string query = "SELECT EnrollmentDate, COUNT(*) AS StudentCount
"
                + "FROM Person "
                + "WHERE Discriminator = 'Student' "
                + "GROUP BY EnrollmentDate";
            command.CommandText = query;
            DbDataReader reader = await command.ExecuteReaderAsync();

            if (reader.HasRows)
            {
                while (await reader.ReadAsync())
                {
                    var row = new EnrollmentDateGroup { EnrollmentDate =
reader.GetDateTime(0), StudentCount = reader.GetInt32(1) };
                    groups.Add(row);
                }
            }
            reader.Dispose();
        }
    }
    finally
    {
        conn.Close();
    }
    return View(groups);
}
```

Add a using statement:

C#



```
using System.Data.Common;
```

Run the app and go to the About page. It displays the same data it did before.

Call an update query

Suppose Contoso University administrators want to perform global changes in the database, such as changing the number of credits for every course. If the university has a large number of courses, it would be inefficient to retrieve them all as entities and change them individually. In this section you'll implement a web page that enables the user to specify a factor by which to change the number of credits for all courses, and you'll make the change by executing a SQL UPDATE statement. The web page will look like the following illustration:

In `CoursesController.cs`, add UpdateCourseCredits methods for HttpGet and HttpPost:

C#

```
public IActionResult UpdateCourseCredits()
{
```

```
    return View();
}
```

C#

```
[HttpPost]
public async Task<IActionResult> UpdateCourseCredits(int? multiplier)
{
    if (multiplier != null)
    {
        ViewData["RowsAffected"] =
            await _context.Database.ExecuteSqlCommandAsync(
                "UPDATE Course SET Credits = Credits * {0}",
                parameters: multiplier);
    }
    return View();
}
```

When the controller processes an HttpGet request, nothing is returned in `ViewData["RowsAffected"]`, and the view displays an empty text box and a submit button, as shown in the preceding illustration.

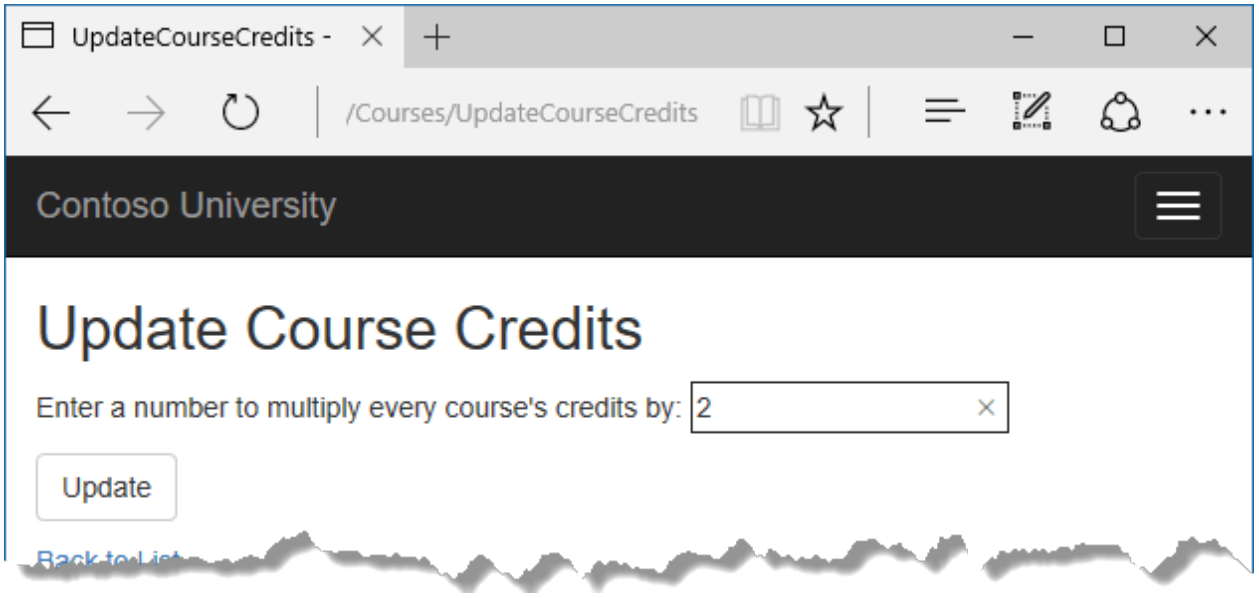
When the **Update** button is clicked, the HttpPost method is called, and multiplier has the value entered in the text box. The code then executes the SQL that updates courses and returns the number of affected rows to the view in `ViewData`. When the view gets a `RowsAffected` value, it displays the number of rows updated.

In **Solution Explorer**, right-click the *Views/Courses* folder, and then click **Add** > **New Item**.

In the **Add New Item** dialog, click **ASP.NET Core** under **Installed** in the left pane, click **Razor View**, and name the new view `UpdateCourseCredits.cshtml`.

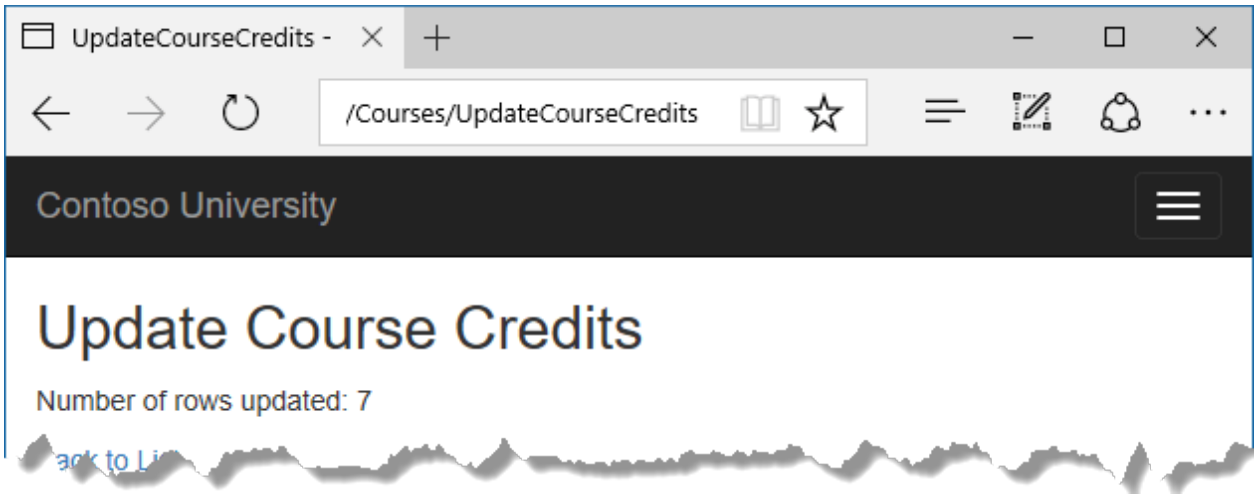
In `Views/Courses/UpdateCourseCredits.cshtml`, replace the template code with the following code:

CSHTML



```
@{
    ViewBag.Title = "UpdateCourseCredits";
}

<h2>Update Course Credits</h2>



@if (ViewData["RowsAffected"] == null)
{
    <form asp-action="UpdateCourseCredits">
        <div class="form-actions no-color">
```

```
            <p>
                Enter a number to multiply every course's credits by:
@Html.TextBox("multiplier")
            </p>
            <p>
                <input type="submit" value="Update" class="btn btn-default"
/>
            </p>
        </div>
    </form>
}
@if (ViewData["RowsAffected"] != null)
{
    <p>
        Number of rows updated: @ViewData["RowsAffected"]
    </p>
}
<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Run the `UpdateCourseCredits` method by selecting the **Courses** tab, then adding "/UpdateCourseCredits" to the end of the URL in the browser's address bar (for example: `http://localhost:5813/Courses/UpdateCourseCredits`). Enter a number in the text box:

Click **Update**. You see the number of rows affected:

Click **Back to List** to see the list of courses with the revised number of credits.

Note that production code would ensure that updates always result in valid data. The simplified code shown here could multiply the number of credits enough to result in numbers greater than 5. (The `Credits` property has a `[Range(0, 5)]` attribute.) The update query would work but the invalid data could cause unexpected results in other parts of the system that assume the number of credits is 5 or less.

For more information about raw SQL queries, see Raw SQL Queries.

Examine SQL queries

Sometimes it's helpful to be able to see the actual SQL queries that are sent to the database. Built-in logging functionality for ASP.NET Core is automatically used by EF Core to write logs that contain the SQL for queries and updates. In this section you'll see some examples of SQL logging.

Open `StudentsController.cs` and in the `Details` method set a breakpoint on the `if (student == null)` statement.

Run the app in debug mode, and go to the Details page for a student.

Go to the **Output** window showing debug output, and you see the query:

```
Microsoft.EntityFrameworkCore.Database.Command:Information: Executed
DbCommand (56ms) [Parameters=[@__id_0='?'], CommandType='Text',
CommandTimeout='30']
SELECT TOP(2) [s].[ID], [s].[Discriminator], [s].[FirstName], [s].
[LastName], [s].[EnrollmentDate]
FROM [Person] AS [s]
WHERE ([s].[Discriminator] = N'Student') AND ([s].[ID] = @__id_0)
ORDER BY [s].[ID]
```

```
Microsoft.EntityFrameworkCore.Database.Command:Information: Executed
DbCommand (122ms) [Parameters=[@__id_0='?'], CommandType='Text',
CommandTimeout='30']
SELECT [s.Enrollments].[EnrollmentID], [s.Enrollments].[CourseID],
[s.Enrollments].[Grade], [s.Enrollments].[StudentID], [e.Course].[CourseID],
[e.Course].[Credits], [e.Course].[DepartmentID], [e.Course].[Title]
FROM [Enrollment] AS [s.Enrollments]
INNER JOIN [Course] AS [e.Course] ON [s.Enrollments].[CourseID] =
[e.Course].[CourseID]
INNER JOIN (
    SELECT TOP(1) [s0].[ID]
    FROM [Person] AS [s0]
    WHERE ([s0].[Discriminator] = N'Student') AND ([s0].[ID] = @__id_0)
    ORDER BY [s0].[ID]
) AS [t] ON [s.Enrollments].[StudentID] = [t].[ID]
ORDER BY [t].[ID]
```

You'll notice something here that might surprise you: the SQL selects up to 2 rows (`TOP(2)`) from the Person table. The `SingleOrDefaultAsync` method doesn't resolve to 1 row on the server. Here's why:

- If the query would return multiple rows, the method returns null.
- To determine whether the query would return multiple rows, EF has to check if it returns at least 2.

Note that you don't have to use debug mode and stop at a breakpoint to get logging output in the **Output** window. It's just a convenient way to stop the logging at the point you want to look at the output. If you don't do that, logging continues and you have to scroll back to find the parts you're interested in.

Create an abstraction layer

Many developers write code to implement the repository and unit of work patterns as a wrapper around code that works with the Entity Framework. These patterns are intended to create an abstraction layer between the data access layer and the business logic layer of an application. Implementing these patterns can help insulate your application from changes in the data store and can facilitate automated unit testing or test-driven development (TDD). However, writing additional code to implement these patterns isn't always the best choice for applications that use EF, for several reasons:

- The EF context class itself insulates your code from data-store-specific code.
- The EF context class can act as a unit-of-work class for database updates that you do using EF.
- EF includes features for implementing TDD without writing repository code.

For information about how to implement the repository and unit of work patterns, see the Entity Framework 5 version of this tutorial series.

Entity Framework Core implements an in-memory database provider that can be used for testing. For more information, see Test with InMemory.

Automatic change detection

The Entity Framework determines how an entity has changed (and therefore which updates need to be sent to the database) by comparing the current values of an entity with the original values. The original values are stored when the entity is queried or attached. Some of the methods that cause automatic change detection are the following:

- DbContext.SaveChanges
- DbContext.Entry
- ChangeTracker.Entries

If you're tracking a large number of entities and you call one of these methods many times in a loop, you might get significant performance improvements by temporarily turning off automatic change detection using the `ChangeTracker.AutoDetectChangesEnabled` property. For example:

```
C#

_context.ChangeTracker.AutoDetectChangesEnabled = false;
```

EF Core source code and development plans

The Entity Framework Core source is at https://github.com/dotnet/efcore. The EF Core repository contains nightly builds, issue tracking, feature specs, design meeting notes, and the roadmap for future development. You can file or find bugs, and contribute.

Although the source code is open, Entity Framework Core is fully supported as a Microsoft product. The Microsoft Entity Framework team keeps control over which contributions are accepted and tests all code changes to ensure the quality of each release.

Reverse engineer from existing database

To reverse engineer a data model including entity classes from an existing database, use the scaffold-dbcontext command. See the getting-started tutorial.

Use dynamic LINQ to simplify code

The third tutorial in this series shows how to write LINQ code by hard-coding column names in a `switch` statement. With two columns to choose from, this works fine, but if you have many columns the code could get verbose. To solve that problem, you can use the `EF.Property` method to specify the name of the property as a string. To try out this approach, replace the `Index` method in the `StudentsController` with the following code.

C#

```
 public async Task<IActionResult> Index(
     string sortOrder,
     string currentFilter,
     string searchString,
     int? pageNumber)
 {
     ViewData["CurrentSort"] = sortOrder;
     ViewData["NameSortParm"] =
         String.IsNullOrEmpty(sortOrder) ? "LastName_desc" : "";
     ViewData["DateSortParm"] =
         sortOrder == "EnrollmentDate" ? "EnrollmentDate_desc" :
"EnrollmentDate";

     if (searchString != null)
     {
         pageNumber = 1;
     }
     else
     {
         searchString = currentFilter;
     }

     ViewData["CurrentFilter"] = searchString;

     var students = from s in _context.Students
                    select s;

     if (!String.IsNullOrEmpty(searchString))
     {
         students = students.Where(s => s.LastName.Contains(searchString)
                                || s.FirstMidName.Contains(searchString));
     }

     if (string.IsNullOrEmpty(sortOrder))
     {
         sortOrder = "LastName";
     }
```

```
      bool descending = false;
      if (sortOrder.EndsWith("_desc"))
      {
          sortOrder = sortOrder.Substring(0, sortOrder.Length - 5);
          descending = true;
      }

      if (descending)
      {
          students = students.OrderByDescending(e => EF.Property<object>(e,
sortOrder));
      }
      else
      {
          students = students.OrderBy(e => EF.Property<object>(e,
sortOrder));
      }

      int pageSize = 3;
      return View(await
PaginatedList<Student>.CreateAsync(students.AsNoTracking(),
          pageNumber ?? 1, pageSize));
  }
```

Acknowledgments

Tom Dykstra and Rick Anderson (twitter @RickAndMSFT) wrote this tutorial. Rowan Miller, Diego Vega, and other members of the Entity Framework team assisted with code reviews and helped debug issues that arose while we were writing code for the tutorials. John Parente and Paul Goldman worked on updating the tutorial for ASP.NET Core 2.2.

Troubleshoot common errors

ContosoUniversity.dll used by another process

Error message:

> Cannot open '...bin\Debug\netcoreapp1.0\ContosoUniversity.dll' for writing -- 'The process cannot access the file '...\bin\Debug\netcoreapp1.0\ContosoUniversity.dll' because it is being used by another process.

Solution:

Stop the site in IIS Express. Go to the Windows System Tray, find IIS Express and right-click its icon, select the Contoso University site, and then click **Stop Site**.

Migration scaffolded with no code in Up and Down methods

Possible cause:

The EF CLI commands don't automatically close and save code files. If you have unsaved changes when you run the `migrations add` command, EF won't find your changes.

Solution:

Run the `migrations remove` command, save your code changes and rerun the `migrations add` command.

Errors while running database update

It's possible to get other errors when making schema changes in a database that has existing data. If you get migration errors you can't resolve, you can either change the database name in the connection string or delete the database. With a new database, there's no data to migrate, and the update-database command is much more likely to complete without errors.

The simplest approach is to rename the database in `appsettings.json`. The next time you run `database update`, a new database will be created.

To delete a database in SSOX, right-click the database, click **Delete**, and then in the **Delete Database** dialog box select **Close existing connections** and click **OK**.

To delete a database by using the CLI, run the `database drop` CLI command:

.NET CLI

```
dotnet ef database drop
```

Error locating SQL Server instance

Error Message:

> A network-related or instance-specific error occurred while establishing a connection to SQL Server. The server was not found or was not accessible. Verify

> that the instance name is correct and that SQL Server is configured to allow remote connections. (provider: SQL Network Interfaces, error: 26 - Error Locating Server/Instance Specified)

Solution:

Check the connection string. If you have manually deleted the database file, change the name of the database in the construction string to start over with a new database.

Get the code

Download or view the completed application.

Additional resources

For more information about EF Core, see the Entity Framework Core documentation. A book is also available: Entity Framework Core in Action.

For information on how to deploy a web app, see Host and deploy ASP.NET Core.

For information about other topics related to ASP.NET Core MVC, such as authentication and authorization, see Overview of ASP.NET Core.

Next steps

In this tutorial, you:

- ✓ Performed raw SQL queries
- ✓ Called a query to return entities
- ✓ Called a query to return other types
- ✓ Called an update query
- ✓ Examined SQL queries
- ✓ Created an abstraction layer
- ✓ Learned about Automatic change detection
- ✓ Learned about EF Core source code and development plans
- ✓ Learned how to use dynamic LINQ to simplify code

This completes this series of tutorials on using the Entity Framework Core in an ASP.NET Core MVC application. This series worked with a new database; an alternative is to reverse engineer a model from an existing database.

Tutorial: EF Core with MVC, existing database

ASP.NET Core and Entity Framework 6

Article • 04/10/2024

> **Important**

Tutorial: Connect to SQL Database from .NET App Service without secrets using a managed identity

Article • 04/17/2024

App Service provides a highly scalable, self-patching web hosting service in Azure. It also provides a managed identity for your app, which is a turn-key solution for securing access to Azure SQL Database and other Azure services. Managed identities in App Service make your app more secure by eliminating secrets from your app, such as credentials in the connection strings. In this tutorial, you add managed identity to the sample web app you built in one of the following tutorials:

- Tutorial: Build an ASP.NET app in Azure with Azure SQL Database
- Tutorial: Build an ASP.NET Core and Azure SQL Database app in Azure App Service

When you're finished, your sample app will connect to SQL Database securely without the need of username and passwords.

> **Note**
>
> The steps covered in this tutorial support the following versions:
>
> - .NET Framework 4.8 and above
> - .NET 6.0 and above
>
> For guidance for Azure Database for MySQL or Azure Database for PostgreSQL in other language frameworks (Node.js, Python, and Java), see Tutorial: Connect to Azure databases from App Service without secrets using a managed identity.

What you will learn:

- ✓ Enable managed identities
- ✓ Grant SQL Database access to the managed identity

- ✓ Configure Entity Framework to use Microsoft Entra authentication with SQL Database
- ✓ Connect to SQL Database from Visual Studio using Microsoft Entra authentication

> **Note**
>
> Microsoft Entra authentication is *different* from Integrated Windows authentication in on-premises Active Directory (AD DS). AD DS and Microsoft Entra ID use completely different authentication protocols. For more information, see Microsoft Entra Domain Services documentation.

If you don't have an Azure subscription, create an Azure free account before you begin.

Prerequisites

This article continues where you left off in either one of the following tutorials:

- Tutorial: Build an ASP.NET app in Azure with SQL Database
- Tutorial: Build an ASP.NET Core and SQL Database app in Azure App Service.

If you haven't already, follow one of the two tutorials first. Alternatively, you can adapt the steps for your own .NET app with SQL Database.

To debug your app using SQL Database as the back end, make sure that you've allowed client connection from your computer. If not, add the client IP by following the steps at Manage server-level IP firewall rules using the Azure portal.

Prepare your environment for the Azure CLI.

- Use the Bash environment in Azure Cloud Shell. For more information, see Quickstart for Bash in Azure Cloud Shell.

  Launch Cloud Shell

- If you prefer to run CLI reference commands locally, install the Azure CLI. If you're running on Windows or macOS, consider running Azure CLI in a Docker container. For more information, see How to run the Azure CLI in a Docker container.
  - If you're using a local installation, sign in to the Azure CLI by using the az login command. To finish the authentication process, follow the steps displayed in your terminal. For other sign-in options, see Sign in with the Azure CLI.

- When you're prompted, install the Azure CLI extension on first use. For more information about extensions, see Use extensions with the Azure CLI.
- Run az version to find the version and dependent libraries that are installed. To upgrade to the latest version, run az upgrade.

1. Grant database access to Microsoft Entra user

First, enable Microsoft Entra authentication to SQL Database by assigning a Microsoft Entra user as the admin of the server. This user is different from the Microsoft account you used to sign up for your Azure subscription. It must be a user that you created, imported, synced, or invited into Microsoft Entra ID. For more information on allowed Microsoft Entra users, see Microsoft Entra features and limitations in SQL Database.

1. If your Microsoft Entra tenant doesn't have a user yet, create one by following the steps at Add or delete users using Microsoft Entra ID.
2. Find the object ID of the Microsoft Entra user using the az ad user list and replace *<user-principal-name>*. The result is saved to a variable.

   Azure CLI

   ```
   $azureaduser=(az ad user list --filter "userPrincipalName eq '<user-principal-name>'" --query '[].id' --output tsv)
   ```

   > **Tip**
   >
   > To see the list of all user principal names in Microsoft Entra ID, run `az ad user list --query '[].userPrincipalName'`.

3. Add this Microsoft Entra user as an Active Directory admin using az sql server ad-admin create command in the Cloud Shell. In the following command, replace *<server-name>* with the server name (without the `.database.windows.net` suffix).

   Azure CLI

   ```
   az sql server ad-admin create --resource-group myResourceGroup --server-name <server-name> --display-name ADMIN --object-id $azureaduser
   ```

For more information on adding an Active Directory admin, see Provision a Microsoft Entra administrator for your server

2. Set up your dev environment

Visual Studio Windows

1. Visual Studio for Windows is integrated with Microsoft Entra authentication. To enable development and debugging in Visual Studio, add your Microsoft Entra user in Visual Studio by selecting **File** > **Account Settings** from the menu, and select **Sign in** or **Add**.
2. To set the Microsoft Entra user for Azure service authentication, select **Tools** > **Options** from the menu, then select **Azure Service Authentication** > **Account Selection**. Select the Microsoft Entra user you added and select **OK**.

For more information about setting up your dev environment for Microsoft Entra authentication, see Azure Identity client library for .NET.

You're now ready to develop and debug your app with the SQL Database as the back end, using Microsoft Entra authentication.

3. Modify your project

> **Note**
>
> **Microsoft.Azure.Services.AppAuthentication** is no longer recommended to use with new Azure SDK. It is replaced with new **Azure Identity client library** available for .NET, Java, TypeScript and Python and should be used for all new development. Information about how to migrate to `Azure Identity` can be found here: AppAuthentication to Azure.Identity Migration Guidance.

The steps you follow for your project depends on whether you're using Entity Framework Core (default for ASP.NET Core) or Entity Framework (default for ASP.NET).

Entity Framework Core

1. In Visual Studio, open the Package Manager Console and add the NuGet package Microsoft.Data.SqlClient:

   PowerShell

```
Install-Package Microsoft.Data.SqlClient -Version 5.1.0
```

2. In the ASP.NET Core and SQL Database tutorial, the `MyDbConnection` connection string in *appsettings.json* isn't used at all yet. The local environment and the Azure environment both get connection strings from their respective environment variables in order to keep connection secrets out of the source file. But now with Active Directory authentication, there are no more secrets. In *appsettings.json*, replace the value of the `MyDbConnection` connection string with:

   JSON

   ```
   "Server=tcp:<server-name>.database.windows.net;Authentication=Active Directory Default; Database=<database-name>;"
   ```

   > **Note**
   >
   > The Active Directory Default authentication type can be used both on your local machine and in Azure App Service. The driver attempts to acquire a token from Microsoft Entra ID using various means. If the app is deployed, it gets a token from the app's system-assigned managed identity. It can also authenticate with a user-assigned managed identity if you include: `User Id=<client-id-of-user-assigned-managed-identity>;` in your connection string. If the app is running locally, it tries to get a token from Visual Studio, Visual Studio Code, and Azure CLI.

   That's everything you need to connect to SQL Database. When you debug in Visual Studio, your code uses the Microsoft Entra user you configured in 2. Set up your dev environment. You'll set up SQL Database later to allow connection from the managed identity of your App Service app. The `DefaultAzureCredential` class caches the token in memory and retrieves it from Microsoft Entra ID just before expiration. You don't need any custom code to refresh the token.

3. Type `Ctrl+F5` to run the app again. The same CRUD app in your browser is now connecting to the Azure SQL Database directly, using Microsoft Entra authentication. This setup lets you run database migrations from Visual Studio.

4. Use managed identity connectivity

Next, you configure your App Service app to connect to SQL Database with a system-assigned managed identity.

> ⓘ Note
>
> The instructions in this section are for a system-assigned identity, To use a user-assigned identity, see Tutorial: Connect to Azure databases from App Service without secrets using a managed identity.

Enable managed identity on app

To enable a managed identity for your Azure app, use the az webapp identity assign command in the Cloud Shell. In the following command, replace *<app-name>*.

Azure CLI

```
az webapp identity assign --resource-group myResourceGroup --name <app-name>
```

> ⓘ Note
>
> To enable managed identity for a deployment slot, add `--slot <slot-name>` and use the name of the slot in *<slot-name>*.

Here's an example of the output:

```
{
  "additionalProperties": {},
  "principalId": "aaaaaaaa-bbbb-cccc-1111-222222222222",
  "tenantId": "aaaabbbb-0000-cccc-1111-dddd2222eeee",
  "type": "SystemAssigned"
}
```

Grant permissions to managed identity

> ⓘ Note
>
> If you want, you can add the identity to an Microsoft Entra group, then grant SQL Database access to the Microsoft Entra group instead of the identity. For example,

the following commands add the managed identity from the previous step to a new group called *myAzureSQLDBAccessGroup*:

Azure CLI

```
$groupid=(az ad group create --display-name myAzureSQLDBAccessGroup --
mail-nickname myAzureSQLDBAccessGroup --query objectId --output tsv)
$msiobjectid=(az webapp identity show --resource-group myResourceGroup
--name <app-name> --query principalId --output tsv)
az ad group member add --group $groupid --member-id $msiobjectid
az ad group member list -g $groupid
```

1. In the Cloud Shell, sign in to SQL Database by using the SQLCMD command. Replace <*server-name*> with your server name, <*db-name*> with the database name your app uses, and <*aad-user-name*> and <*aad-password*> with your Microsoft Entra user's credentials.

   Bash

   ```
   sqlcmd -S <server-name>.database.windows.net -d <db-name> -U <aad-user-
   name> -P "<aad-password>" -G -l 30
   ```

2. In the SQL prompt for the database you want, run the following commands to grant the minimum permissions your app needs. For example,

   SQL

   ```
   CREATE USER [<identity-name>] FROM EXTERNAL PROVIDER;
   ALTER ROLE db_datareader ADD MEMBER [<identity-name>];
   ALTER ROLE db_datawriter ADD MEMBER [<identity-name>];
   ALTER ROLE db_ddladmin ADD MEMBER [<identity-name>];
   GO
   ```

   <*identity-name*> is the name of the managed identity in Microsoft Entra ID. If the identity is system-assigned, the name is always the same as the name of your App Service app. For a deployment slot, the name of its system-assigned identity is <*app-name*>/slots/<*slot-name*>. To grant permissions for a Microsoft Entra group, use the group's display name instead (for example, *myAzureSQLDBAccessGroup*).

3. Type `EXIT` to return to the Cloud Shell prompt.

   Note

The back-end services of managed identities also maintains a token cache that updates the token for a target resource only when it expires. If you make a mistake configuring your SQL Database permissions and try to modify the permissions *after* trying to get a token with your app, you don't actually get a new token with the updated permissions until the cached token expires.

> **Note**
>
> Microsoft Entra ID and managed identities are not supported for on-premises SQL Server.

Modify connection string

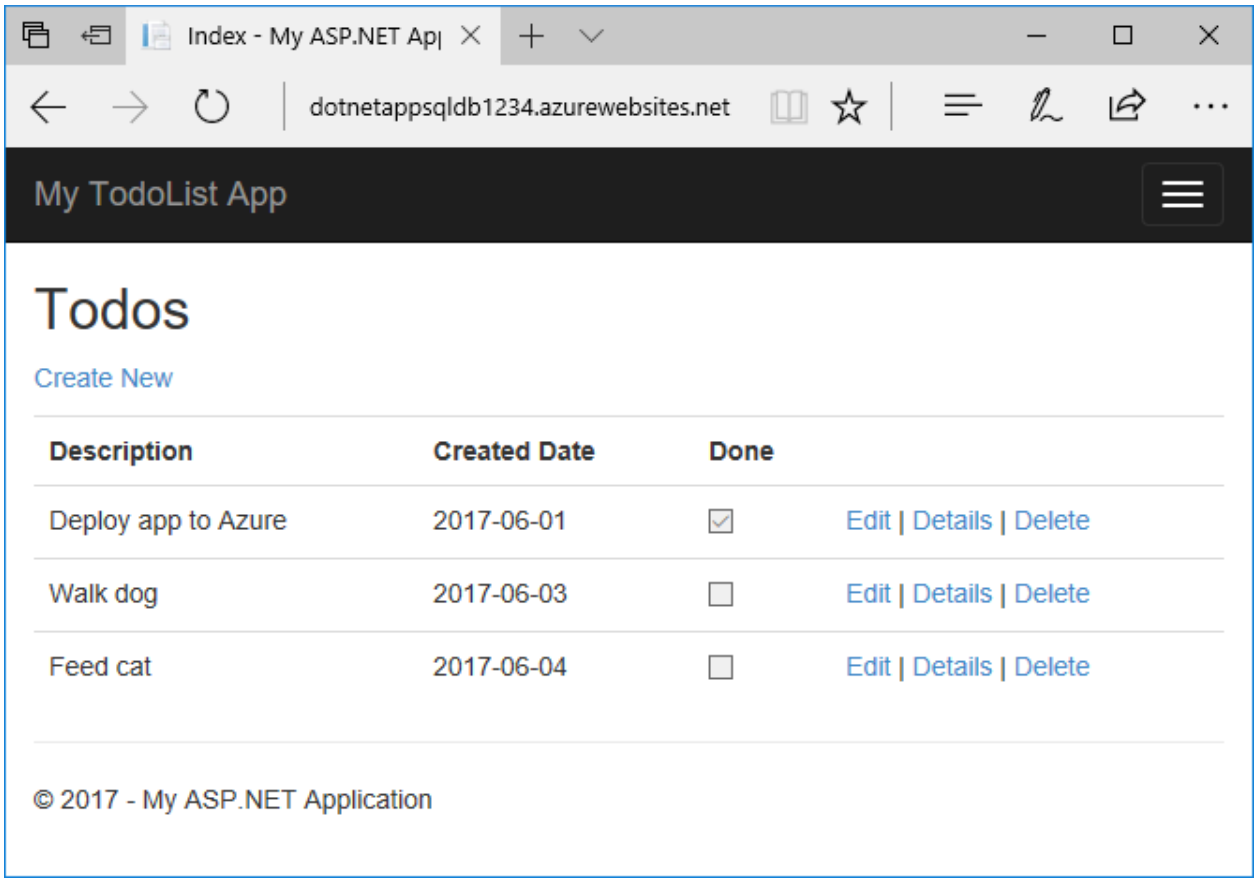
Remember that the same changes you made in *Web.config* or *appsettings.json* works with the managed identity, so the only thing to do is to remove the existing connection string in App Service, which Visual Studio created deploying your app the first time. Use the following command, but replace <*app-name*> with the name of your app.

Azure CLI

```
az webapp config connection-string delete --resource-group myResourceGroup -
-name <app-name> --setting-names MyDbConnection
```

5. Publish your changes

All that's left now is to publish your changes to Azure.



ASP.NET Core

If you came from Tutorial: Build an ASP.NET Core and SQL Database app in Azure App Service, publish your changes using Git, with the following commands:

Bash

```
git commit -am "configure managed identity"
git push azure main
```

When the new webpage shows your to-do list, your app is connecting to the database using the managed identity.

You should now be able to edit the to-do list as before.

Clean up resources

In the preceding steps, you created Azure resources in a resource group. If you don't expect to need these resources in the future, delete the resource group by running the following command in the Cloud Shell:

Azure CLI

```
az group delete --name myResourceGroup
```

This command may take a minute to run.

Next steps

What you learned:

- ✓ Enable managed identities
- ✓ Grant SQL Database access to the managed identity
- ✓ Configure Entity Framework to use Microsoft Entra authentication with SQL Database
- ✓ Connect to SQL Database from Visual Studio using Microsoft Entra authentication

Secure with custom domain and certificate

Adding Azure Storage by using Visual Studio Connected Services

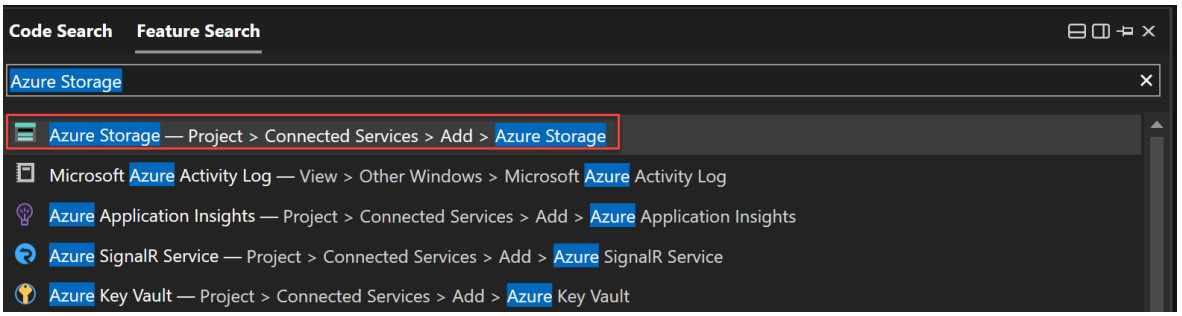
Article • 10/31/2024

With Visual Studio, you can connect any of the following to Azure Storage by using the **Connected Services** feature:

- .NET Framework console app
- ASP.NET Model-View-Controller (MVC) (.NET Framework)
- ASP.NET Core
- .NET Core (including console app, WPF, Windows Forms, class library)
- .NET Core Worker Role
- Azure Functions
- Universal Windows Platform App
- Xamarin
- Cordova

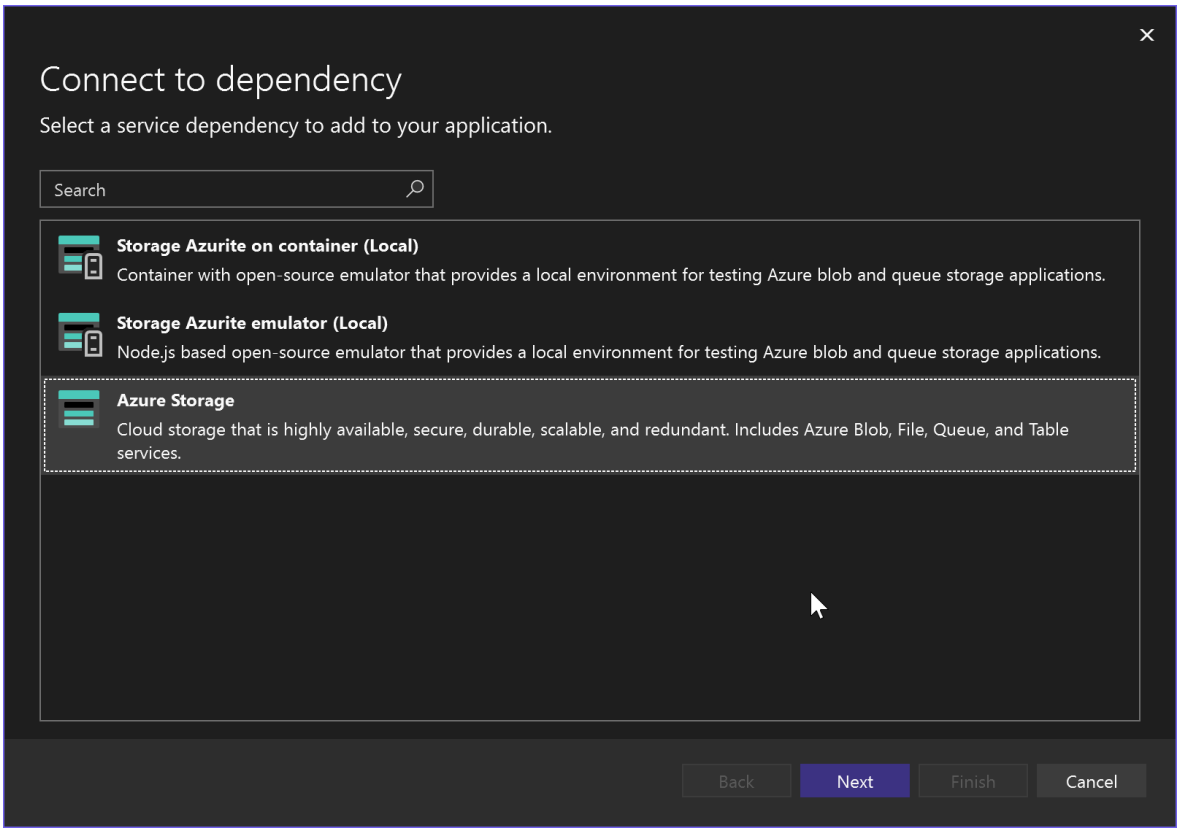
The connected service functionality adds all the needed references and connection code to your project, and modifies your configuration files appropriately.

Prerequisites



- Visual Studio (see [Visual Studio downloads] (https://visualstudio.microsoft.com/downloads/?cid=learn-onpage-download-cta)) with the **Azure development** workload installed.
- A project of one of the supported types
- An Azure account. If you don't have an Azure account, activate your Azure benefits for Visual Studio subscribers or sign up for a free trial.

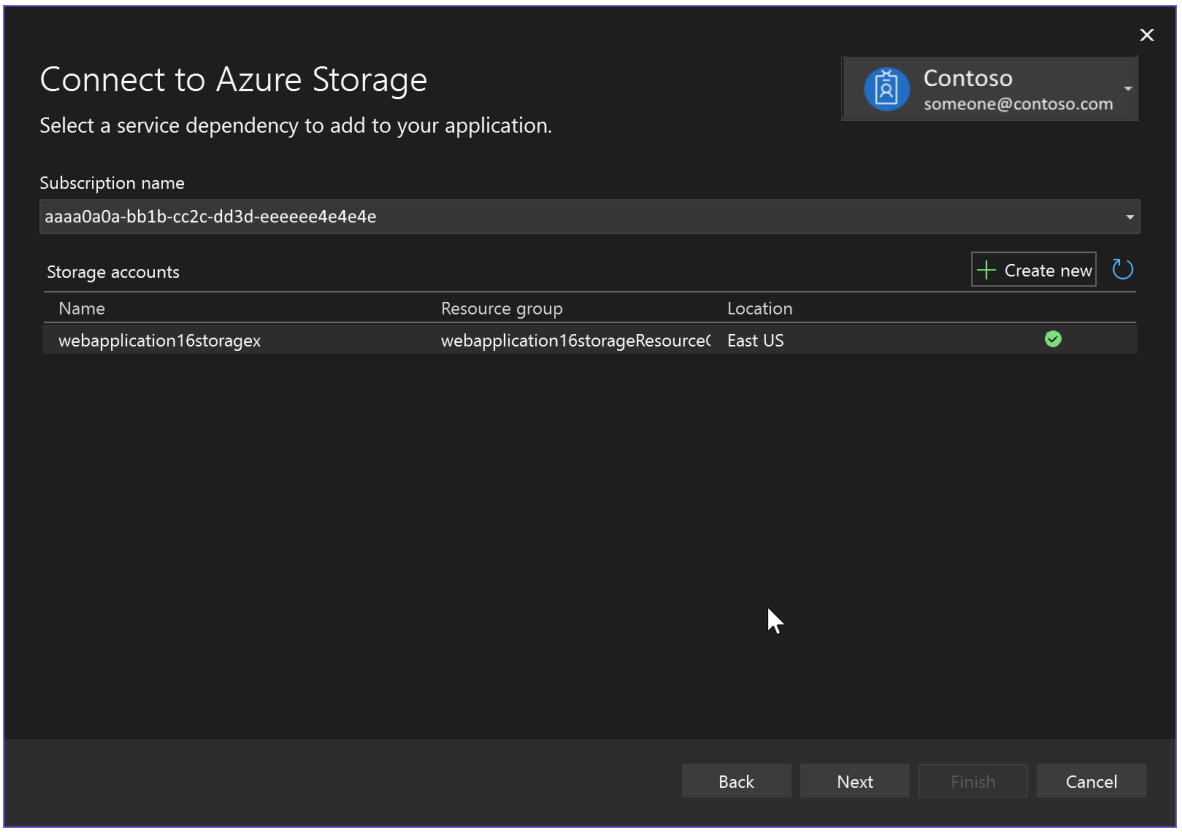
Connect to Azure Storage using Connected Services



1. Open your project in Visual Studio.

2. Press **Ctrl**+**Q** (or use the **Search** button in the Visual Studio IDE to the right of the main menu bar).

3. In **Feature search**, enter `Azure Storage`, and choose **Azure Storage - Project > Connected Services > Add > Azure Storage**.



4. In the **Connect to dependency** page, select **Azure Storage**, and then select **Next**.

   If you aren't signed in already, sign in to your Azure account. If you don't have an Azure account, you can sign up for a free trial.

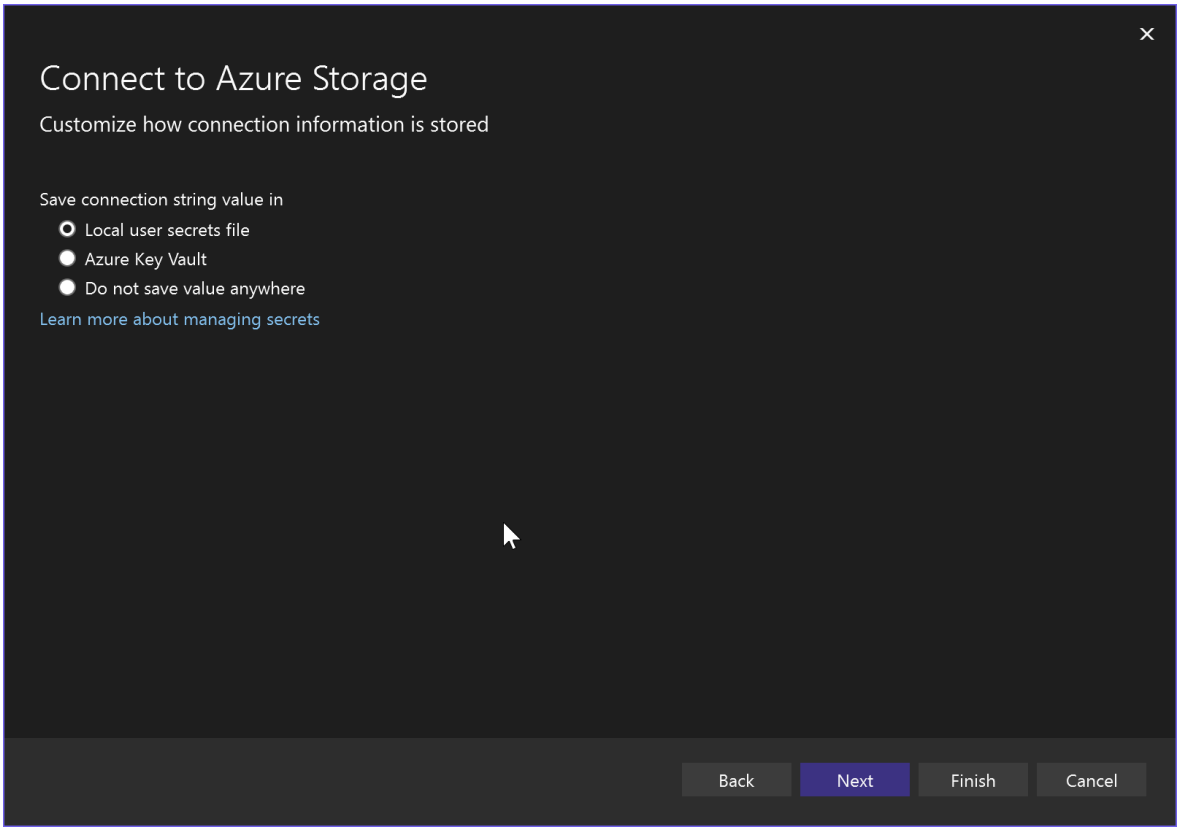
5. In the **Connect to Azure Storage** screen, select an existing storage account, and select **Next**.

   If you need to create a storage account, go to the next step. Otherwise, skip to the following step.

6. To create a storage account:

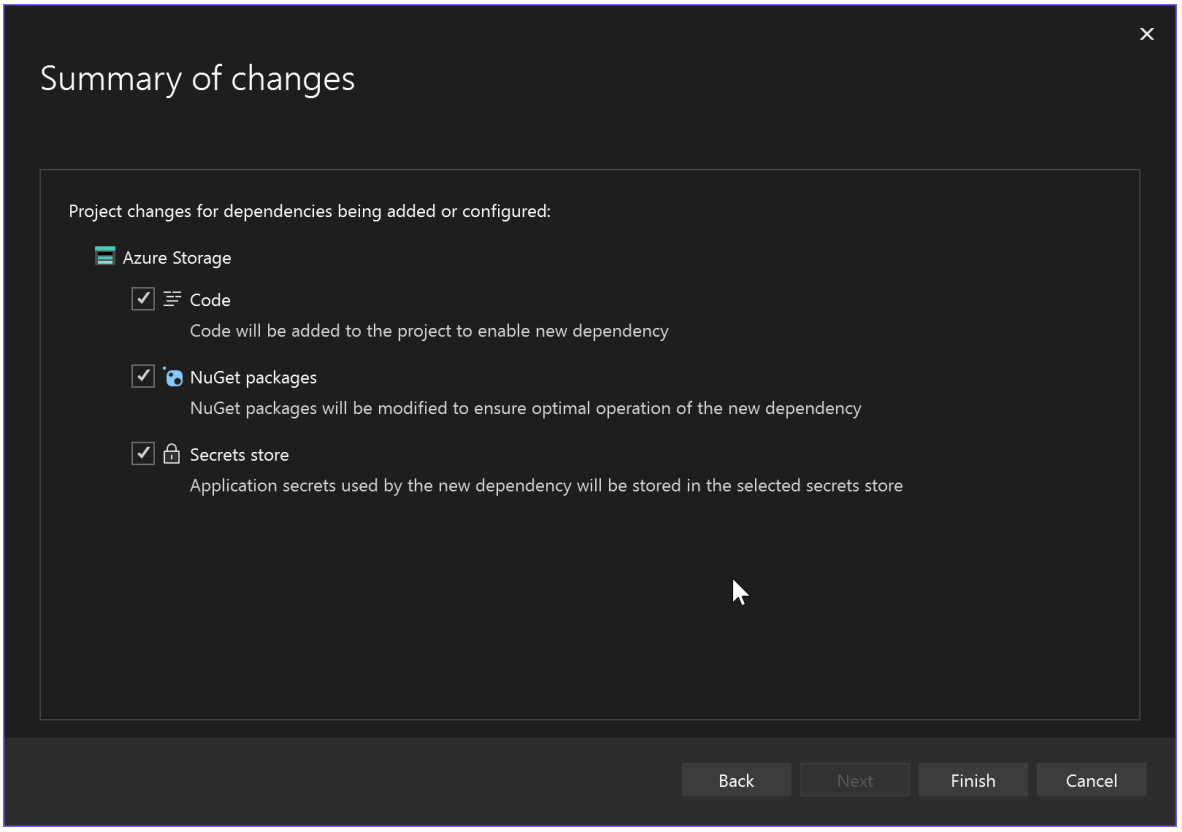
   a. Select **Create new** by the green plus sign.

   b. Fill out the **Azure Storage: Create new** dialog, and select **Create**.



c. When the **Azure Storage** dialog is displayed, the new storage account appears in the list. Select the new storage account in the list, and select **Next**.

7. Enter a connection string setting name. The setting name references the name of the connection string setting as it appears in the *secrets.json* file, or in Azure Key Vault.



8. Choose whether you want the connection string stored in a local secrets file, in Azure Key Vault, or not stored anywhere.

> **⊗ Caution**
>
> If you're using a version of Visual Studio earlier than Visual Studio 17.12, and you choose to use a *secrets.json* file, you must take security precautions, since

the connection string in the local secrets.json file could be exposed. If you're using Visual Studio 2022 version 17.12 or later, this procedure produces more secure result, because it yields a connection setting value, instead of a connection string with authentication credentials.

9. The **Summary of changes** screen shows all the modifications that will be made to your project if you complete the process. If the changes look OK, choose **Finish**.

10. The storage connected service appears under the **Connected Services** node of your project.

Understand authentication

After you run the previous procedure, your app is set up to use authentication to access the storage account. The connection information for this authentication are stored locally, if you chose the *secrets.json* method, or in your Azure Key Vault.

If you used the *secrets.json* file, open the file by using the three dots next to **Secrets.json** on the **Connected Services** tab to open a menu, and choose **Manage user secrets**. With Visual Studio 2022 version 17.12 and later, this file contains settings that reference a Uri to obtain the secure connection string, rather than the connection string itself.

```
JSON
```

```
{
  "StorageConnection:blobServiceUri":
"https://webapplication16storagex.blob.core.windows.net/",
  "StorageConnection:queueServiceUri":
"https://webapplication16storagex.queue.core.windows.net/",
  "StorageConnection:tableServiceUri":
"https://webapplication16storagex.table.core.windows.net/"
}
```

With these settings in Visual Studio 17.12 and later, authentication is automatic and flexible. When you run or debug locally from Visual Studio, your Azure credentials saved by Visual Studio are used to access the Azure storage account. If you launch your app from the command-line, you first need to sign in using the Azure CLI, and those credentials are automatically detected and used. But when your app is deployed to Azure and runs in Azure, it uses managed identity, without any code changes. The authentication works in all hosting environments because the Azure Identity APIs check for all chained credentials in sequence and use them when they're found. See DefaultAzureCredential.

Next steps

Azure Storage supports blobs and queues, as well as other features.

To learn about working with blobs, you can continue with the quickstart for blob storage, but instead of starting at the beginning, you can start at Azure blobs quickstart (.NET) - Code examples.

To learn about working with queues, start at Azure Queue Storage quickstart (.NET) - Code examples.

Quickstart: Azure Blob Storage client library for .NET

Article • 09/13/2024

> **Note**
>
> The **Build from scratch** option walks you step by step through the process of creating a new project, installing packages, writing the code, and running a basic console app. This approach is recommended if you want to understand all the details involved in creating an app that connects to Azure Blob Storage. If you prefer to automate deployment tasks and start with a completed project, choose Start with a template.

Get started with the Azure Blob Storage client library for .NET. Azure Blob Storage is Microsoft's object storage solution for the cloud, and is optimized for storing massive amounts of unstructured data.

In this article, you follow steps to install the package and try out example code for basic tasks.

API reference documentation | Library source code | Package (NuGet) | Samples

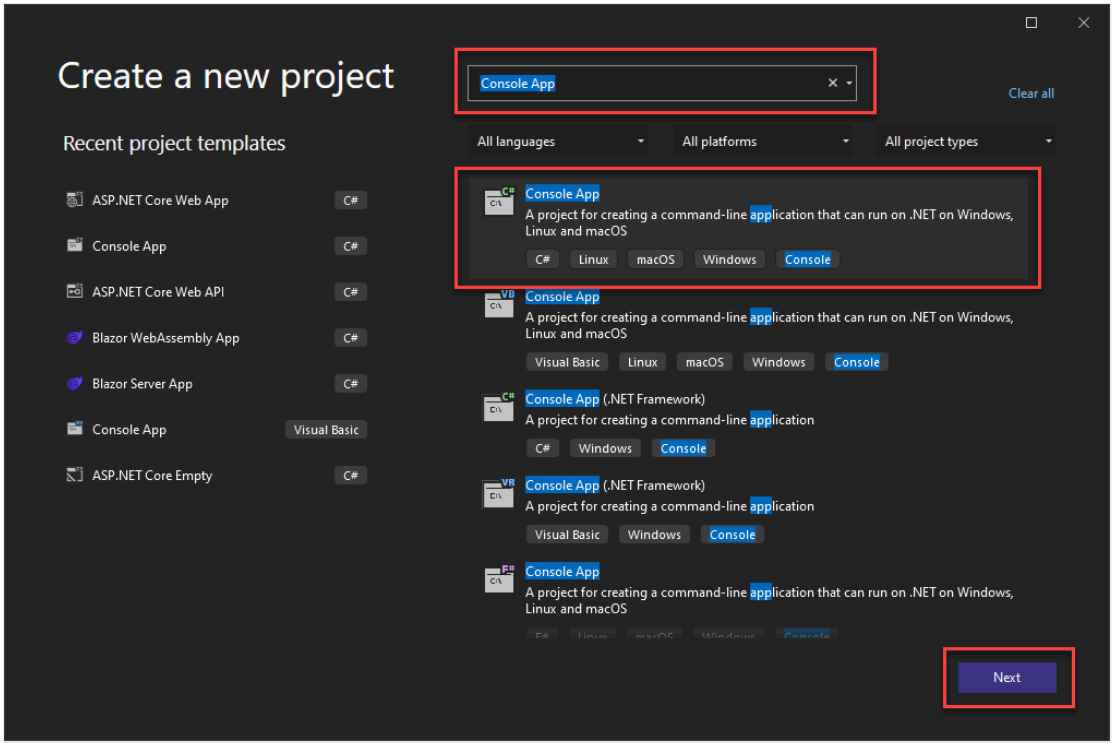
This video shows you how to start using the Azure Blob Storage client library for .NET. https://learn-video.azurefd.net/vod/player?id=cdae65e7-1892-48fe-934a-70edfbe147be&locale=en-us&embedUrl=%2Fazure%2Fstorage%2Fblobs%2Fstorage-quickstart-blobs-dotnet

The steps in the video are also described in the following sections.

Prerequisites

- Azure subscription - create one for free
- Azure storage account - create a storage account
- Latest .NET SDK for your operating system. Be sure to get the SDK and not the runtime.

Setting up



This section walks you through preparing a project to work with the Azure Blob Storage client library for .NET.

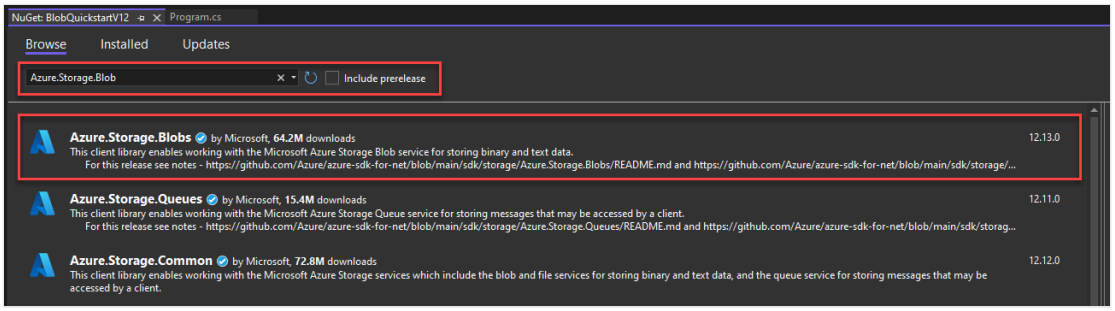
Create the project

Create a .NET console app using either the .NET CLI or Visual Studio 2022.

Visual Studio 2022

1. At the top of Visual Studio, navigate to **File** > **New** > **Project...**
2. In the dialog window, enter *console app* into the project template search box and select the first result. Choose **Next** at the bottom of the dialog.

3. For the **Project Name**, enter *BlobQuickstart*. Leave the default values for the rest of the fields and select **Next**.
4. For the **Framework**, ensure the latest installed version of .NET is selected. Then choose **Create**. The new project opens inside the Visual Studio environment.



Install the package

To interact with Azure Blob Storage, install the Azure Blob Storage client library for .NET.

Visual Studio 2022

1. In **Solution Explorer**, right-click the **Dependencies** node of your project. Select **Manage NuGet Packages**.

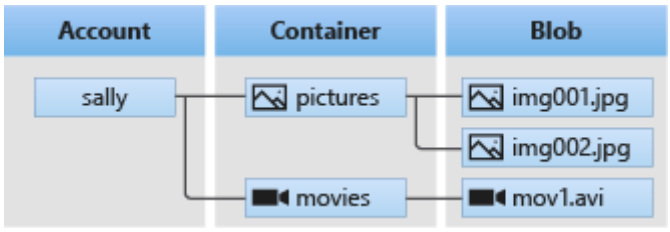
2. In the resulting window, search for *Azure.Storage.Blobs*. Select the appropriate result, and select **Install**.

Set up the app code

Replace the starting code in the `Program.cs` file so that it matches the following example, which includes the necessary `using` statements for this exercise.

C#

```
using Azure.Storage.Blobs;
using Azure.Storage.Blobs.Models;
using System;
using System.IO;



// See https://aka.ms/new-console-template for more information
Console.WriteLine("Hello, World!");
```

Object model

Azure Blob Storage is optimized for storing massive amounts of unstructured data. Unstructured data doesn't adhere to a particular data model or definition, such as text or binary data. Blob storage offers three types of resources:

- The storage account
- A container in the storage account
- A blob in the container

The following diagram shows the relationship between these resources.

Use the following .NET classes to interact with these resources:

- BlobServiceClient: The `BlobServiceClient` class allows you to manipulate Azure Storage resources and blob containers.
- BlobContainerClient: The `BlobContainerClient` class allows you to manipulate Azure Storage containers and their blobs.
- BlobClient: The `BlobClient` class allows you to manipulate Azure Storage blobs.

Code examples

The sample code snippets in the following sections demonstrate how to perform the following tasks with the Azure Blob Storage client library for .NET:

- Authenticate to Azure and authorize access to blob data
- Create a container
- Upload a blob to a container
- List blobs in a container
- Download a blob
- Delete a container

> ⓘ **Important**
>
> Make sure you've installed the correct NuGet packages and added the necessary using statements in order for the code samples to work, as described in the **setting up** section.

Authenticate to Azure and authorize access to blob data

Application requests to Azure Blob Storage must be authorized. Using the `DefaultAzureCredential` class provided by the Azure Identity client library is the recommended approach for implementing passwordless connections to Azure services in your code, including Blob Storage.

You can also authorize requests to Azure Blob Storage by using the account access key. However, this approach should be used with caution. Developers must be diligent to

never expose the access key in an unsecure location. Anyone who has the access key is able to authorize requests against the storage account, and effectively has access to all the data. `DefaultAzureCredential` offers improved management and security benefits over the account key to allow passwordless authentication. Both options are demonstrated in the following example.

Passwordless (Recommended)

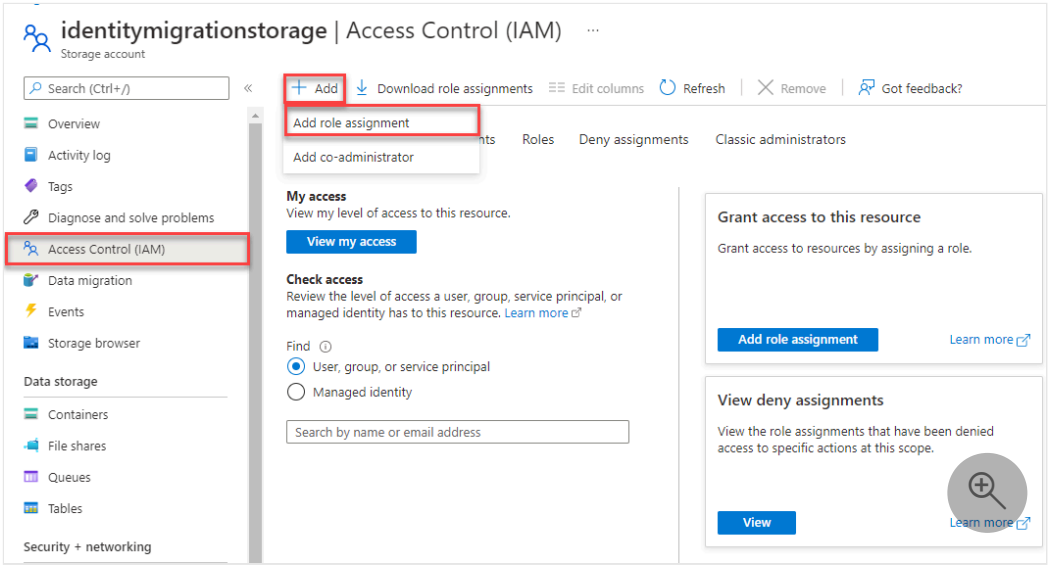
`DefaultAzureCredential` is a class provided by the Azure Identity client library for .NET, which you can learn more about on the DefaultAzureCredential overview. `DefaultAzureCredential` supports multiple authentication methods and determines which method should be used at runtime. This approach enables your app to use different authentication methods in different environments (local vs. production) without implementing environment-specific code.

The order and locations in which `DefaultAzureCredential` looks for credentials can be found in the Azure Identity library overview.

For example, your app can authenticate using your Visual Studio sign-in credentials with when developing locally. Your app can then use a managed identity once it has been deployed to Azure. No code changes are required for this transition.

Assign roles to your Microsoft Entra user account

When developing locally, make sure that the user account that is accessing blob data has the correct permissions. You'll need **Storage Blob Data Contributor** to read and write blob data. To assign yourself this role, you'll need to be assigned the **User Access Administrator** role, or another role that includes the **Microsoft.Authorization/roleAssignments/write** action. You can assign Azure RBAC roles to a user using the Azure portal, Azure CLI, or Azure PowerShell. You can learn more about the available scopes for role assignments on the scope overview page.



In this scenario, you'll assign permissions to your user account, scoped to the storage account, to follow the Principle of Least Privilege. This practice gives users only the minimum permissions needed and creates more secure production environments.

The following example will assign the **Storage Blob Data Contributor** role to your user account, which provides both read and write access to blob data in your storage account.

> **Important**
>
> In most cases it will take a minute or two for the role assignment to propagate in Azure, but in rare cases it may take up to eight minutes. If you receive authentication errors when you first run your code, wait a few moments and try again.

Azure portal

1. In the Azure portal, locate your storage account using the main search bar or left navigation.
2. On the storage account overview page, select **Access control (IAM)** from the left-hand menu.
3. On the **Access control (IAM)** page, select the **Role assignments** tab.
4. Select **+ Add** from the top menu and then **Add role assignment** from the resulting drop-down menu.

5. Use the search box to filter the results to the desired role. For this example, search for *Storage Blob Data Contributor* and select the matching result and then choose **Next**.
6. Under **Assign access to**, select **User, group, or service principal**, and then choose **+ Select members**.
7. In the dialog, search for your Microsoft Entra username (usually your *user@domain* email address) and then choose **Select** at the bottom of the

dialog.

8. Select **Review + assign** to go to the final page, and then **Review + assign** again to complete the process.

Sign in and connect your app code to Azure using DefaultAzureCredential

You can authorize access to data in your storage account using the following steps:

1. For local development, make sure you're authenticated with the same Microsoft Entra account you assigned the role to. You can authenticate via popular development tools, such as the Azure CLI or Azure PowerShell. The development tools with which you can authenticate vary across languages.

   Azure CLI

   Sign-in to Azure through the Azure CLI using the following command:

   Azure CLI

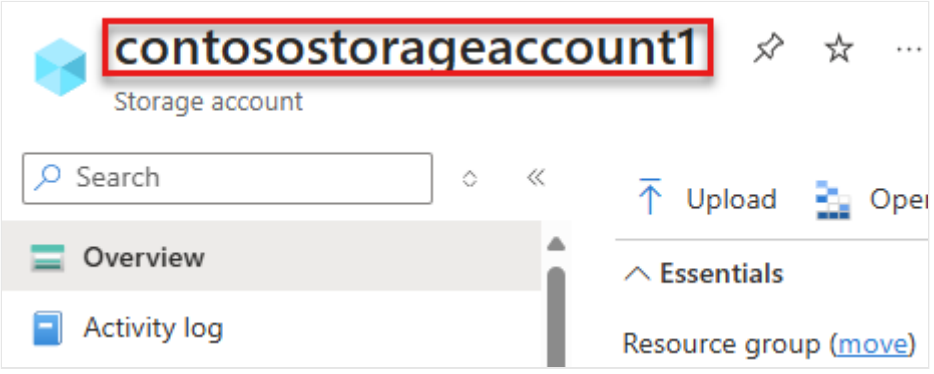
   ```
   az login
   ```

2. To use `DefaultAzureCredential`, add the **Azure.Identity** package to your application.

   Visual Studio

   a. In **Solution Explorer**, right-click the **Dependencies** node of your project. Select **Manage NuGet Packages**.

   b. In the resulting window, search for *Azure.Identity*. Select the appropriate result, and select **Install**.



3. Update your *Program.cs* code to match the following example. When the code is run on your local workstation during development, it will use the developer credentials of the prioritized tool you're logged into to authenticate to Azure, such as the Azure CLI or Visual Studio.

C#

```
using Azure.Storage.Blobs;
using Azure.Storage.Blobs.Models;
using System;
using System.IO;
using Azure.Identity;

// TODO: Replace <storage-account-name> with your actual storage
account name
var blobServiceClient = new BlobServiceClient(
        new Uri("https://<storage-account-
name>.blob.core.windows.net"),
        new DefaultAzureCredential());
```

4. Make sure to update the storage account name in the URI of your `BlobServiceClient`. The storage account name can be found on the overview page of the Azure portal.

> ⓘ Note

When deployed to Azure, this same code can be used to authorize requests to Azure Storage from an application running in Azure. However, you'll need to enable managed identity on your app in Azure. Then configure your storage account to allow that managed identity to connect. For detailed instructions on configuring this connection between Azure services, see the Auth from Azure-hosted apps tutorial.

Create a container

Create a new container in your storage account by calling the CreateBlobContainerAsync method on the `blobServiceClient` object. In this example, the code appends a GUID value to the container name to ensure that it's unique.

Add the following code to the end of the `Program.cs` file:

C#

```
// TODO: Replace <storage-account-name> with your actual storage account name
var blobServiceClient = new BlobServiceClient(
        new Uri("https://<storage-account-name>.blob.core.windows.net"),
        new DefaultAzureCredential());

//Create a unique name for the container
string containerName = "quickstartblobs" + Guid.NewGuid().ToString();

// Create the container and return a container client object
BlobContainerClient containerClient = await
blobServiceClient.CreateBlobContainerAsync(containerName);
```

To learn more about creating a container, and to explore more code samples, see Create a blob container with .NET.

ⓘ Important

Container names must be lowercase. For more information about naming containers and blobs, see Naming and Referencing Containers, Blobs, and Metadata.

Upload a blob to a container

Upload a blob to a container using UploadAsync. The example code creates a text file in the local *data* directory to upload to the container.

Add the following code to the end of the `Program.cs` file:

C#

```
// Create a local file in the ./data/ directory for uploading and
downloading
string localPath = "data";
Directory.CreateDirectory(localPath);
string fileName = "quickstart" + Guid.NewGuid().ToString() + ".txt";
string localFilePath = Path.Combine(localPath, fileName);

// Write text to the file
await File.WriteAllTextAsync(localFilePath, "Hello, World!");

// Get a reference to a blob
BlobClient blobClient = containerClient.GetBlobClient(fileName);

Console.WriteLine("Uploading to Blob storage as blob:\n\t {0}\n",
blobClient.Uri);

// Upload data from the local file, overwrite the blob if it already exists
await blobClient.UploadAsync(localFilePath, true);
```

To learn more about uploading blobs, and to explore more code samples, see Upload a blob with .NET.

List blobs in a container

List the blobs in the container by calling the GetBlobsAsync method.

Add the following code to the end of the `Program.cs` file:

C#

```
Console.WriteLine("Listing blobs...");

// List all blobs in the container
await foreach (BlobItem blobItem in containerClient.GetBlobsAsync())
{
    Console.WriteLine("\t" + blobItem.Name);
}
```

To learn more about listing blobs, and to explore more code samples, see List blobs with .NET.

Download a blob

Download the blob we created earlier by calling the DownloadToAsync method. The example code appends the string "DOWNLOADED" to the file name so that you can see both files in local file system.

Add the following code to the end of the `Program.cs` file:

C#

```
// Download the blob to a local file
// Append the string "DOWNLOADED" before the .txt extension
// so you can compare the files in the data directory
string downloadFilePath = localFilePath.Replace(".txt", "DOWNLOADED.txt");

Console.WriteLine("\nDownloading blob to\n\t{0}\n", downloadFilePath);

// Download the blob's contents and save it to a file
await blobClient.DownloadToAsync(downloadFilePath);
```

To learn more about downloading blobs, and to explore more code samples, see Download a blob with .NET.

Delete a container

The following code cleans up the resources the app created by deleting the container using DeleteAsync. The code example also deletes the local files created by the app.

The app pauses for user input by calling `Console.ReadLine` before it deletes the blob, container, and local files. This is a good chance to verify that the resources were created correctly, before they're deleted.

Add the following code to the end of the `Program.cs` file:

C#

```
// Clean up
Console.Write("Press any key to begin clean up");
Console.ReadLine();

Console.WriteLine("Deleting blob container...");
await containerClient.DeleteAsync();

Console.WriteLine("Deleting the local source and downloaded files...");
File.Delete(localFilePath);
File.Delete(downloadFilePath);
```

```
Console.WriteLine("Done");
```

To learn more about deleting a container, and to explore more code samples, see Delete and restore a blob container with .NET.

The completed code

After completing these steps, the code in your `Program.cs` file should now resemble the following:

Passwordless (Recommended)

C#

```
using Azure.Storage.Blobs;
using Azure.Storage.Blobs.Models;
using Azure.Identity;

// TODO: Replace <storage-account-name> with your actual storage account
name
var blobServiceClient = new BlobServiceClient(
        new Uri("https://<storage-account-name>.blob.core.windows.net"),
        new DefaultAzureCredential());

//Create a unique name for the container
string containerName = "quickstartblobs" + Guid.NewGuid().ToString();

// Create the container and return a container client object
BlobContainerClient containerClient = await
blobServiceClient.CreateBlobContainerAsync(containerName);

// Create a local file in the ./data/ directory for uploading and
downloading
string localPath = "data";
Directory.CreateDirectory(localPath);
string fileName = "quickstart" + Guid.NewGuid().ToString() + ".txt";
string localFilePath = Path.Combine(localPath, fileName);

// Write text to the file
await File.WriteAllTextAsync(localFilePath, "Hello, World!");

// Get a reference to a blob
BlobClient blobClient = containerClient.GetBlobClient(fileName);

Console.WriteLine("Uploading to Blob storage as blob:\n\t {0}\n",
blobClient.Uri);

// Upload data from the local file
await blobClient.UploadAsync(localFilePath, true);
```

```
Console.WriteLine("Listing blobs...");

// List all blobs in the container
await foreach (BlobItem blobItem in containerClient.GetBlobsAsync())
{
    Console.WriteLine("\t" + blobItem.Name);
}

// Download the blob to a local file
// Append the string "DOWNLOADED" before the .txt extension
// so you can compare the files in the data directory
string downloadFilePath = localFilePath.Replace(".txt",
"DOWNLOADED.txt");

Console.WriteLine("\nDownloading blob to\n\t{0}\n", downloadFilePath);

// Download the blob's contents and save it to a file
await blobClient.DownloadToAsync(downloadFilePath);

// Clean up
Console.Write("Press any key to begin clean up");
Console.ReadLine();

Console.WriteLine("Deleting blob container...");
await containerClient.DeleteAsync();

Console.WriteLine("Deleting the local source and downloaded files...");
File.Delete(localFilePath);
File.Delete(downloadFilePath);

Console.WriteLine("Done");
```

Run the code

This app creates a test file in your local *data* folder and uploads it to Blob storage. The example then lists the blobs in the container and downloads the file with a new name so that you can compare the old and new files.

If you're using Visual Studio, press F5 to build and run the code and interact with the console app. If you're using the .NET CLI, navigate to your application directory, then build and run the application.

Console

```
dotnet build
```

Console

```
dotnet run
```

The output of the app is similar to the following example (GUID values omitted for readability):

Output

```
Azure Blob Storage - .NET quickstart sample

Uploading to Blob storage as blob:

https://mystorageacct.blob.core.windows.net/quickstartblobsGUID/quickstartGU
ID.txt

Listing blobs...
        quickstartGUID.txt

Downloading blob to
        ./data/quickstartGUIDDOWNLOADED.txt

Press any key to begin clean up
Deleting blob container...
Deleting the local source and downloaded files...
Done
```

Before you begin the clean-up process, check your *data* folder for the two files. You can open them and observe that they're identical.

Clean up resources

After you verify the files and finish testing, press the **Enter** key to delete the test files along with the container you created in the storage account. You can also use Azure CLI to delete resources.

What is Azure Table storage?

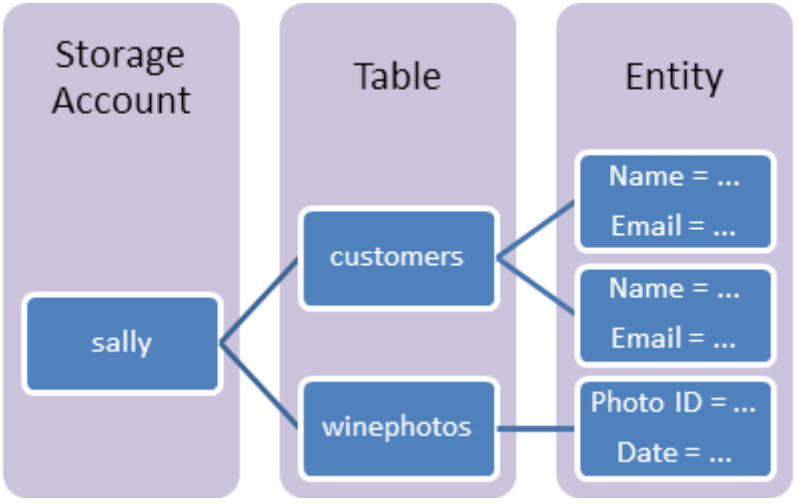
Article • 11/29/2022

> **Tip**
>
> The content in this article applies to the original Azure Table storage. However, the same concepts apply to the newer Azure Cosmos DB for Table, which offers higher performance and availability, global distribution, and automatic secondary indexes. It is also available in a consumption-based **serverless** mode. There are some **feature differences** between Table API in Azure Cosmos DB and Azure Table storage. For more information, see **Azure Cosmos DB for Table**. For ease of development, we now provide a unified **Azure Tables SDK** that can be used to target both Azure Table storage and Azure Cosmos DB for Table.

Azure Table storage is a service that stores non-relational structured data (also known as structured NoSQL data) in the cloud, providing a key/attribute store with a schemaless design. Because Table storage is schemaless, it's easy to adapt your data as the needs of your application evolve. Access to Table storage data is fast and cost-effective for many types of applications, and is typically lower in cost than traditional SQL for similar volumes of data.

You can use Table storage to store flexible datasets like user data for web applications, address books, device information, or other types of metadata your service requires. You can store any number of entities in a table, and a storage account may contain any number of tables, up to the capacity limit of the storage account.

What is Table storage



Azure Table storage stores large amounts of structured data. The service is a NoSQL datastore which accepts authenticated calls from inside and outside the Azure cloud. Azure tables are ideal for storing structured, non-relational data. Common uses of Table storage include:

- Storing TBs of structured data capable of serving web scale applications
- Storing datasets that don't require complex joins, foreign keys, or stored procedures and can be denormalized for fast access
- Quickly querying data using a clustered index
- Accessing data using the OData protocol and LINQ queries with WCF Data Service .NET Libraries

You can use Table storage to store and query huge sets of structured, non-relational data, and your tables will scale as demand increases.

Table storage concepts

Table storage contains the following components:

- **URL format:** Azure Table Storage accounts use this format: `http://<storage account>.table.core.windows.net/<table>`

  You can address Azure tables directly using this address with the OData protocol. For more information, see OData.org.

- **Accounts:** All access to Azure Storage is done through a storage account. For more information about storage accounts, see Storage account overview.

  All access to Azure Cosmos DB is done through an Azure Cosmos DB for Table account. For more information, see Create an Azure Cosmos DB for Table account.

- **Table**: A table is a collection of entities. Tables don't enforce a schema on entities, which means a single table can contain entities that have different sets of properties.

- **Entity**: An entity is a set of properties, similar to a database row. An entity in Azure Storage can be up to 1MB in size. An entity in Azure Cosmos DB can be up to 2MB in size.

- **Properties**: A property is a name-value pair. Each entity can include up to 252 properties to store data. Each entity also has three system properties that specify a partition key, a row key, and a timestamp. Entities with the same partition key can be queried more quickly, and inserted/updated in atomic operations. An entity's row key is its unique identifier within a partition.

For details about naming tables and properties, see Understanding the Table Service Data Model.

Host and deploy ASP.NET Core

Article • 09/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

In general, to deploy an ASP.NET Core app to a hosting environment:

- Deploy the published app to a folder on the hosting server.
- Set up a process manager that starts the app when requests arrive and restarts the app after it crashes or the server reboots.
- For configuration of a reverse proxy, set up a reverse proxy to forward requests to the app.

For Blazor host and deploy guidance, which adds to or supersedes the guidance in this node, see Host and deploy ASP.NET Core Blazor.

Publish to a folder

The dotnet publish command compiles app code and copies the files required to run the app into a *publish* folder. When deploying from Visual Studio, the `dotnet publish` step occurs automatically before the files are copied to the deployment destination.

Run the published app locally

To run the published app locally, run `dotnet <ApplicationName>.dll` from the *publish* folder.

Publish settings files

`*.json` files are published by default. To publish other settings files, specify them in an <ItemGroup><Content Include= ... /> element in the project file. The following example publishes XML files:

XML

```xml
<ItemGroup>
  <Content Include="**\*.xml" Exclude="bin\**\*;obj\**\*"
    CopyToOutputDirectory="PreserveNewest" />
</ItemGroup>
```

Folder contents

The *publish* folder contains one or more app assembly files, dependencies, and optionally the .NET runtime.

A .NET Core app can be published as *self-contained deployment* or *framework-dependent deployment*. If the app is self-contained, the assembly files that contain the .NET runtime are included in the *publish* folder. If the app is framework-dependent, the .NET runtime files aren't included because the app has a reference to a version of .NET that's installed on the server. The default deployment model is framework-dependent. For more information, see .NET Core application deployment.

In addition to *.exe* and *.dll* files, the *publish* folder for an ASP.NET Core app typically contains configuration files, static assets, and MVC views. For more information, see ASP.NET Core directory structure.

Set up a process manager

An ASP.NET Core app is a console app that must be started when a server boots and restarted if it crashes. To automate starts and restarts, a process manager is required. The most common process managers for ASP.NET Core are:

- Linux
  - Nginx
- Windows
  - IIS
  - Windows Service

Set up a reverse proxy

If the app uses the Kestrel server, Nginx, or IIS can be used as a reverse proxy server. A reverse proxy server receives HTTP requests from the Internet and forwards them to Kestrel.

Either configuration—with or without a reverse proxy server—is a supported hosting configuration. For more information, see When to use Kestrel with a reverse proxy.

Proxy server and load balancer scenarios

Additional configuration might be required for apps hosted behind proxy servers and load balancers. Without additional configuration, an app might not have access to the scheme (HTTP/HTTPS) and the remote IP address where a request originated. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Use Visual Studio and MSBuild to automate deployments

Deployment often requires additional tasks besides copying the output from dotnet publish to a server. For example, extra files might be required or excluded from the *publish* folder. Visual Studio uses MSBuild for web deployment, and MSBuild can be customized to do many other tasks during deployment. For more information, see Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment and the Using MSBuild and Team Foundation Build book.

By using the Publish Web feature apps can be deployed directly from Visual Studio to the Azure App Service. Azure DevOps Services supports continuous deployment to Azure App Service. For more information, see DevOps for ASP.NET Core Developers.

Publish to Azure

See Publish an ASP.NET Core app to Azure with Visual Studio for instructions on how to publish an app to Azure using Visual Studio. An additional example is provided by Create an ASP.NET Core web app in Azure.

Publish with MSDeploy on Windows

See Visual Studio publish profiles (.pubxml) for ASP.NET Core app deployment for instructions on how to publish an app with a Visual Studio publish profile, including from a Windows command prompt using the dotnet msbuild command.

Internet Information Services (IIS)

For deployments to Internet Information Services (IIS) with configuration provided by the *web.config* file, see the articles under Host ASP.NET Core on Windows with IIS.

Host in a web farm

For information on configuration for hosting ASP.NET Core apps in a web farm environment (for example, deployment of multiple instances of your app for scalability), see Host ASP.NET Core in a web farm.

Host on Docker

For more information, see Host ASP.NET Core in Docker containers.

Perform health checks

Use Health Check Middleware to perform health checks on an app and its dependencies. For more information, see Health checks in ASP.NET Core.

Additional resources

>
> For the current release, see the .NET 8 version of this article.

Azure App Service is a Microsoft cloud computing platform service for hosting web apps, including ASP.NET Core.

Reliable web app patterns

See *The Reliable Web App Pattern for.NET* YouTube videos and article for guidance on creating a modern, reliable, performant, testable, cost-efficient, and scalable ASP.NET Core app, whether from scratch or refactoring an existing app.

Useful resources

App Service Documentation is the home for Azure Apps documentation, tutorials, samples, how-to guides, and other resources. Two notable tutorials that pertain to hosting ASP.NET Core apps are:

Create an ASP.NET Core web app in Azure
Use Visual Studio to create and deploy an ASP.NET Core web app to Azure App Service on Windows.

Create an ASP.NET Core app in App Service on Linux
Use the command line to create and deploy an ASP.NET Core web app to Azure App Service on Linux.

See the ASP.NET Core on App Service Dashboard for the version of ASP.NET Core available on Azure App service.

Subscribe to the App Service Announcements repository and monitor the issues. The App Service team regularly posts announcements and scenarios arriving in App Service.

The following articles are available in ASP.NET Core documentation:

Publish an ASP.NET Core app to Azure with Visual Studio
Learn how to publish an ASP.NET Core app to Azure App Service using Visual Studio.

Create your first pipeline
Set up a CI build for an ASP.NET Core app, then create a continuous deployment release to Azure App Service.

Azure Web App sandbox
Discover Azure App Service runtime execution limitations enforced by the Azure Apps platform.

Troubleshoot and debug ASP.NET Core projects
Understand and troubleshoot warnings and errors with ASP.NET Core projects.

Application configuration

Platform

The platform architecture (x86/x64) of an App Services app is set in the app's settings in the Azure Portal for apps that are hosted on an A-series compute (Basic) or higher hosting tier. Confirm that the app's publish settings (for example, in the Visual Studio publish profile (.pubxml)) match the setting in the app's service configuration in the Azure Portal.

ASP.NET Core apps can be published framework-dependent because the runtimes for 64-bit (x64) and 32-bit (x86) apps are present on Azure App Service. The .NET Core SDK available on App Service is 32-bit, but you can deploy 64-bit apps built locally using the Kudu console or the publish process in Visual Studio. For more information, see the Publish and deploy the app section.

For more information on .NET Core framework components and distribution methods, such as information on the .NET Core runtime and the .NET Core SDK, see About .NET Core: Composition.

Packages

Include the following NuGet packages to provide automatic logging features for apps deployed to Azure App Service:

- Microsoft.AspNetCore.AzureAppServices.HostingStartup uses IHostingStartup to provide ASP.NET Core logging integration with Azure App Service. The added logging features are provided by the `Microsoft.AspNetCore.AzureAppServicesIntegration` package.
- Microsoft.AspNetCore.AzureAppServicesIntegration executes AddAzureWebAppDiagnostics to add Azure App Service diagnostics logging providers in the `Microsoft.Extensions.Logging.AzureAppServices` package.
- Microsoft.Extensions.Logging.AzureAppServices provides logger implementations to support Azure App Service diagnostics logs and log streaming features.

The preceding packages must be explicitly referenced in the app's project file.

Override app configuration using the Azure Portal

App settings in the Azure Portal permit you to set environment variables for the app. Environment variables can be consumed by the Environment Variables Configuration Provider.

When an app setting is created or modified in the Azure Portal and the **Save** button is selected, the Azure App is restarted. The environment variable is available to the app after the service restarts.

Environment variables are loaded into the app's configuration when CreateBuilder is called to build the host. For more information, see the Environment Variables Configuration Provider.

Proxy server and load balancer scenarios

The IIS Integration Middleware, which configures Forwarded Headers Middleware when hosting out-of-process, and the ASP.NET Core Module are configured to forward the scheme (HTTP/HTTPS) and the remote IP address where the request originated. Additional configuration might be required for apps hosted behind additional proxy servers and load balancers. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Monitoring and logging

ASP.NET Core apps deployed to App Service automatically receive an App Service extension, **ASP.NET Core Logging Integration**. The extension enables logging integration for ASP.NET Core apps on Azure App Service.

For monitoring, logging, and troubleshooting information, see the following articles:

Monitor apps in Azure App Service
Learn how to review quotas and metrics for apps and App Service plans.

Enable diagnostics logging for apps in Azure App Service
Discover how to enable and access diagnostic logging for HTTP status codes, failed requests, and web server activity.

Handle errors in ASP.NET Core
Understand common approaches to handling errors in ASP.NET Core apps.

Troubleshoot ASP.NET Core on Azure App Service and IIS
Learn how to diagnose issues with Azure App Service deployments with ASP.NET Core apps.

Common error troubleshooting for Azure App Service and IIS with ASP.NET Core
See the common deployment configuration errors for apps hosted by Azure App Service/IIS with troubleshooting advice.

Data Protection key ring and deployment slots

Data Protection keys are persisted to the *%HOME%\ASP.NET\DataProtection-Keys* folder. This folder is backed by network storage and is synchronized across all machines hosting the app. Keys aren't protected at rest. This folder supplies the key ring to all instances of an app in a single deployment slot. Separate deployment slots, such as Staging and Production, don't share a key ring.

When swapping between deployment slots, any system using data protection won't be able to decrypt stored data using the key ring inside the previous slot. ASP.NET Cookie Middleware uses data protection to protect its cookies. This leads to users being signed out of an app that uses the standard ASP.NET Cookie Middleware. For a slot-independent key ring solution, use an external key ring provider, such as:

- Azure Blob Storage
- Azure Key Vault
- SQL store

- Redis cache

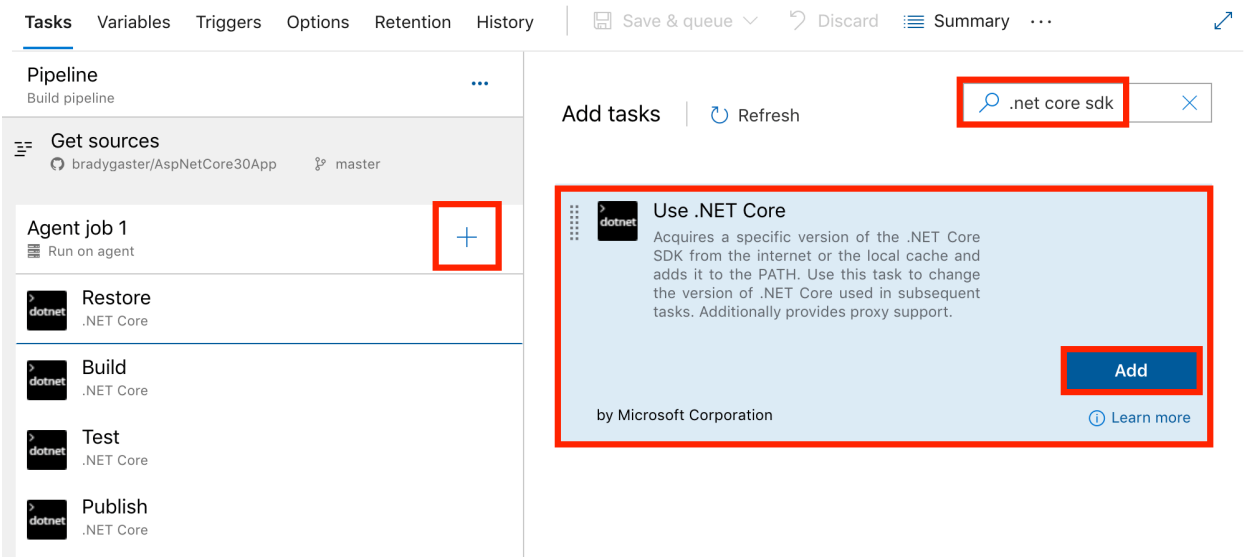
For more information, see Key storage providers in ASP.NET Core.

Deploy an ASP.NET Core app that uses a .NET Core preview

To deploy an app that uses a preview release of .NET Core, see the following resources. These approaches are also used when the runtime is available but the SDK hasn't been installed on Azure App Service.

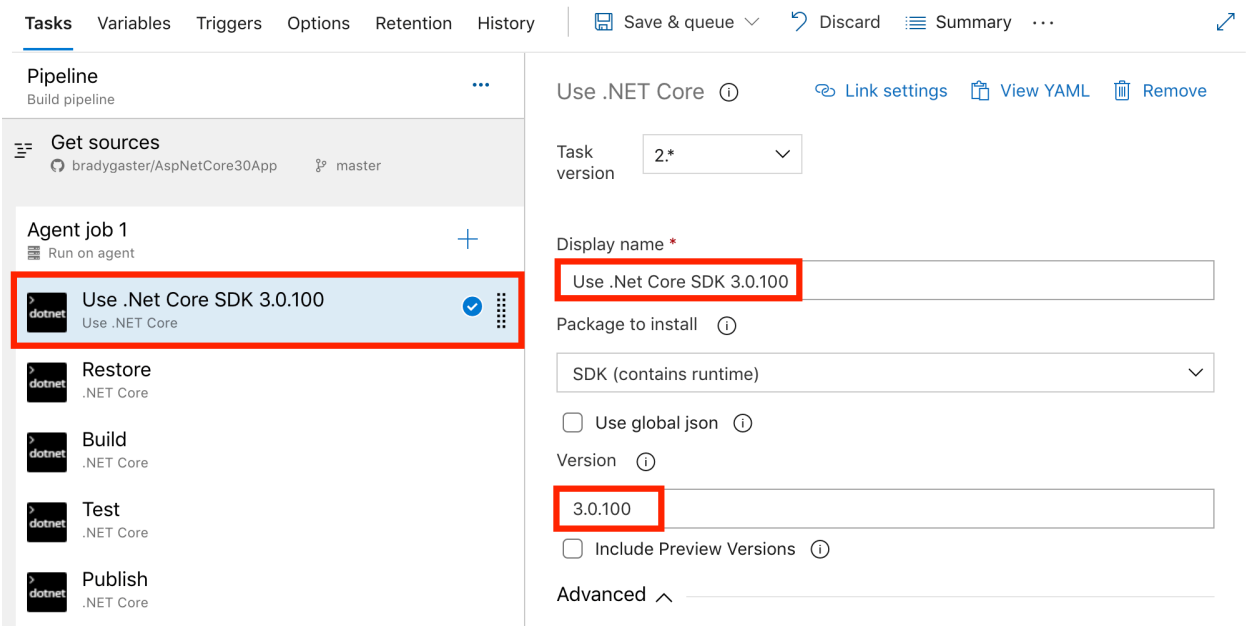
- Specify the .NET Core SDK Version using Azure Pipelines
- Deploy a self-contained preview app
- Use Docker with Web Apps for containers
- Install the preview site extension

See the ASP.NET Core on App Service Dashboard for the version of ASP.NET Core available on Azure App service.



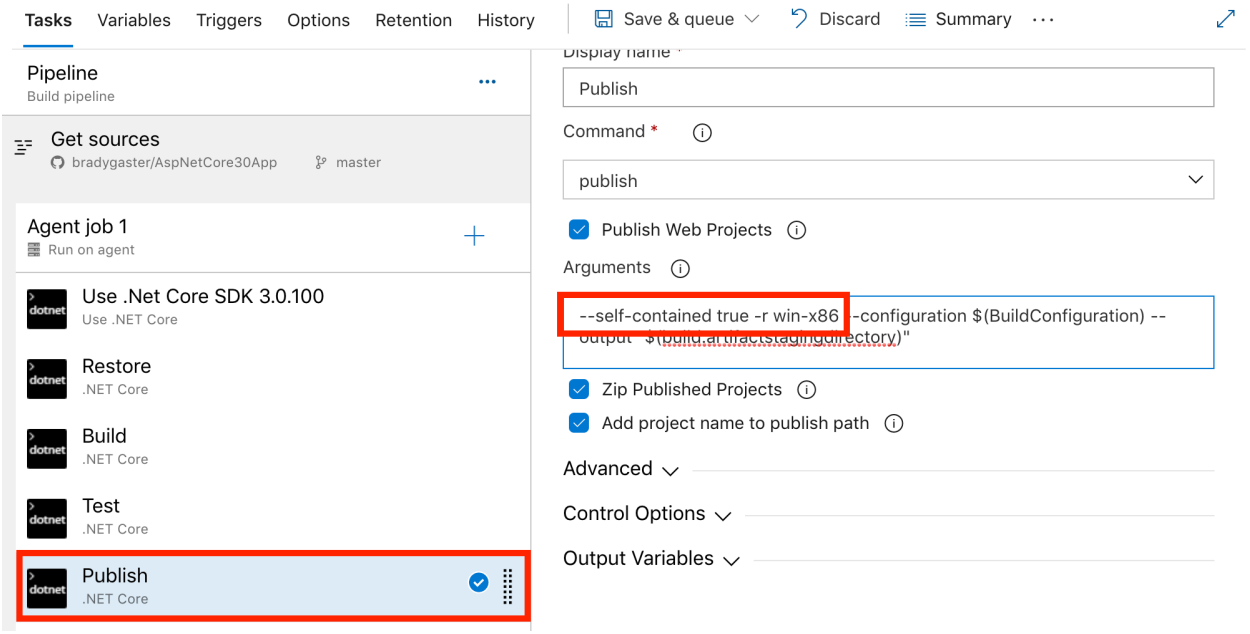
See Select the .NET Core version to use for information on selecting the version of the .NET SDK for self-contained deployments.

Specify the .NET Core SDK Version using Azure Pipelines



Use Azure App Service CI/CD scenarios to set up a continuous integration build with Azure DevOps. After the Azure DevOps build is created, optionally configure the build to use a specific SDK version.

Specify the .NET Core SDK version



When using the App Service deployment center to create an Azure DevOps build, the default build pipeline includes steps for `Restore`, `Build`, `Test`, and `Publish`. To specify the SDK version, select the **Add (+)** button in the Agent job list to add a new step. Search for **.NET Core SDK** in the search bar.

Move the step into the first position in the build so that the steps following it use the specified version of the .NET Core SDK. Specify the version of the .NET Core SDK. In this example, the SDK is set to `3.0.100`.

To publish a self-contained deployment (SCD), configure SCD in the `Publish` step and provide the Runtime Identifier (RID).

Deploy a self-contained preview app

A self-contained deployment (SCD) that targets a preview runtime carries the preview runtime in the deployment.

When deploying a self-contained app:

- The site in Azure App Service doesn't require the preview site extension.
- The app must be published following a different approach than when publishing for a framework-dependent deployment (FDD).

Follow the guidance in the Deploy the app self-contained section.

Use Docker with Web Apps for containers

The Docker Hub at `https://hub.docker.com/_/microsoft-dotnet` contains the latest preview Docker images. The images can be used as a base image. Use the image and deploy to Web Apps for Containers normally.

Install the preview site extension

If a problem occurs using the preview site extension, open an dotnet/AspNetCore issue.

1. From the Azure Portal, navigate to the App Service.
2. Select the web app.
3. Type "ex" in the search box to filter for "Extensions" or scroll down the list of management tools.

4. Select **Extensions**.
5. Select **Add**.
6. Select the **ASP.NET Core {X.Y} ({x64|x86}) Runtime** extension from the list, where `{X.Y}` is the ASP.NET Core preview version and `{x64|x86}` specifies the platform.
7. Select **OK** to accept the legal terms.
8. Select **OK** to install the extension.

When the operation completes, the latest .NET Core preview is installed. Verify the installation:

1. Select **Advanced Tools**.
2. Select **Go** in **Advanced Tools**.
3. Select the **Debug console** > **PowerShell** menu item.
4. At the PowerShell prompt, execute the following command. Substitute the ASP.NET Core runtime version for `{X.Y}` and the platform for `{PLATFORM}` in the command:

   ```
   PowerShell

   Test-Path D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.{PLATFORM}\
   ```

   The command returns `True` when the x64 preview runtime is installed.

> **Note**
>
> The platform architecture (x86/x64) of an App Services app is set in the app's settings in the Azure Portal for apps that are hosted on an A-series compute (Basic) or higher hosting tier. Confirm that the app's publish settings (for example, in the Visual Studio publish profile (.pubxml)) match the setting in the app's service configuration in the Azure portal.
>
> If the app is run in in-process mode and the platform architecture is configured for 64-bit (x64), the ASP.NET Core Module uses the 64-bit preview runtime, if present. Install the **ASP.NET Core {X.Y} (x64) Runtime** extension using the Azure Portal.
>
> After installing the x64 preview runtime, run the following command in the Azure Kudu PowerShell command window to verify the installation. Substitute the ASP.NET Core runtime version for `{X.Y}` in the following command:
>
> ```
> PowerShell
> ```

```
Test-Path D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64\
```

The command returns `True` when the x64 preview runtime is installed.

Use the preview site extension with an ARM template

If an ARM template is used to create and deploy apps, the `Microsoft.Web/sites/siteextensions` resource type can be used to add the site extension to a web app. In the following example, the ASP.NET Core 5.0 (x64) Runtime site extension (`AspNetCoreRuntime.5.0.x64`) is added to the app:

JSON

```
{
    ...
    "parameters": {
        "site_name": {
            "defaultValue": "{SITE NAME}",
            "type": "String"
        },
        ...
    },
    ...
    "resources": [
        ...
        {
            "type": "Microsoft.Web/sites/siteextensions",
            "apiVersion": "2018-11-01",
            "name": "[concat(parameters('site_name'),
'/AspNetCoreRuntime.5.0.x64')]",
            "location": "[resourceGroup().location]",
            "dependsOn": [
                "[resourceId('Microsoft.Web/sites',
parameters('site_name'))]"
            ]
        }
    ]
}
```

For the placeholder `{SITE NAME}`, use the app's name in Azure App Service (for example, `contoso`).

Publish and deploy the app

For a 64-bit deployment:

- Use a 64-bit .NET Core SDK to build a 64-bit app.
- Set the **Platform** to **64 Bit** in the App Service's **Configuration** > **General settings**. The app must use a Basic or higher service plan to enable the choice of platform bitness.

Deploy the app framework-dependent

Apps published as framework-dependent are cross-platform and don't include the .NET runtime in the deployment. Azure App Service includes the .NET runtime.

Visual Studio

1. Right-click the project in **Solution Explorer** and select **Publish**. Alternatively, select **Build** > **Publish {Application Name}** from the Visual Studio toolbar.
2. In the **Publish** dialog, select **Azure** > **Next**.
3. Select the Azure service.
4. Select **Advanced**. The **Publish** dialog opens.
5. Select a Resource group and Hosting plan, or create new ones.
6. Select **Finish**.
7. In the **Publish** page:

    - For **Configuration**, select the pen icon **Edit Configuration**:
        - Confirm that the **Release** configuration is selected.
        - In the **Deployment Mode** drop-down list, select **Framework-Dependent**.
        - In the **Target Runtime** drop-down list, select the desired runtime. The default is `win-x86`.
    - To remove additional files upon deployment, open **File Publish Options** and select the checkbox to remove additional files at the destination.
    - Select **Save**.
    - Select **Publish**.

Deploy the app self-contained

Publishing an app as self-contained produces a platform-specific executable. The output publishing folder contains all components of the app, including the .NET libraries and target runtime. For more information, see [Publish self-contained]/dotnet/core/deploying/#publish-self-contained). Use Visual Studio or the .NET CLI for a self-contained deployment (SCD).

Visual Studio

1. Right-click the project in **Solution Explorer** and select **Publish**. Alternatively, select **Build** > **Publish {Application Name}** from the Visual Studio toolbar.
2. In the **Publish** dialog, select **Azure** > **Next**.
3. Select the Azure service.
4. Select **Advanced**. The **Publish** dialog opens.
5. Select a Resource group and Hosting plan, or create new ones.
6. Select **Finish**.
7. In the **Publish** page:

    - For **Configuration**, select the pen icon **Edit Configuration**:
        - Confirm that the **Release** configuration is selected.
        - In the **Deployment Mode** drop-down list, select **Self-Contained**.
        - In the **Target Runtime** drop-down list, select the desired runtime. The default is `win-x86`.
    - To remove additional files upon deployment, open **File Publish Options** and select the checkbox to remove additional files at the destination.
    - Select **Save**.
    - Select **Publish**.

Protocol settings (HTTPS)

Secure protocol bindings allow specifying a certificate to use when responding to requests over HTTPS. Binding requires a valid private certificate (*.pfx*) issued for the specific hostname. For more information, see Tutorial: Bind an existing custom SSL certificate to Azure App Service.

Transform web.config

If you need to transform *web.config* on publish (for example, set environment variables based on the configuration, profile, or environment), see Transform web.config.

Additional resources

- Azure App Service diagnostics overview
- Host ASP.NET Core in a web farm

- Tutorial: Connect to SQL Database from .NET App Service without secrets using a managed identity

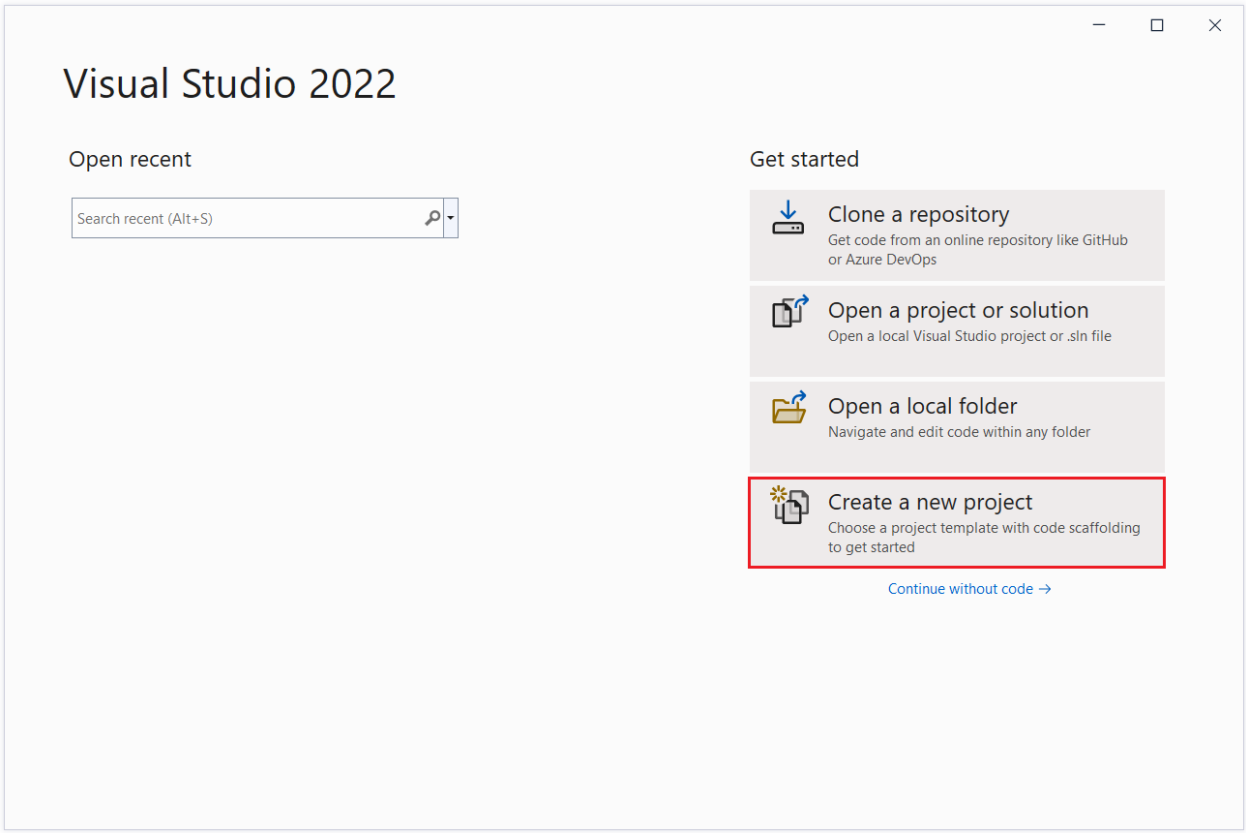
Azure App Service on Windows Server uses Internet Information Services (IIS). Kestrel and YARP on the front end provides the load balancer. The following topics pertain to the underlying IIS technology:

- Host ASP.NET Core on Windows with IIS
- ASP.NET Core Module (ANCM) for IIS
- IIS modules with ASP.NET Core
- Windows Server - IT administrator content for current and previous releases

Publish an ASP.NET Core app to Azure with Visual Studio

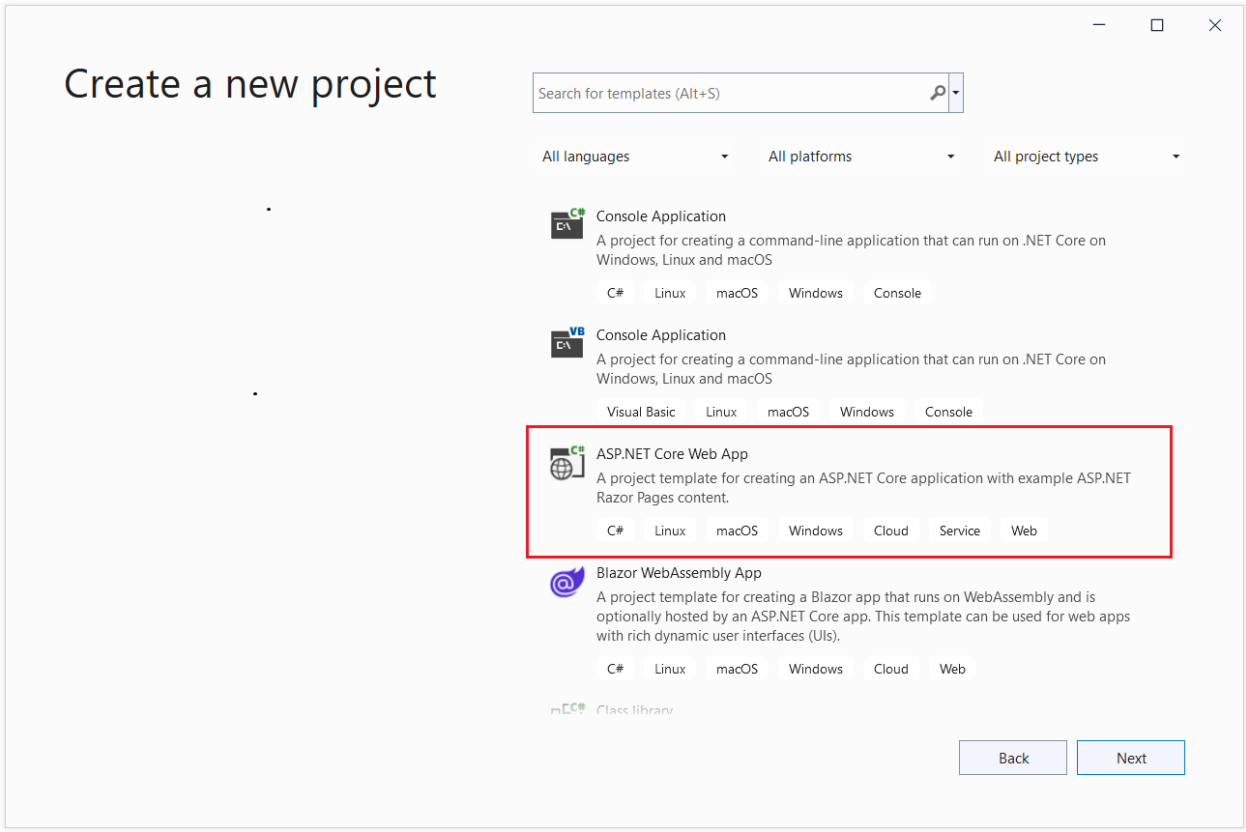
Article • 11/01/2023

> **Important**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see **Deploy ASP.NET Core preview release to Azure App Service**.



To troubleshoot an App Service deployment issue, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Set up

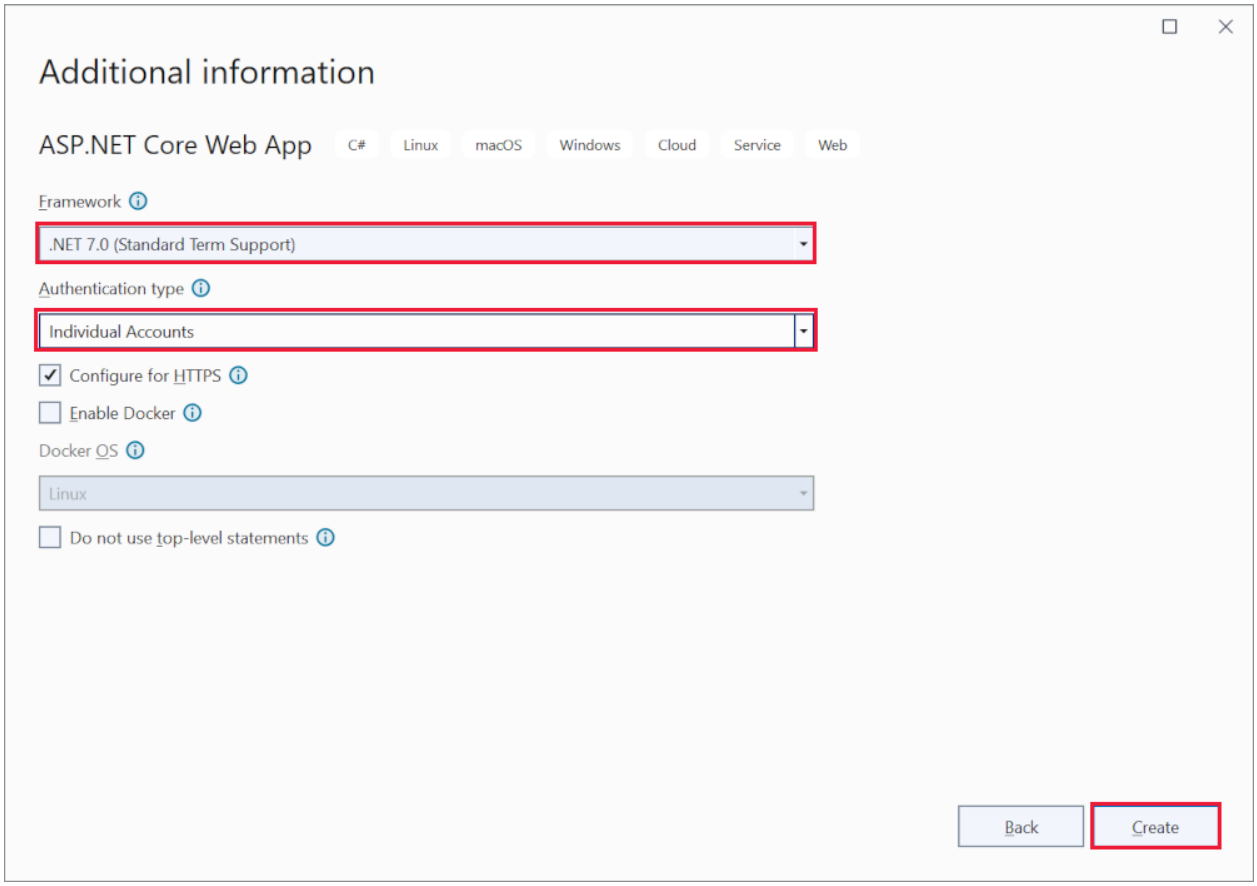


Open a free Azure account if you don't have one.

Create a web app

Start Visual Studio 2022 and select **Create a new project**.

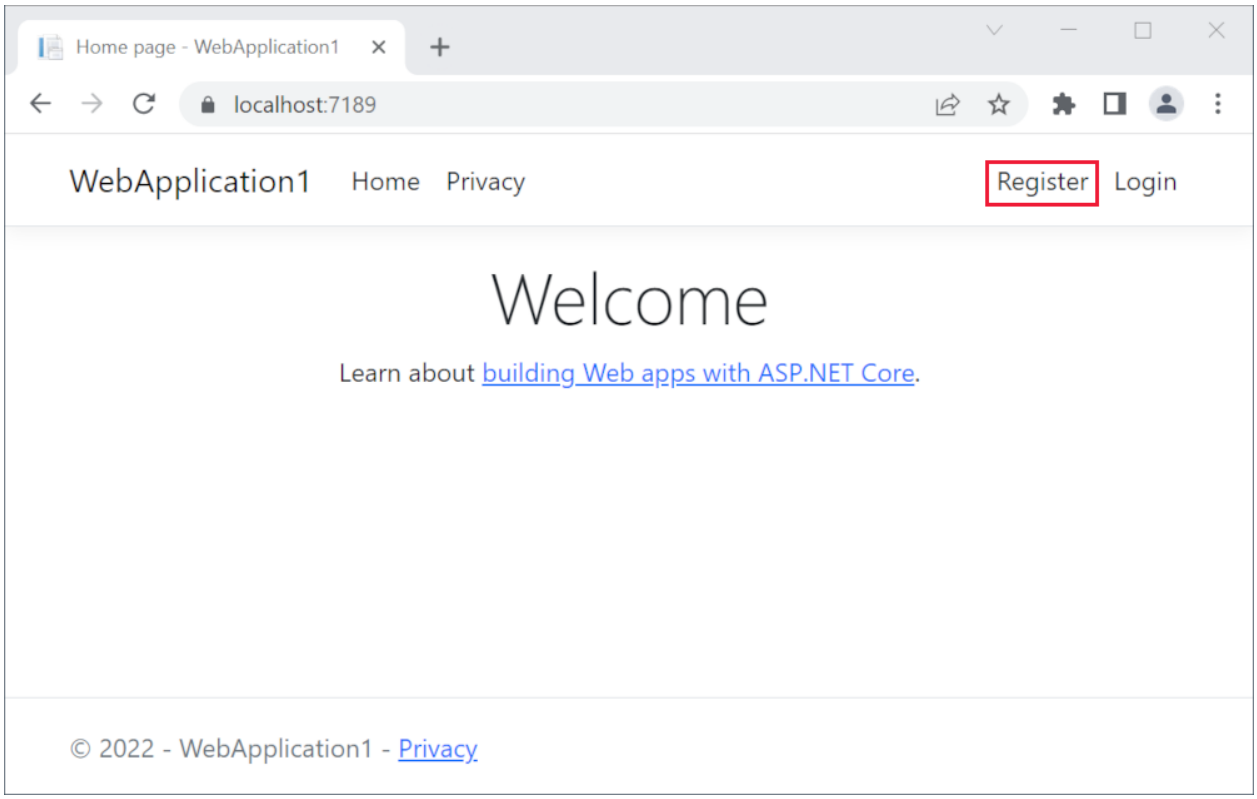
In the **Create a new project** dialog, select **ASP.NET Core Web App**, and then select **Next**.



In the **Configure your new project** dialog, name your project, and then select **Next**.

In the **Additional information** dialog:

- In the **Framework** input, select **.NET 7.0 (Standard Term Support)**.

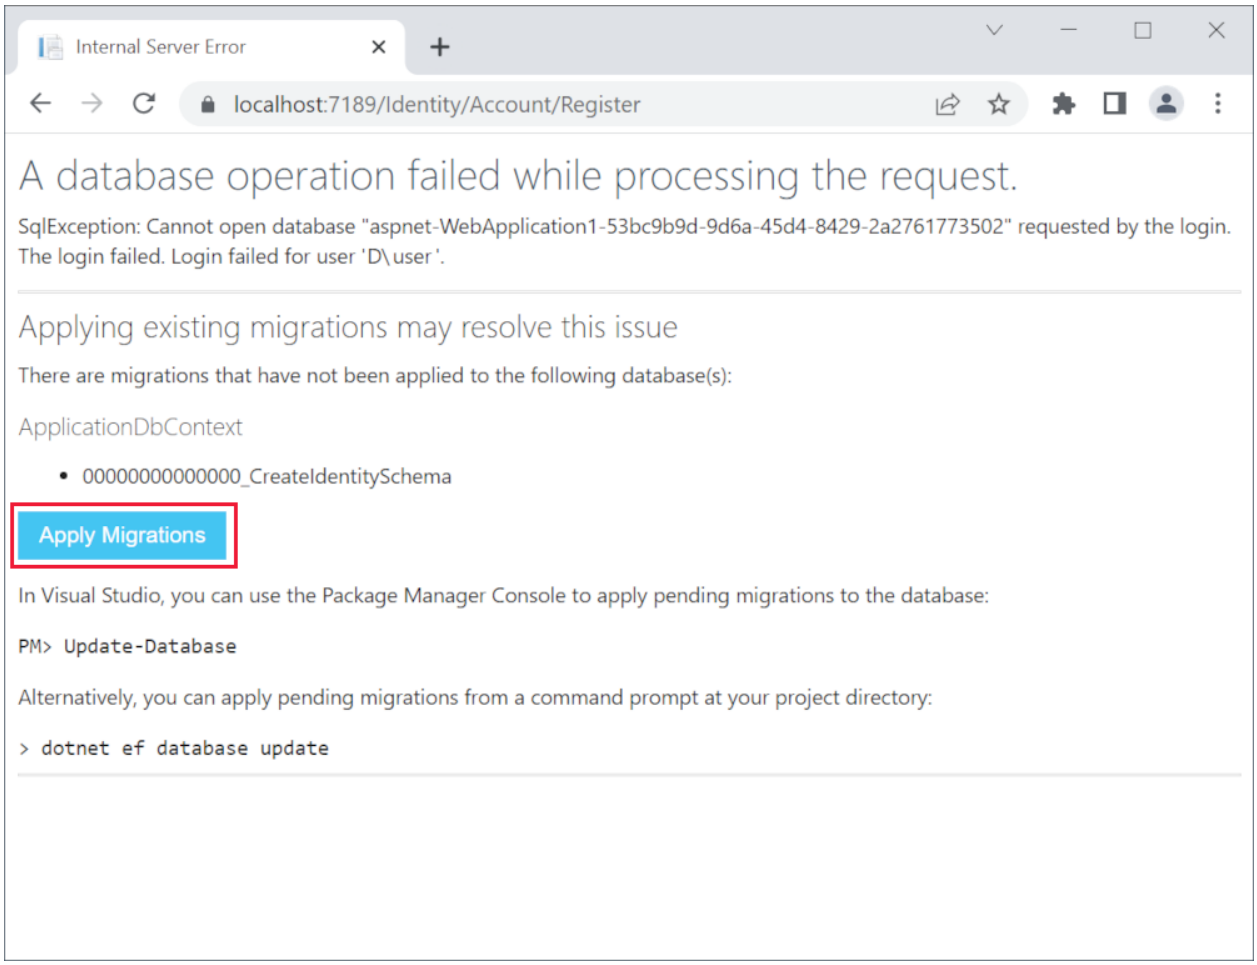


- In the **Authentication type** input, select **Individual Accounts**, and then select **Create**.

Visual Studio creates the solution.

Run the app

- Press F5 to run the project.



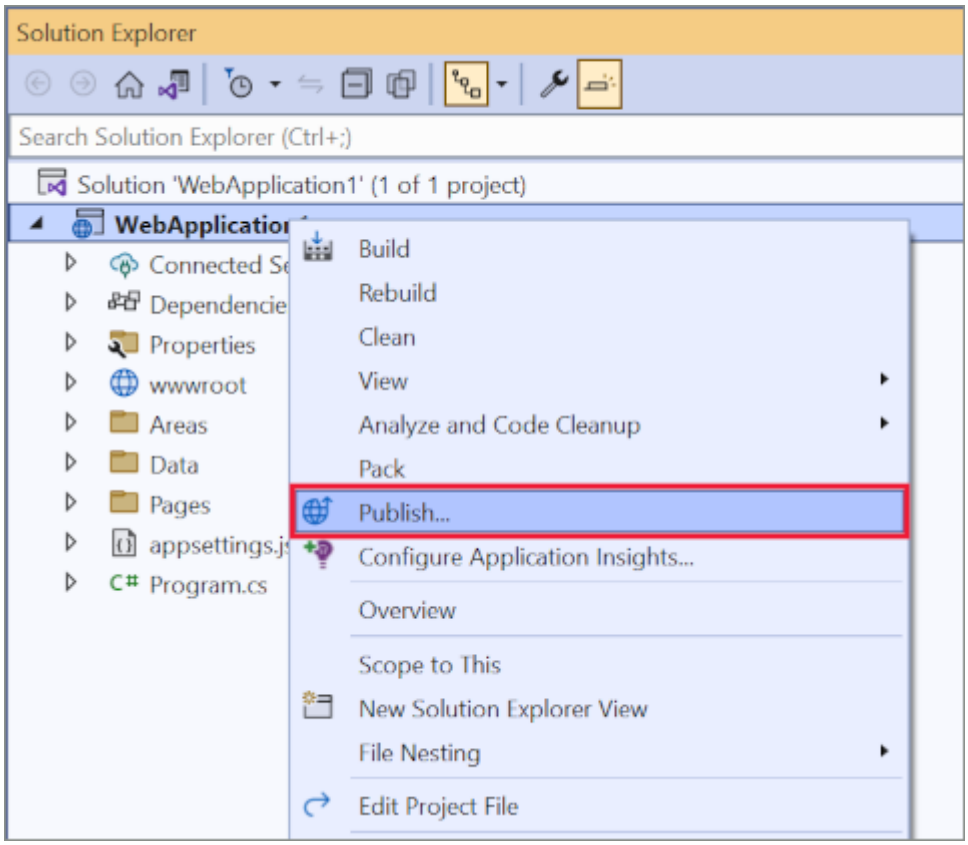
Register a user

- Select **Register** and register a new user. You can use a fictitious email address. When you submit, the page displays the following error:

  "A database operation failed while processing the request. Applying existing migrations may resolve this issue"

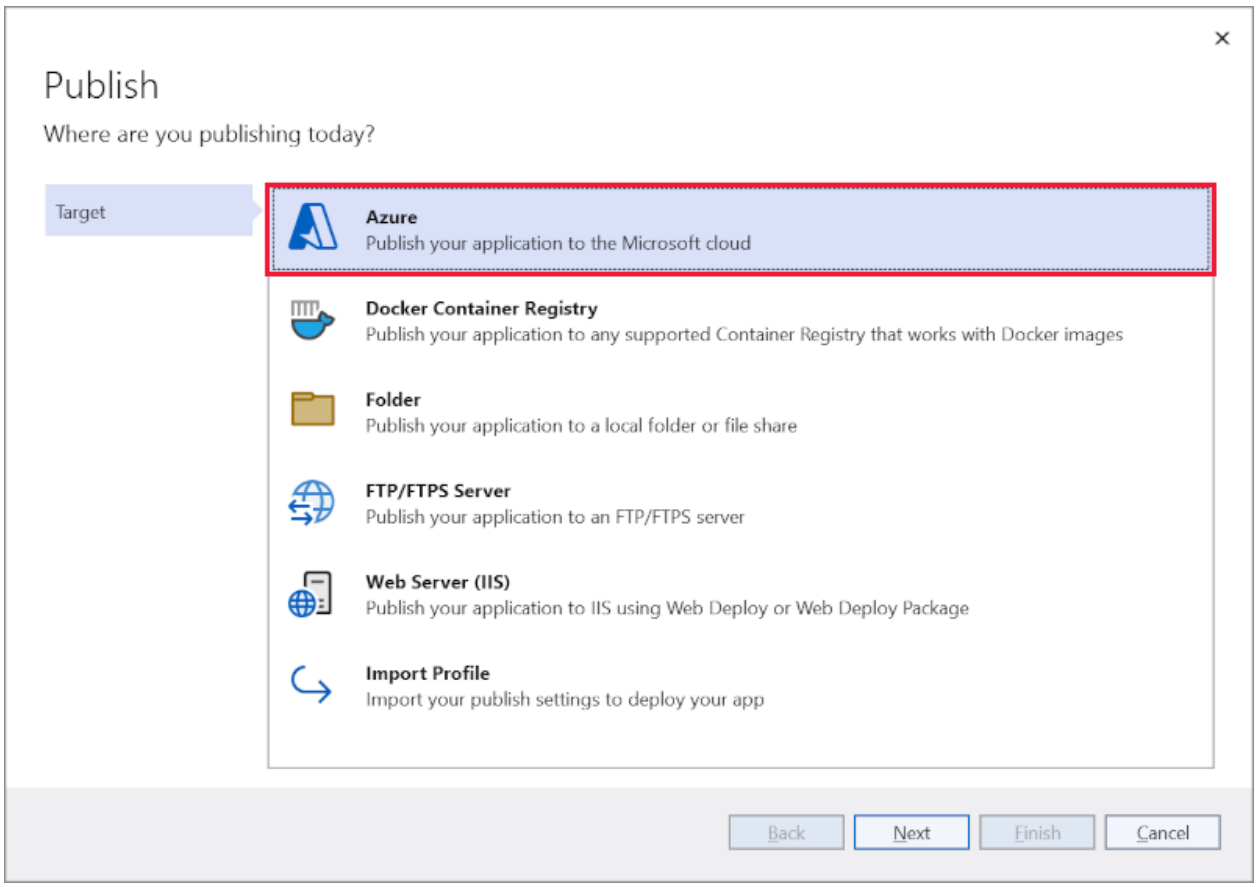
- Select **Apply Migrations** and, once the page updates, refresh the page.

- A **Register confirmation** page is displayed. Select **Click here to confirm your account**.
- A **Confirm email** page is displayed.
- Log in as the new user.



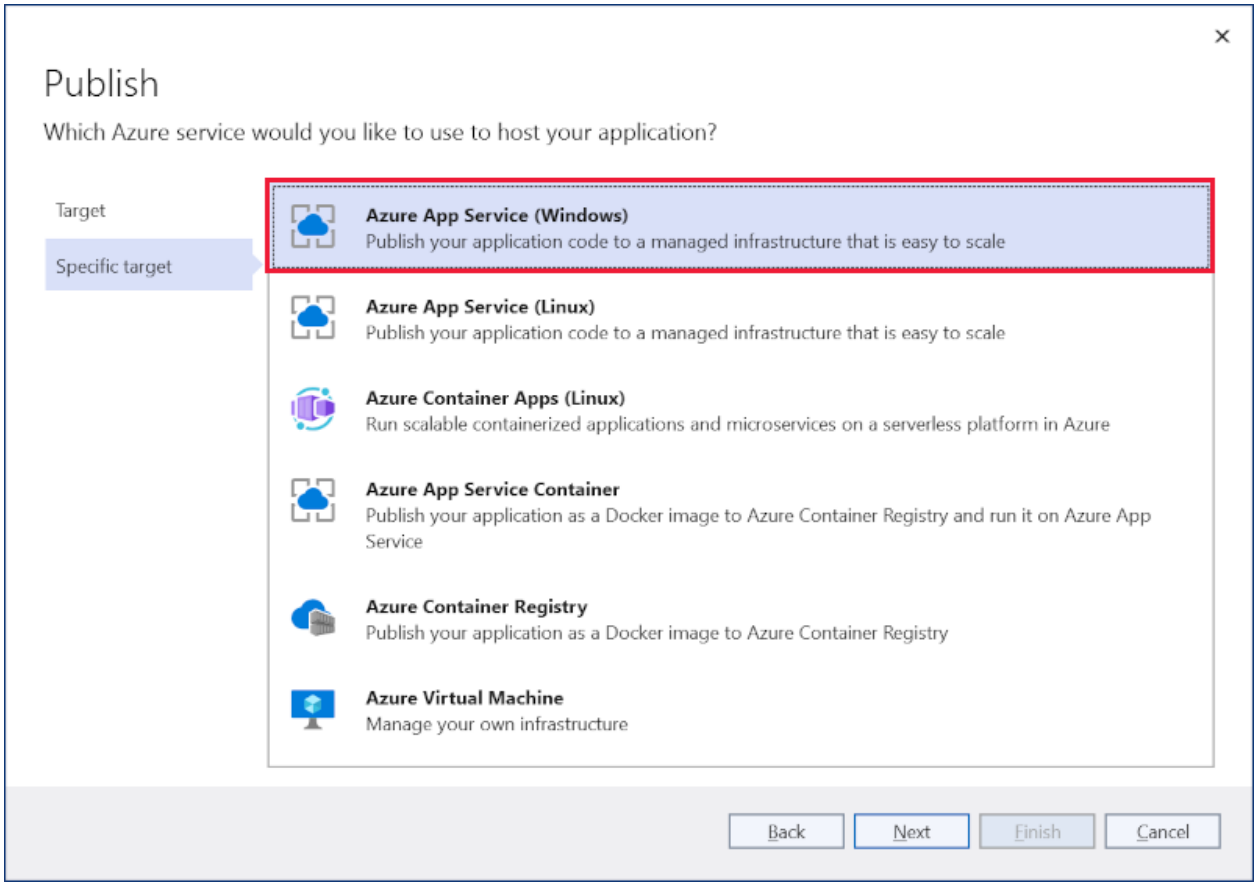
The app displays the email used to register the new user and a **Logout** link.

- Stop the application by closing the browser, or in Visual Studio select **Debug** > **Stop Debugging**.
- In Visual Studio select **Build** > **Clean Solution** to clean project items and avoid file contention.



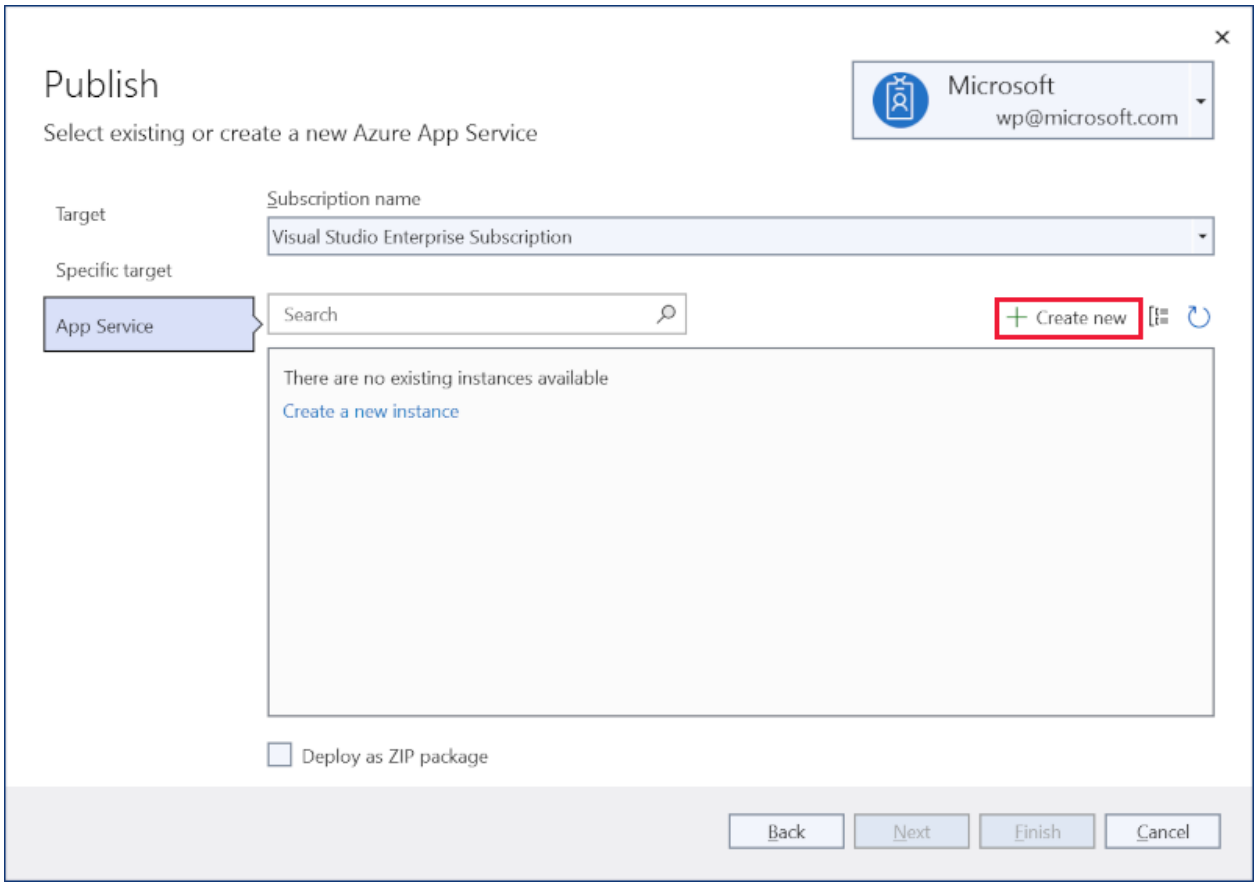
Deploy the app to Azure

Right-click on the project in Solution Explorer and select **Publish**.



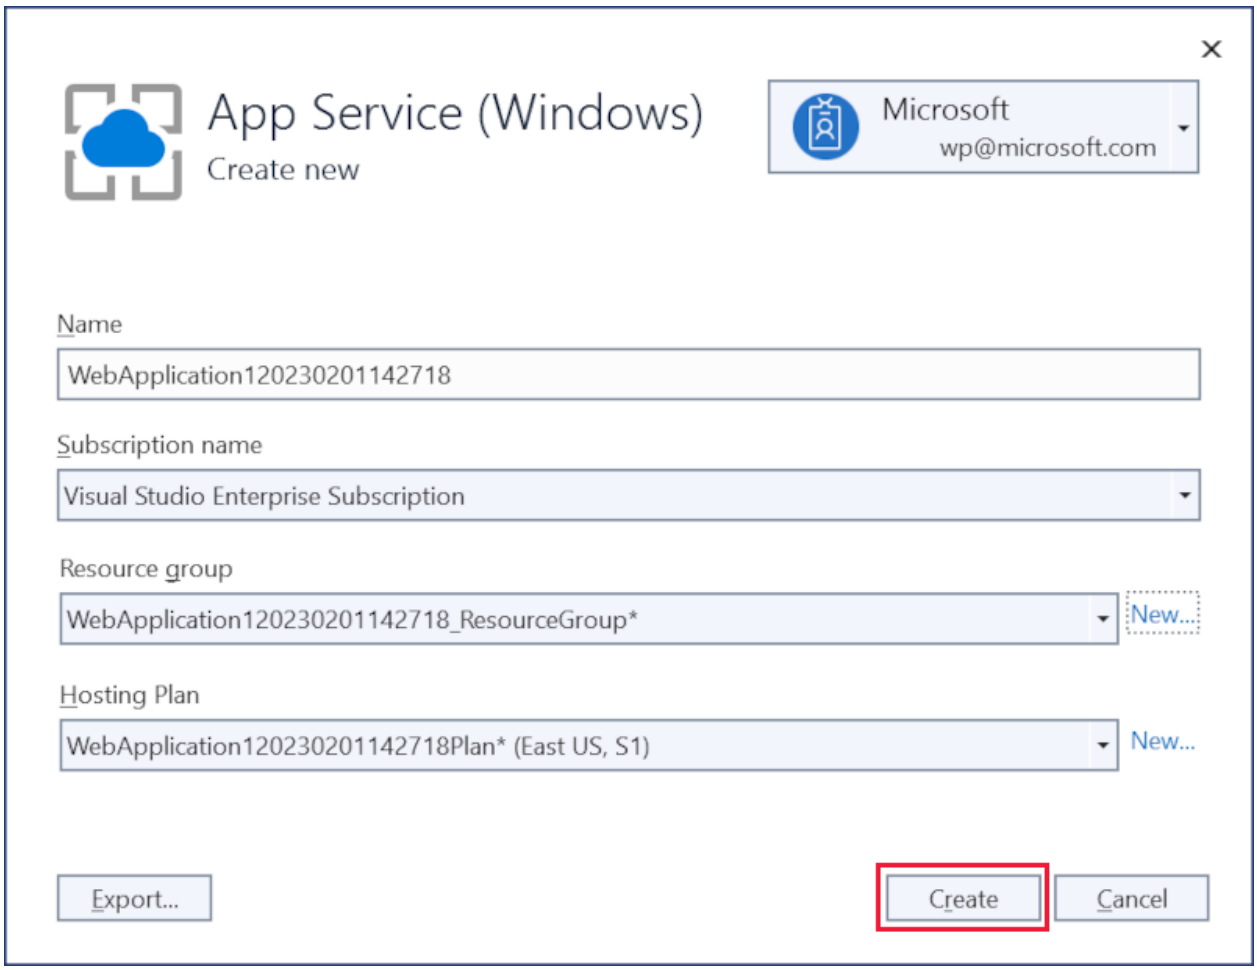
In the **Publish** dialog:

- Select **Azure**.
- Select **Next**.

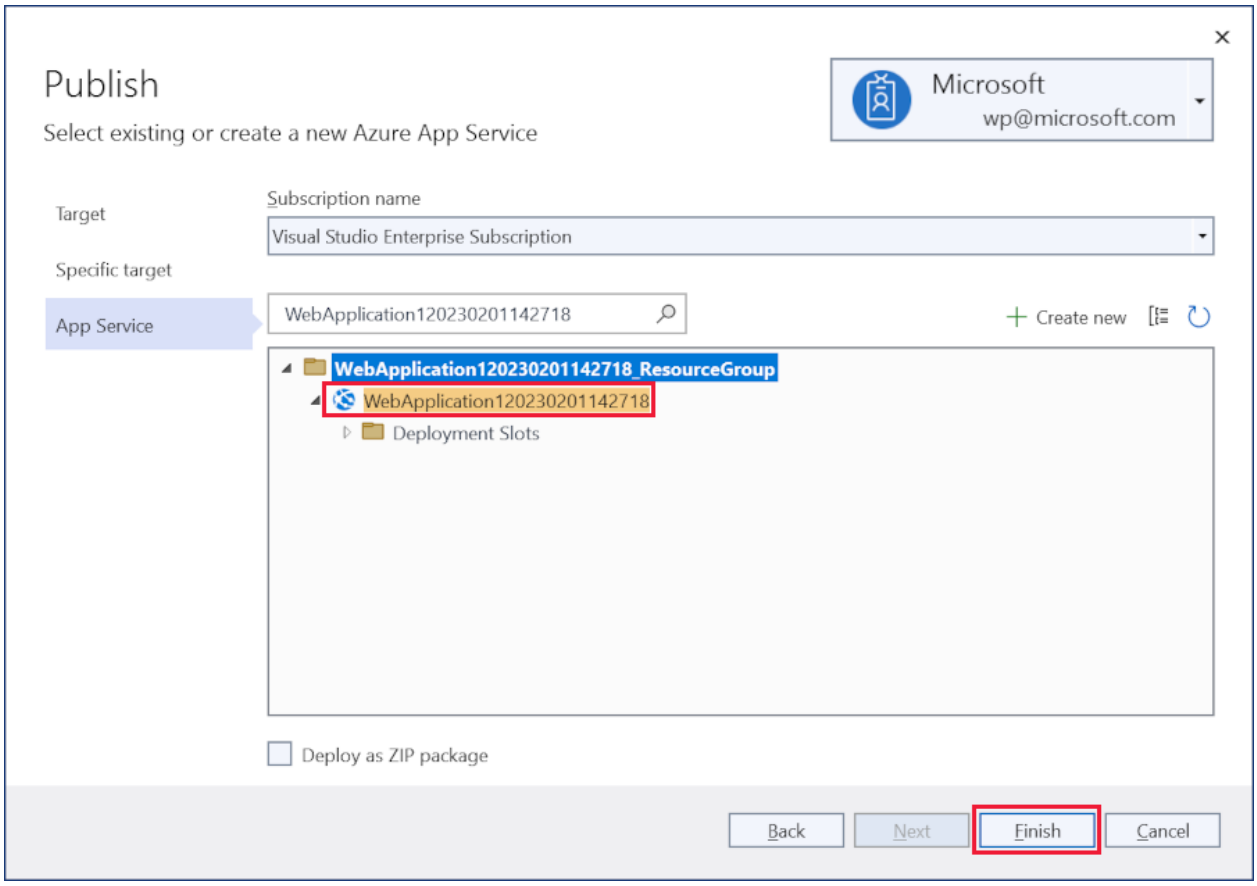


In the **Publish** dialog:

- Select **Azure App Service (Windows)**.
- Select **Next**.

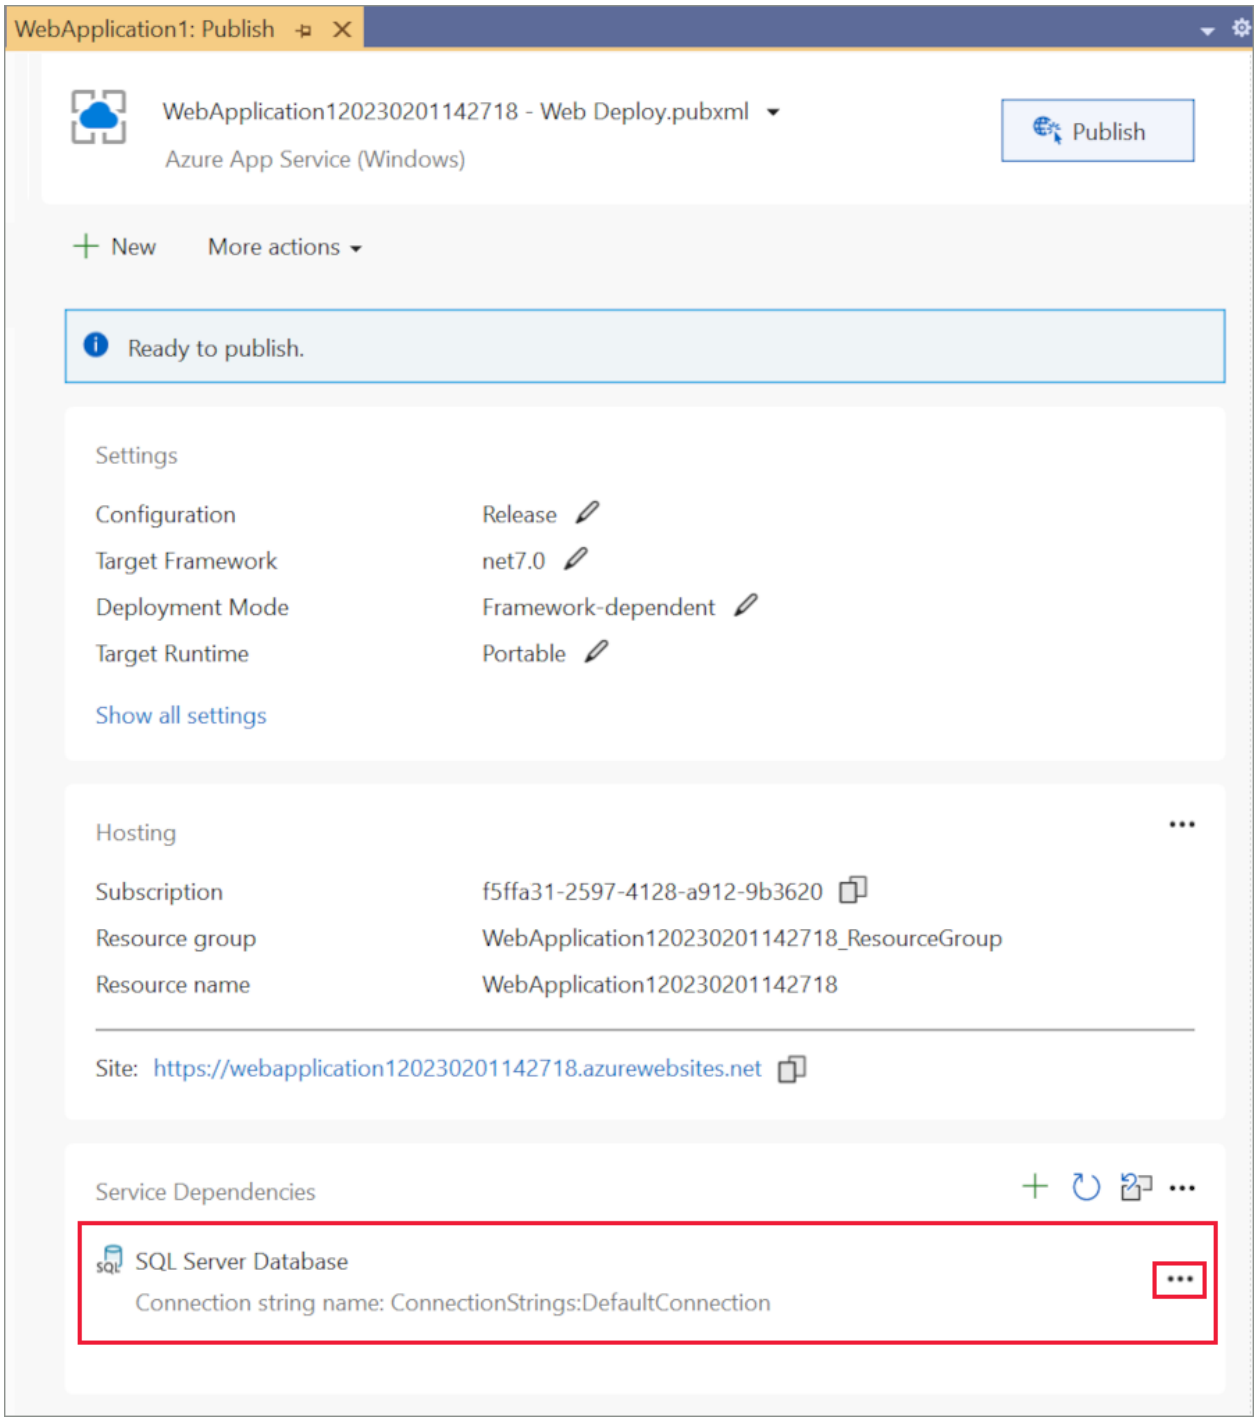


In the **Publish** dialog, in the **App Service** tab, select **Create new**.



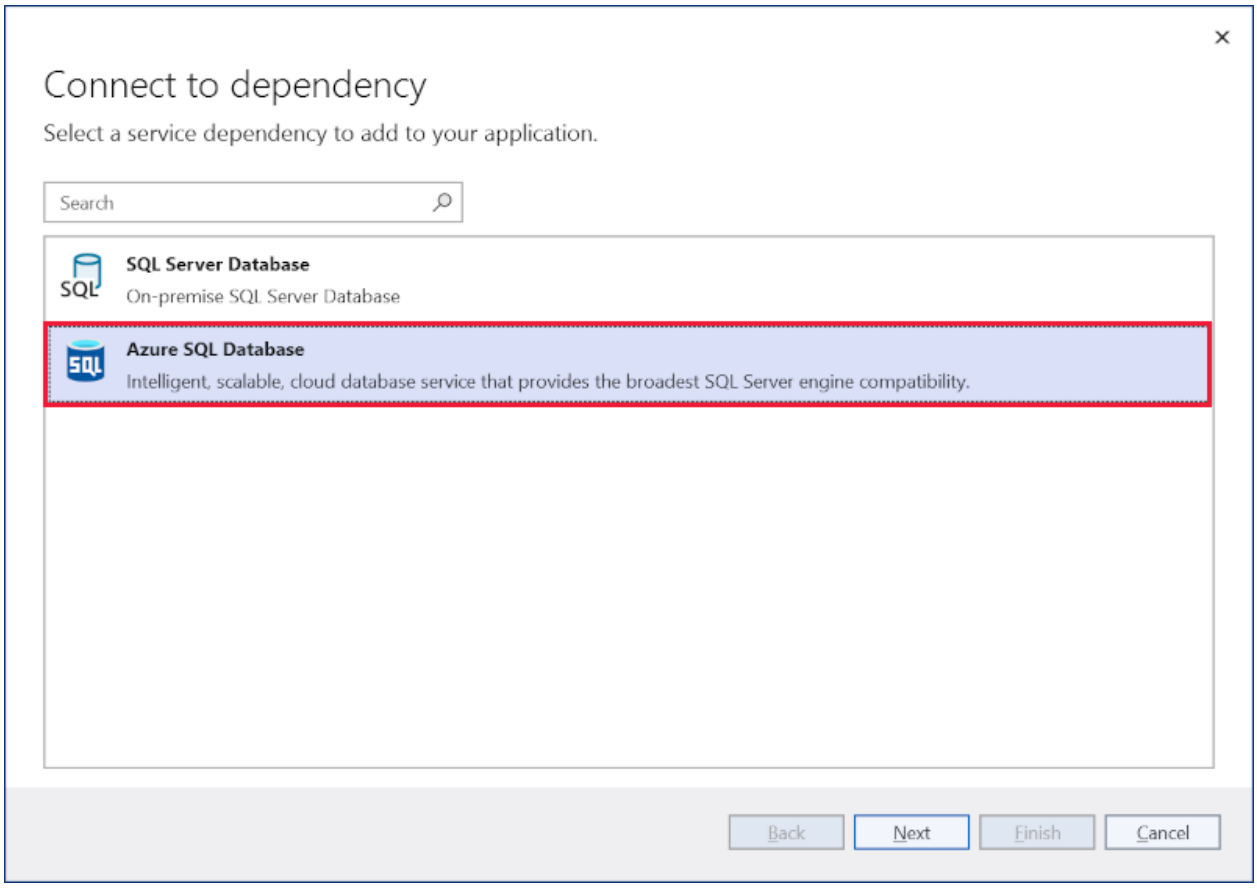
The **Create App Service** dialog appears:

- The **Name**, **Resource Group**, and **Hosting Plan** entry fields are populated. You can keep these names or change them.
- Select **Create**.



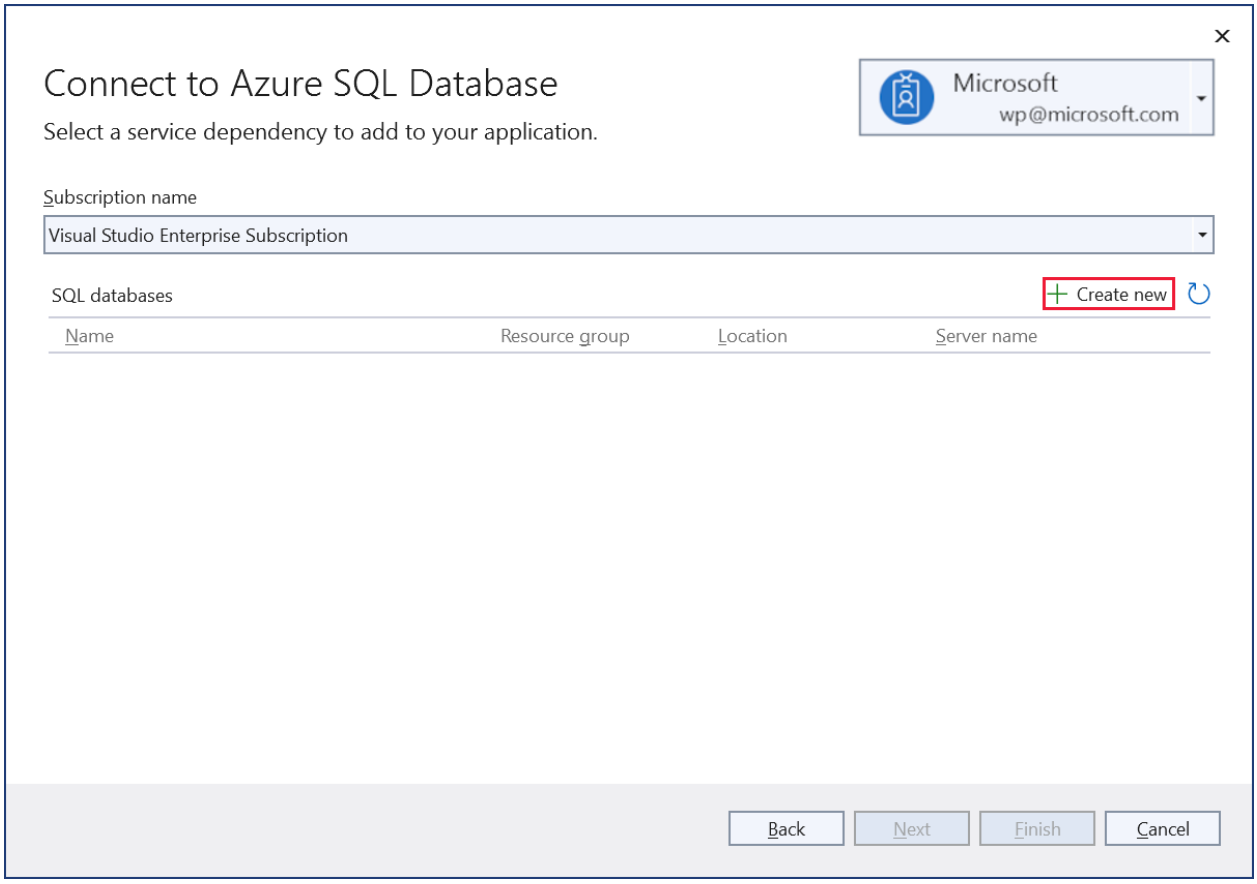
After creation is completed the dialog is automatically closed and the **Publish** dialog gets focus again:

- The new instance that was just created is automatically selected.
- Select **Finish**.



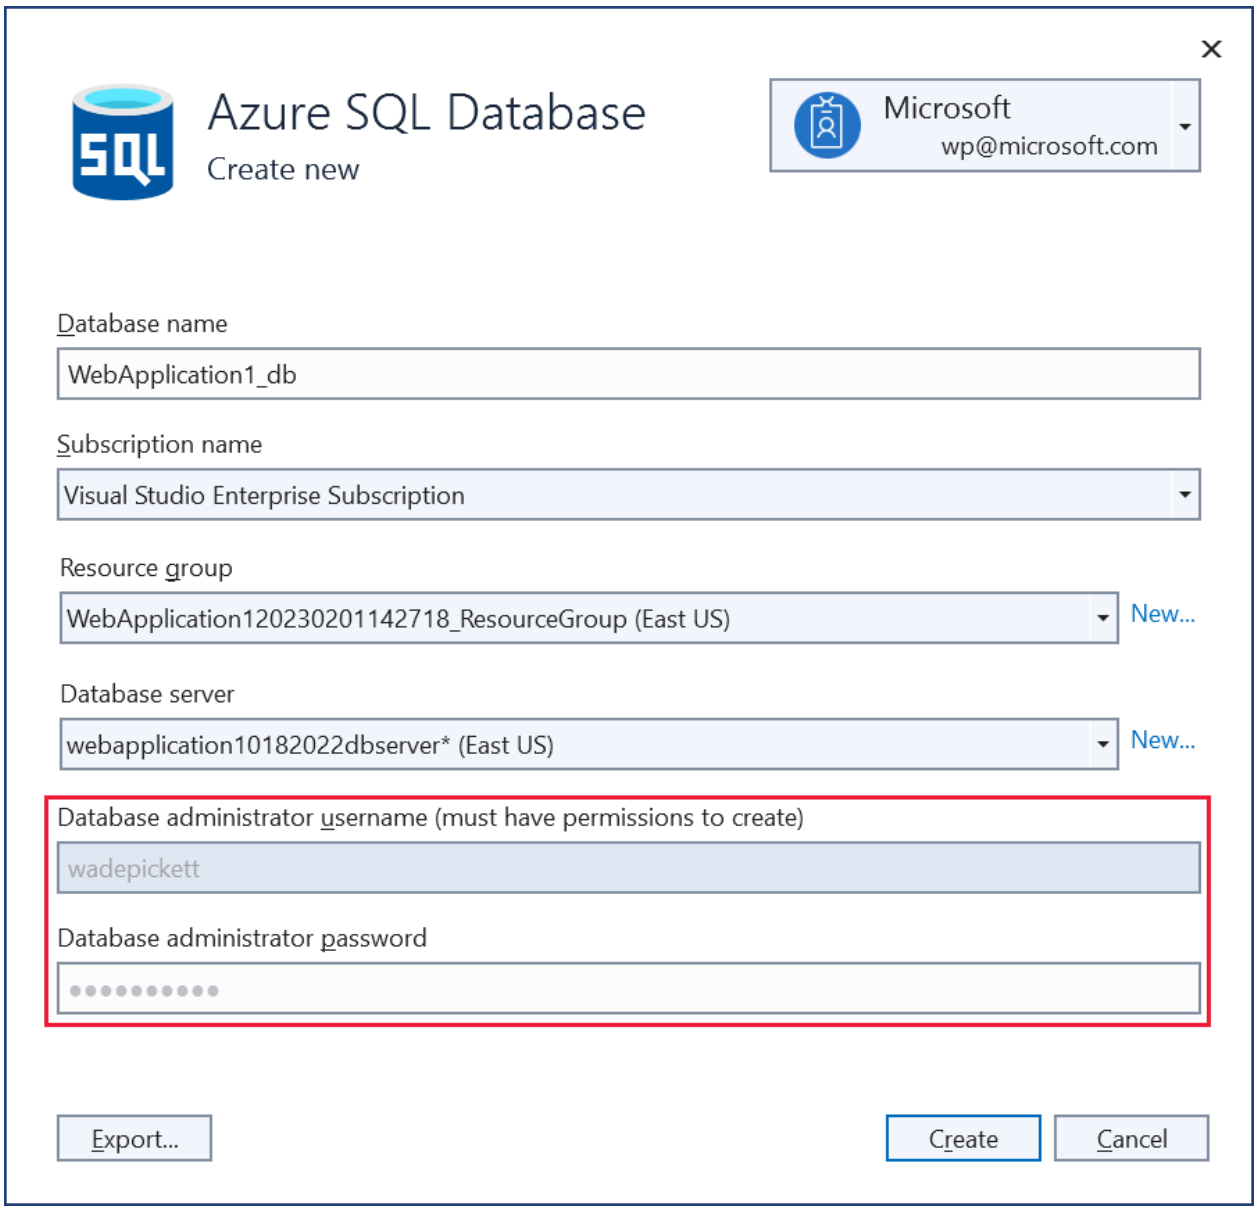
The **Publish profile creation progress** dialog confirms the publish profile was created. Select **Close**.

Next you see the **Publish Profile summary** page. Visual Studio has detected that this application requires a SQL Server database which it has listed in the Service Dependencies pane. Select the ellipsis (...) and then **Connect**.

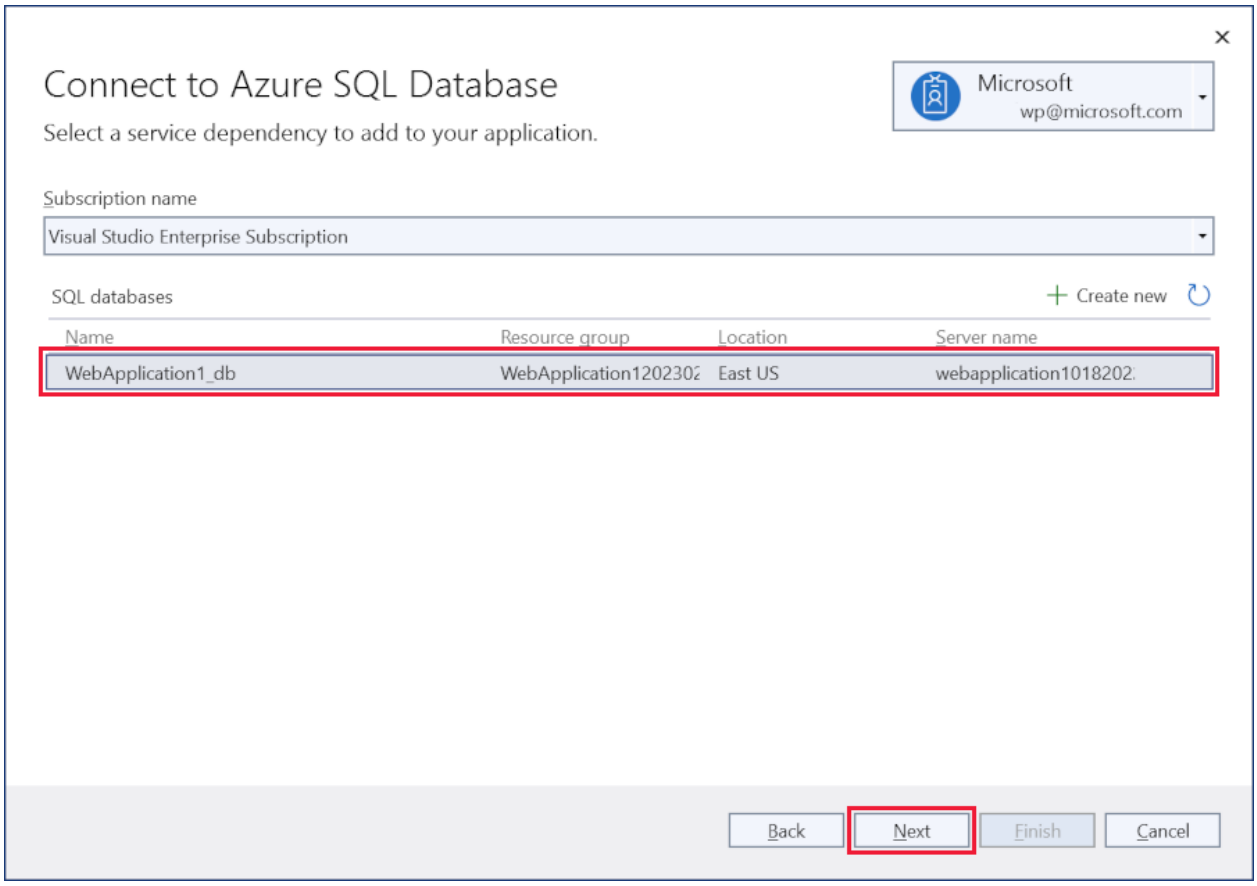


The **Connect to dependency** dialog appears:

- Select **Azure SQL Database**.
- Select **Next**.

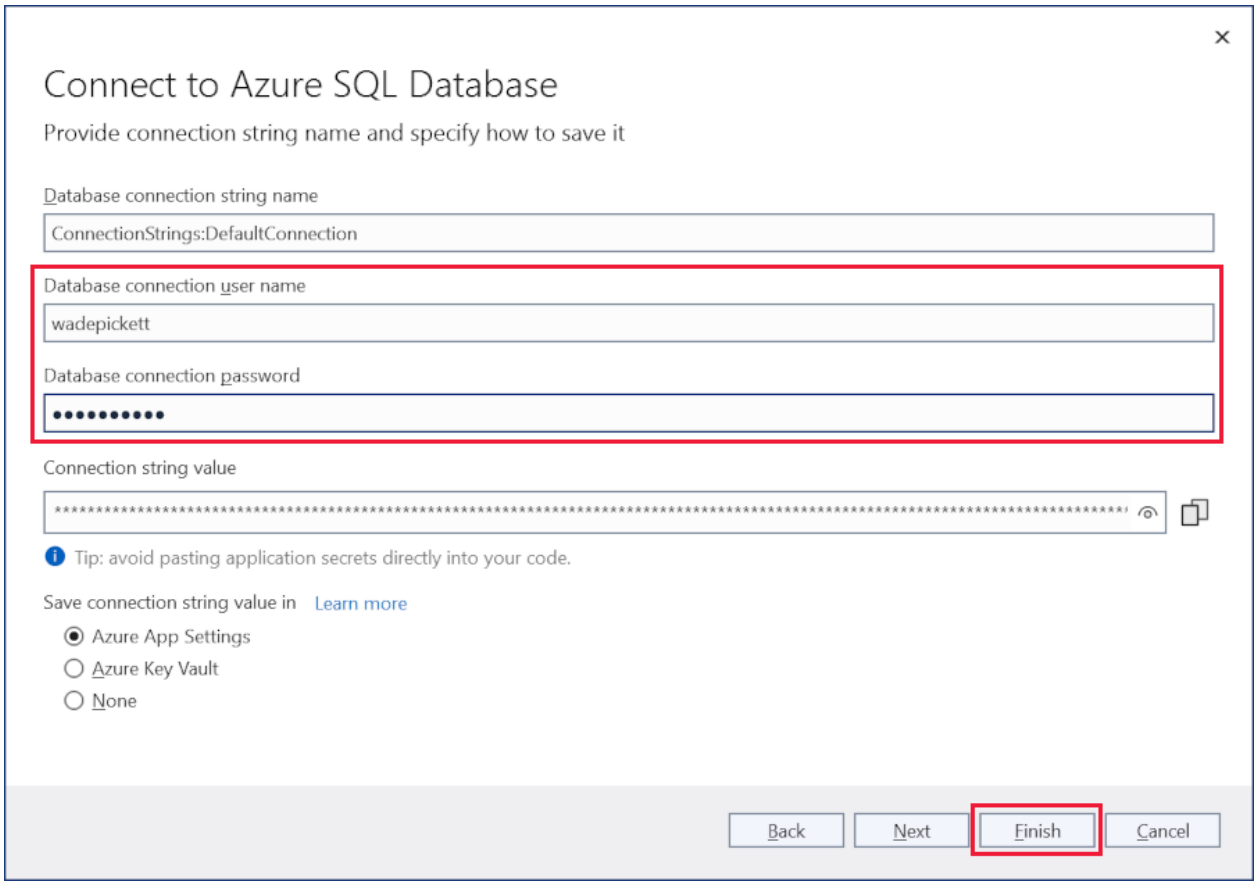


In the **Connect to Azure SQL database** dialog, select **Create new**.



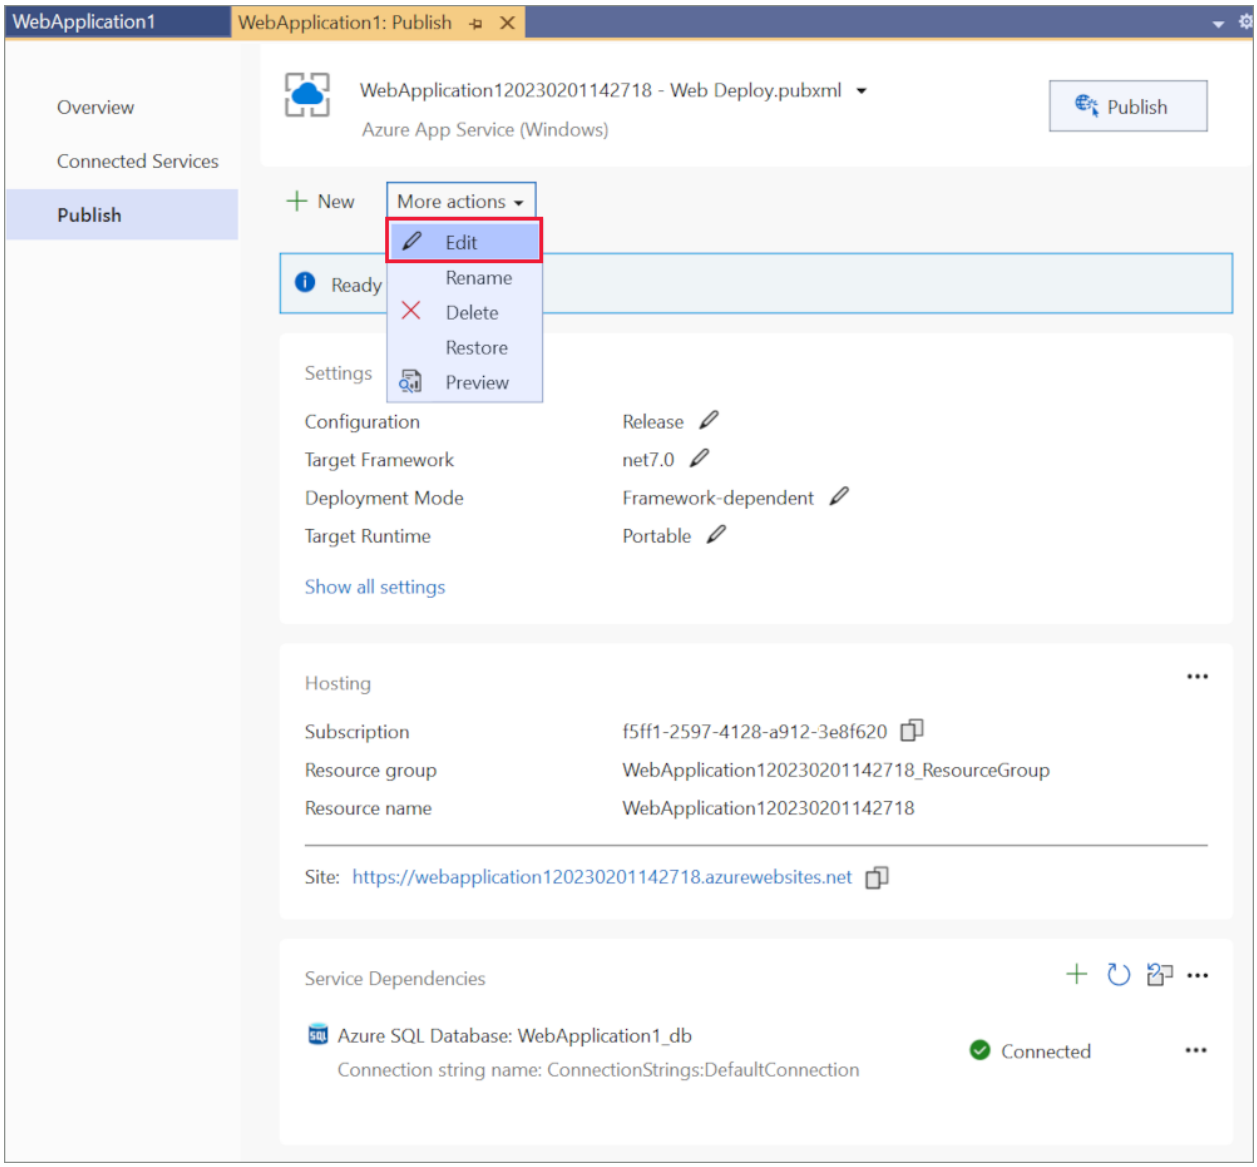
The **Create Azure SQL Database** appears:

- The **Database name**, **Resource Group**, **Database server** and **App Service Plan** entry fields are populated. You can keep these values or change them.
- Enter the **Database administrator username** and **Database administrator password** for the selected **Database server** (note the account you use must have the necessary permissions to create the new Azure SQL database)
- Select **Create**.



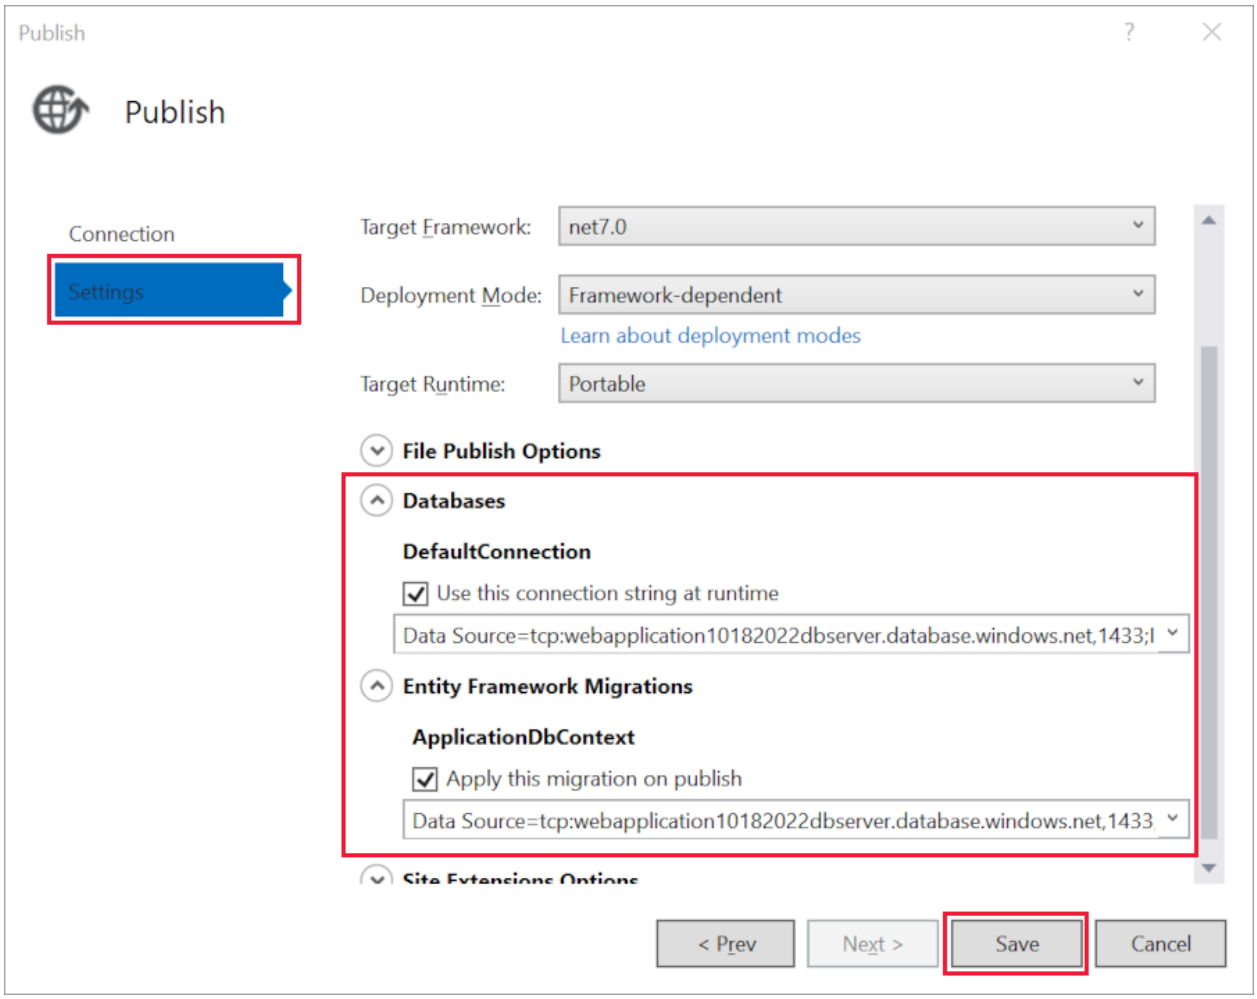
After creation is completed the dialog is automatically closed and the **Connect to Azure SQL Database** dialog gets focus again:

- The new instance that was just created is automatically selected.
- Select **Next**.



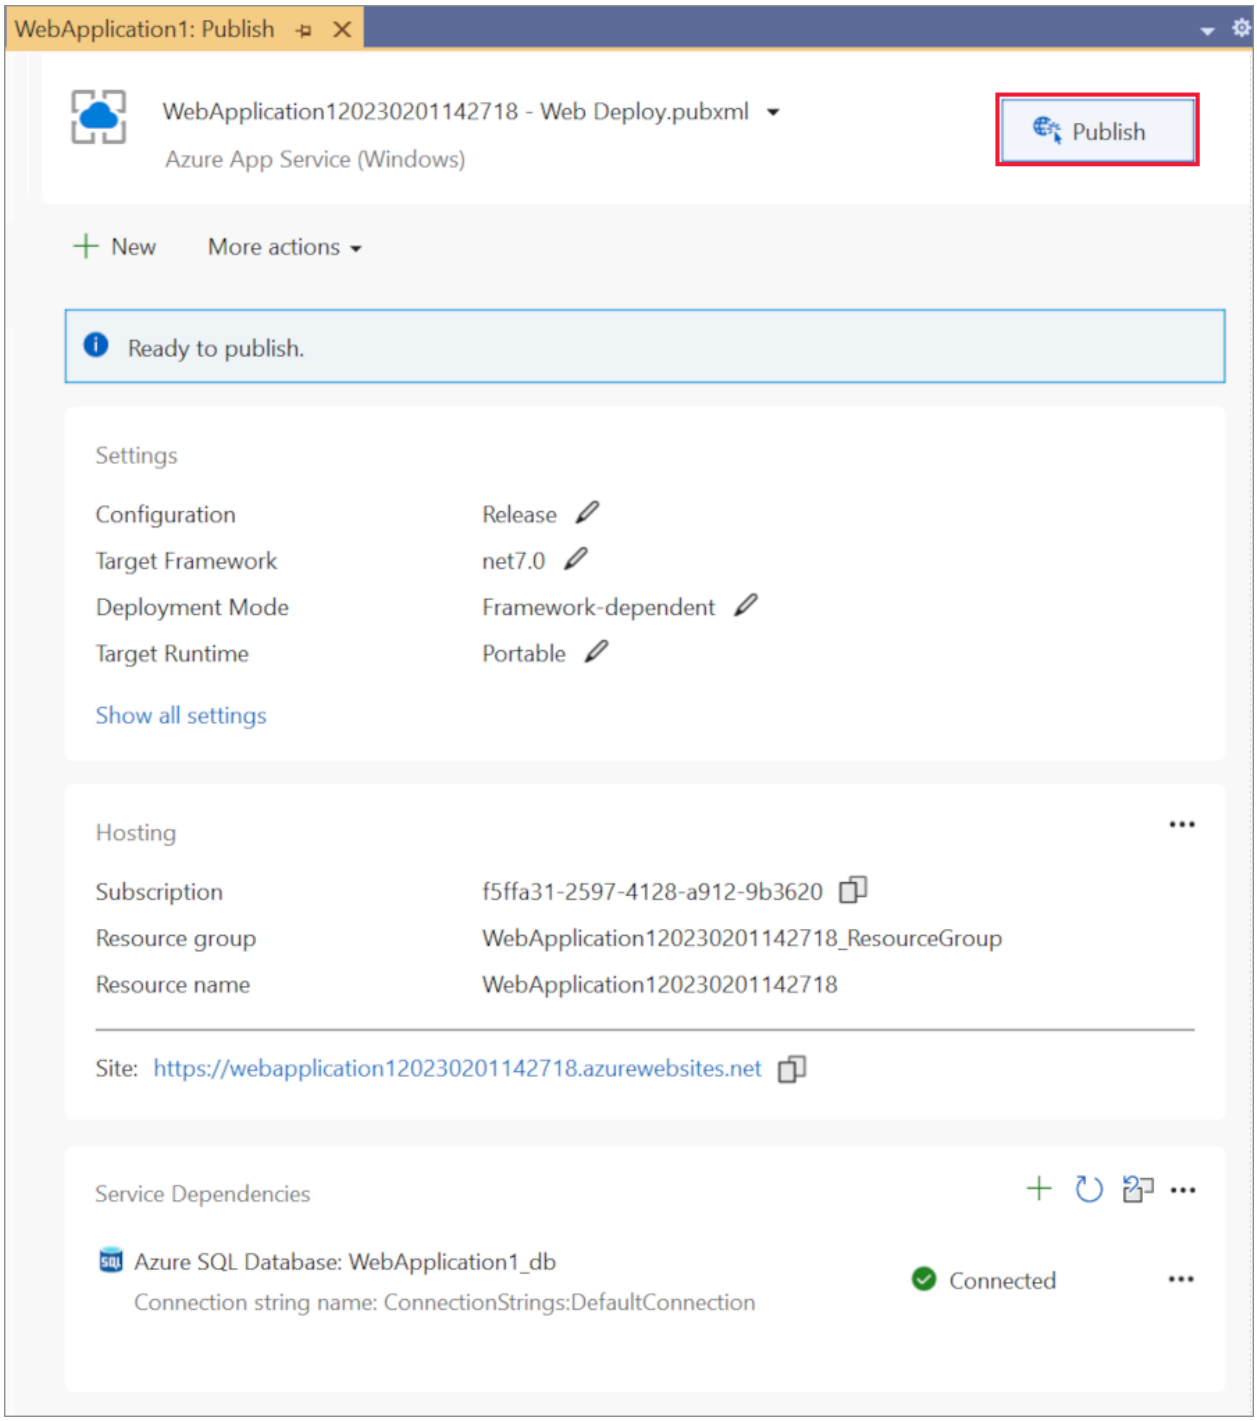
In the next step of the **Connect to Azure SQL Database** dialog:

- Enter the **Database connection user name** and **Database connection password** fields. These are the details your application will use to connect to the database at runtime. Best practice is to avoid using the same details as the admin username and password used in the previous step.
- Select **Finish**.



The **Dependency configuration progress** dialog confirms the Azure SQL Database is configured. Select **Close**.

In the **Publish Profile summary** page select **More actions** > **Edit**:



On the **Settings** tab of the **Publish** dialog:

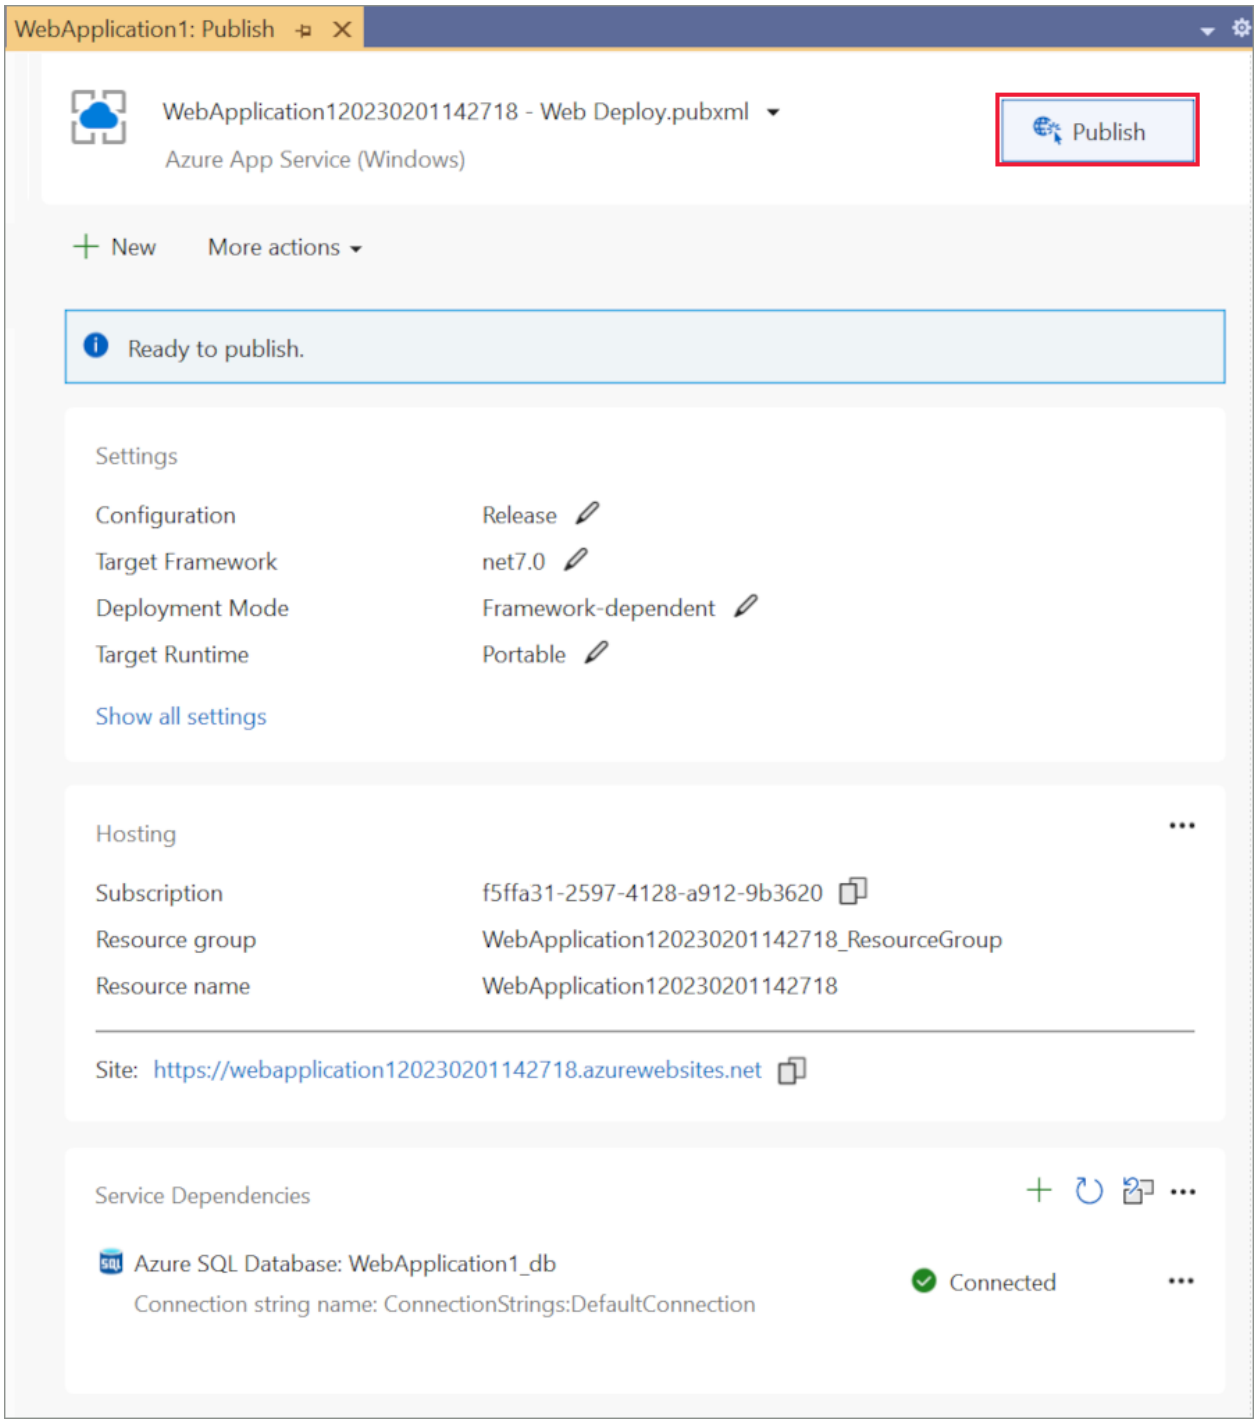
- Expand **Databases** and check **Use this connection string at runtime**.
- Expand **Entity Framework Migrations** and select **Apply this migration on publish**.
- Select **Save**. Visual Studio returns to the **Publish** dialog.

Click **Publish**. Visual Studio publishes your app to Azure. When the deployment completes.

The app is opened in a browser. Register a new user and log in as the new user to validate the database deployment and run-time connection.

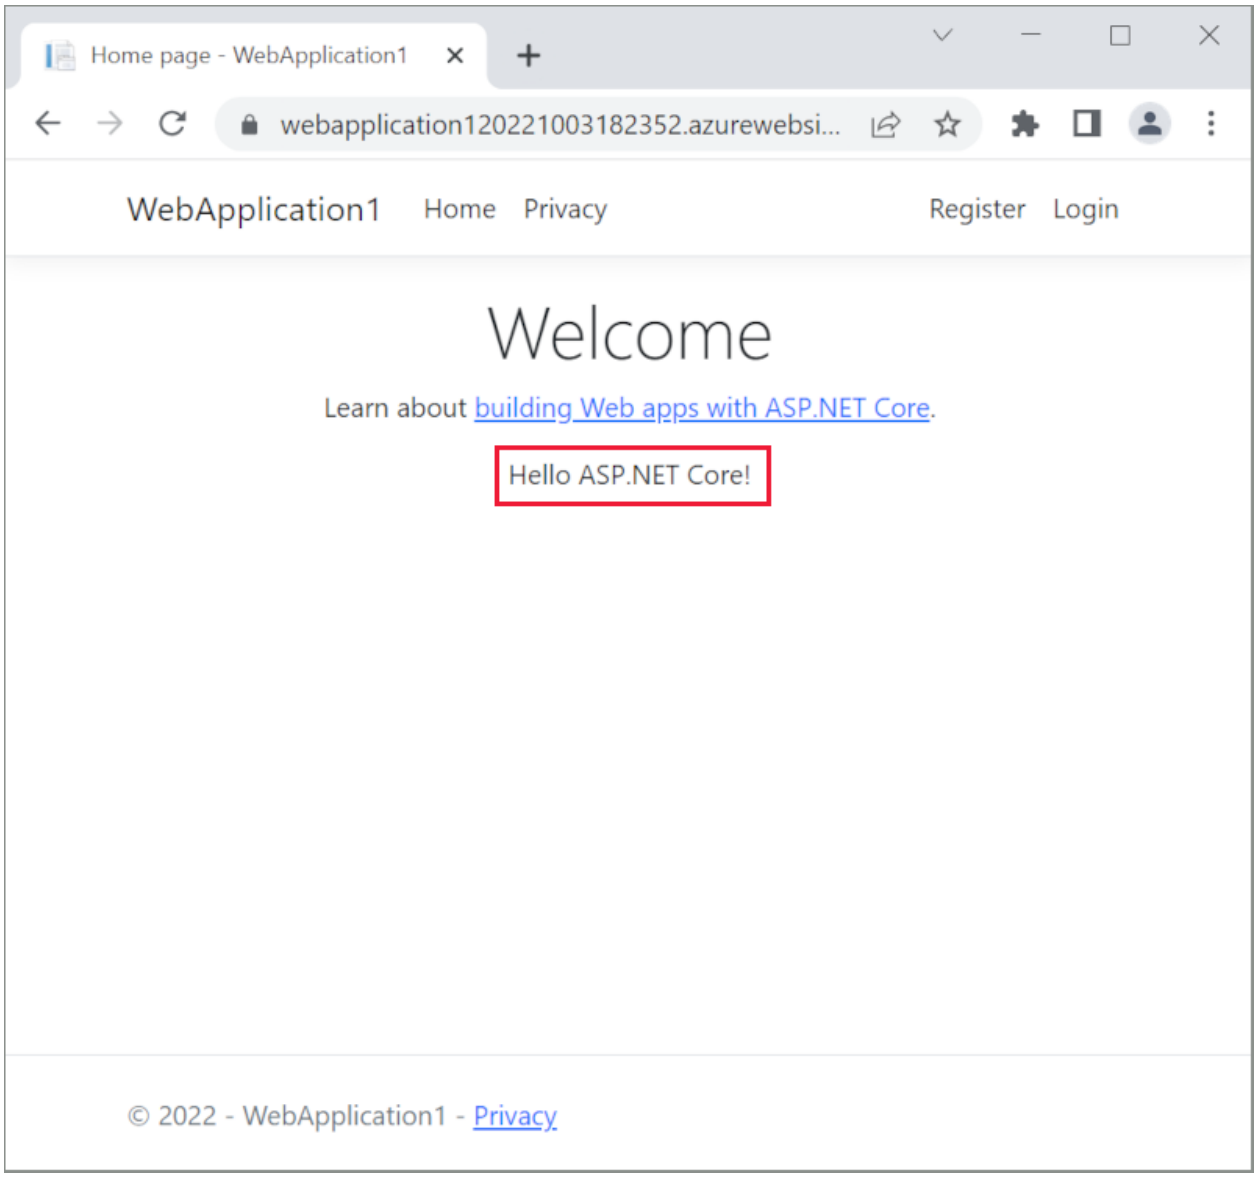
Update the app

- Edit the `Pages/Index.cshtml` Razor page and change its contents, then save the changes. For example, you can modify the paragraph to say "Hello ASP.NET Core!":



```
HTML

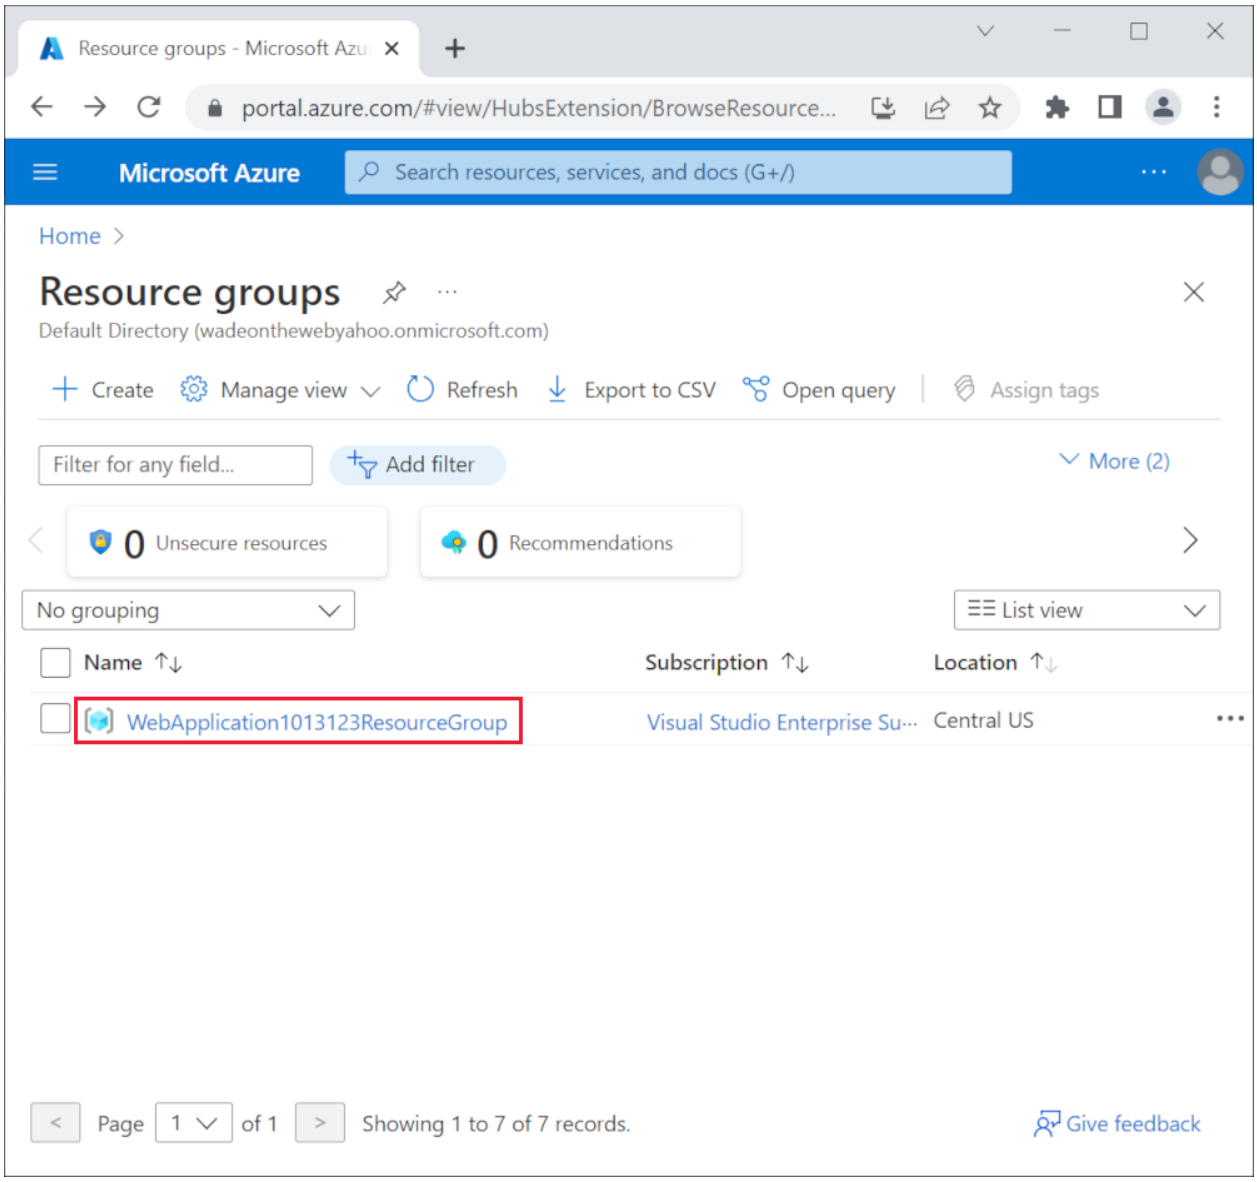
@page
@model IndexModel
@{
```



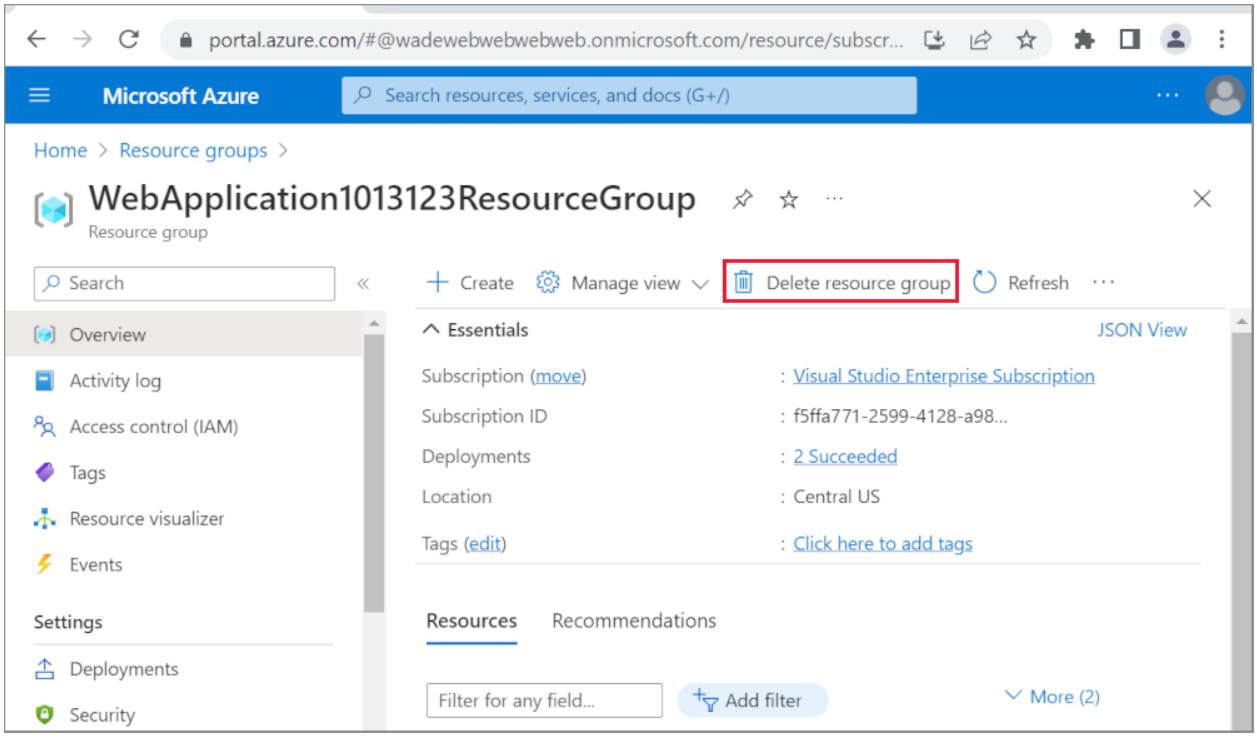
```
    ViewData["Title"] = "Home page";
}

<div class="text-center">
    <h1 class="display-4">Welcome</h1>
    <p>Learn about <a
href="https://docs.microsoft.com/aspnet/core">building Web apps with
ASP.NET Core</a>.</p>
    <p>Hello ASP.NET Core!</p>
</div>
```

- Select **Publish** from the **Publish Profile summary** page again.



- After the app is published, refresh the page and verify that the changes you made are available on Azure.



Clean up

When you have finished testing the app, go to the Azure portal and delete the app.

- Select **Resource groups**, then select the resource group you created.

- In the **Resource group** page, select **Delete resource group**.

- Enter the name of the resource group and select **Delete**. Your app and all other resources created in this tutorial are now deleted from Azure.

Tutorial: Deploy an ASP.NET Core and Azure SQL Database app to Azure App Service

Article • 09/06/2024

In this tutorial, you learn how to deploy a data-driven ASP.NET Core app to Azure App Service and connect to an Azure SQL Database. You'll also deploy an Azure Cache for Redis to enable the caching code in your application. Azure App Service is a highly scalable, self-patching, web-hosting service that can easily deploy apps on Windows or Linux. Although this tutorial uses an ASP.NET Core 8.0 app, the process is the same for other versions of ASP.NET Core.

In this tutorial, you learn how to:

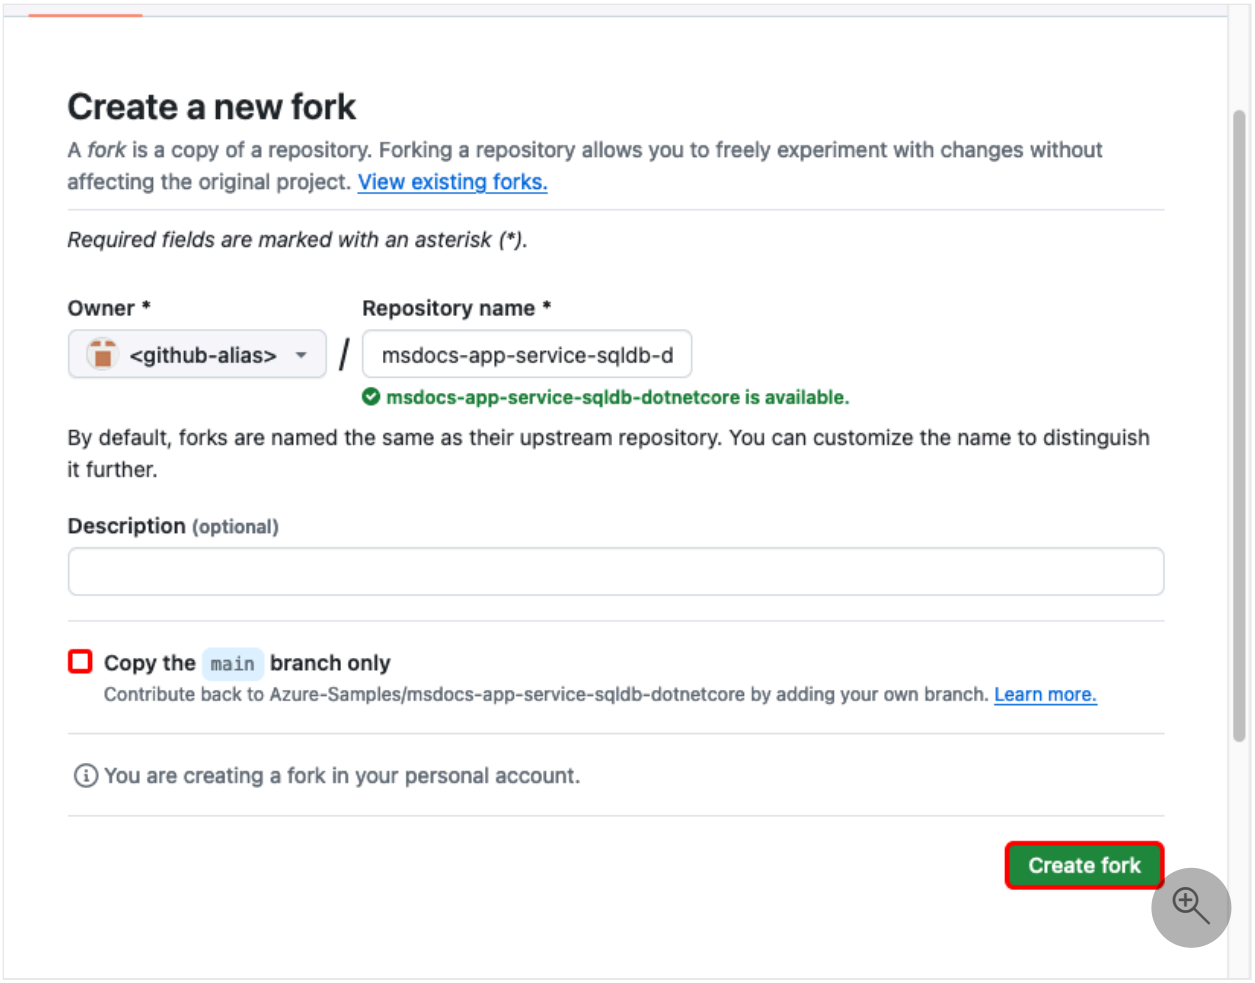
- ✓ Create a secure-by-default App Service, SQL Database, and Redis cache architecture.
- ✓ Secure connection secrets using a managed identity and Key Vault references.
- ✓ Deploy a sample ASP.NET Core app to App Service from a GitHub repository.
- ✓ Acces App Service connection strings and app settings in the application code.
- ✓ Make updates and redeploy the application code.
- ✓ Generate database schema by uploading a migrations bundle.
- ✓ Stream diagnostic logs from Azure.
- ✓ Manage the app in the Azure portal.
- ✓ Provision the same architecture and deploy by using Azure Developer CLI.
- ✓ Optimize your development workflow with GitHub Codespaces and GitHub Copilot.

Prerequisites

- An Azure account with an active subscription. If you don't have an Azure account, you can create one for free.
- A GitHub account. you can also get one for free.
- Knowledge of ASP.NET Core development.
- **(Optional)** To try GitHub Copilot, a GitHub Copilot account. A 30-day free trial is available.

Skip to the end

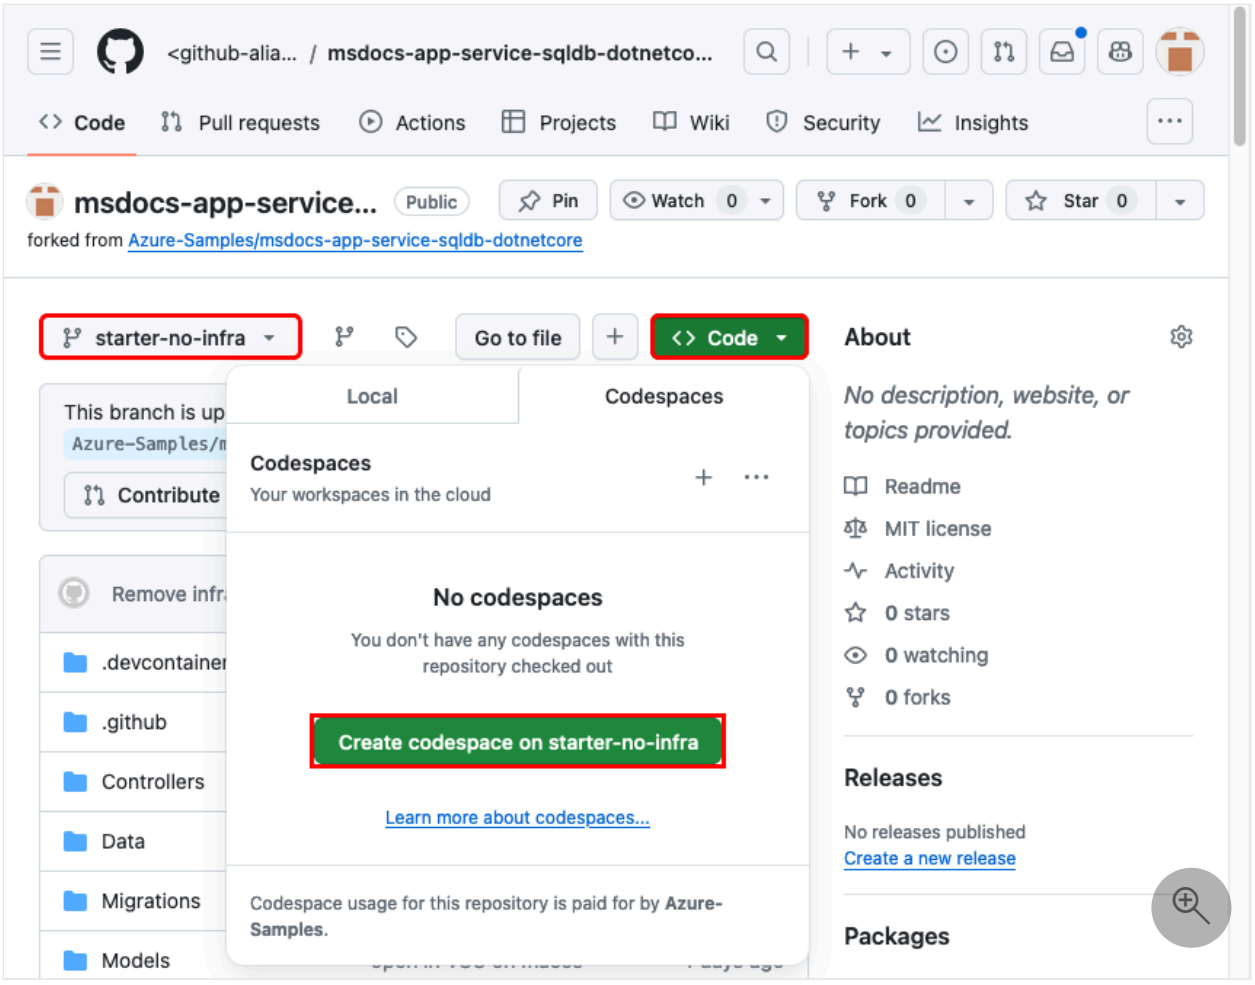
You can quickly deploy the sample app in this tutorial and see it running in Azure. Just run the following commands in the Azure Cloud Shell, and follow the prompt:



```bash
dotnet tool install --global dotnet-ef
mkdir msdocs-app-service-sqldb-dotnetcore
cd msdocs-app-service-sqldb-dotnetcore
azd init --template msdocs-app-service-sqldb-dotnetcore
azd up
```

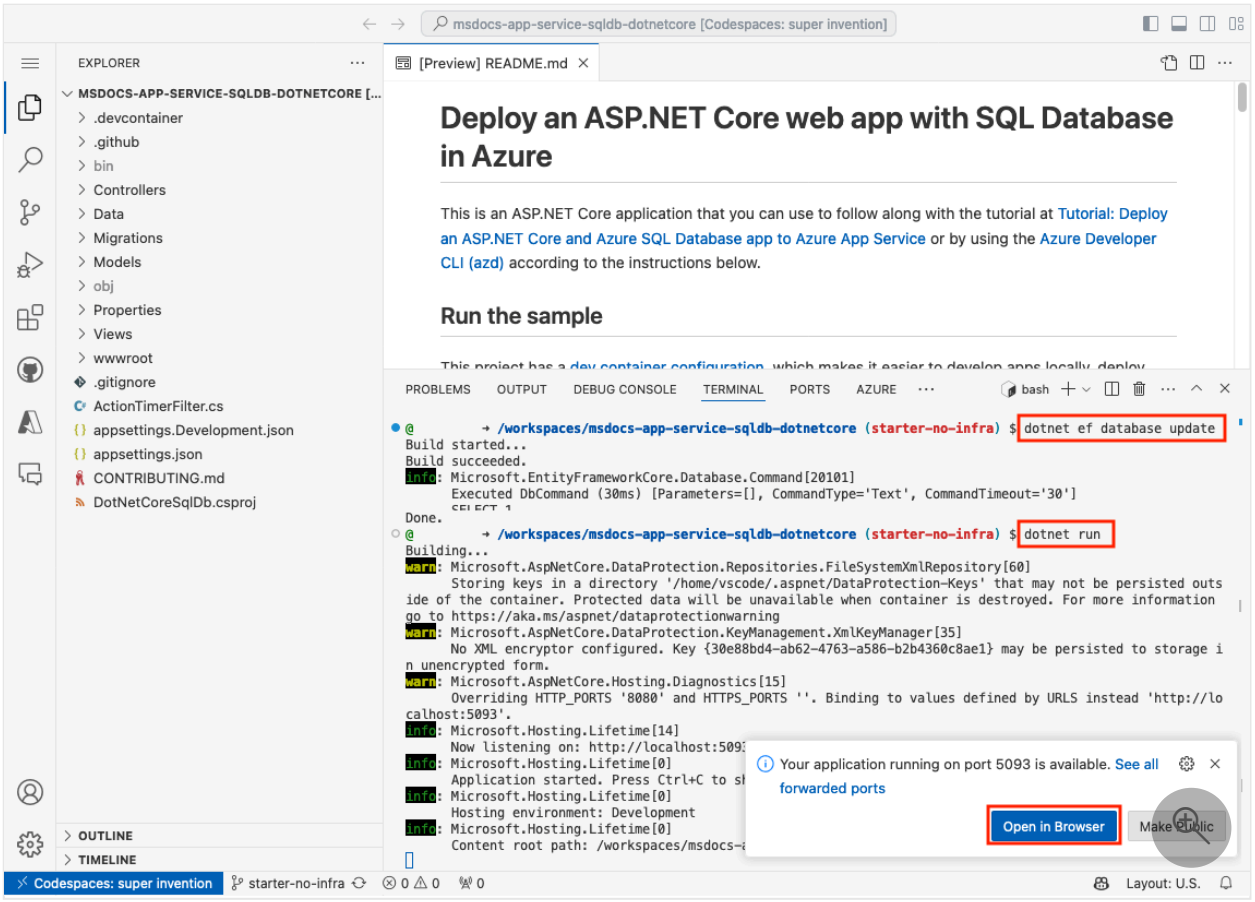
1. Run the sample

First, you set up a sample data-driven app as a starting point. For your convenience, the sample repository, includes a dev container configuration. The dev container has everything you need to develop an application, including the database, cache, and all environment variables needed by the sample application. The dev container can run in a GitHub codespace, which means you can run the sample on any computer with a web browser.



Step 1: In a new browser window:

1. Sign in to your GitHub account.
2. Navigate to https://github.com/Azure-Samples/msdocs-app-service-sqldb-dotnetcore/fork.
3. Unselect **Copy the main branch only**. You want all the branches.
4. Select **Create fork**.



Step 2: In the GitHub fork:

1. Select **main** > **starter-no-infra** for the starter branch. This branch contains just the sample project and no Azure-related files or configuration.
2. Select **Code** > **Create codespace on starter-no-infra**. The codespace takes a few minutes to set up.

Step 3: In the codespace terminal:

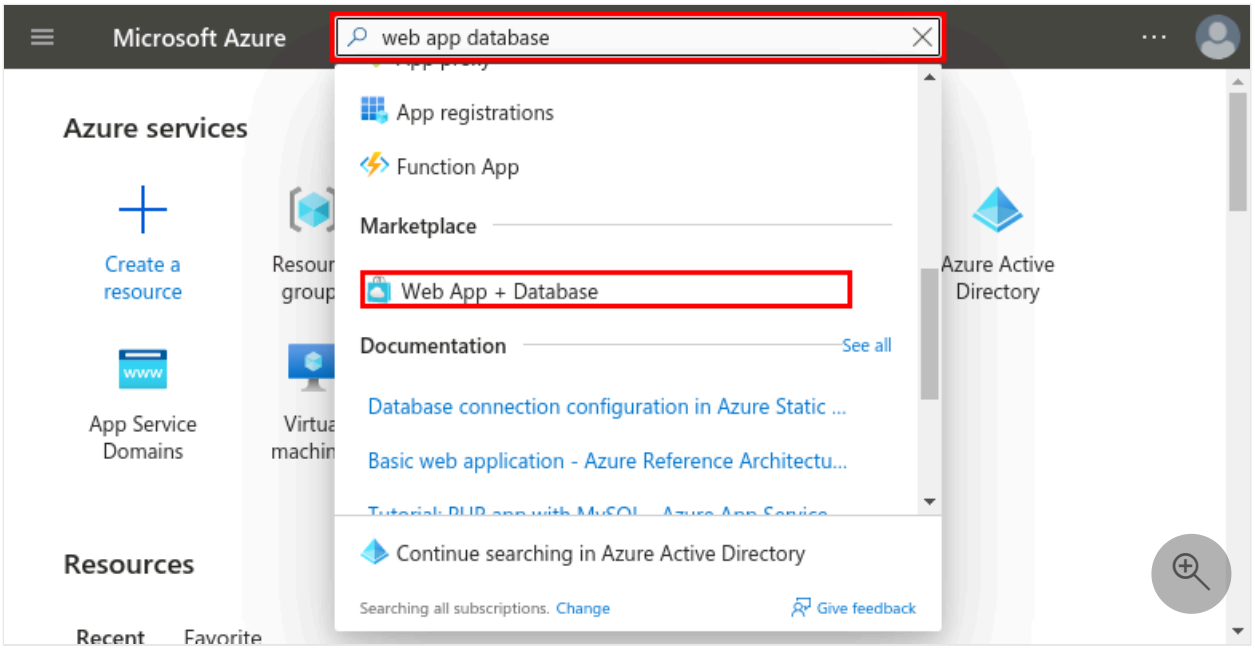
1. Run database migrations with `dotnet ef database update`.
2. Run the app with `dotnet run`.
3. When you see the notification `Your application running on port 5093 is available.`, select **Open in Browser**. You should see the sample application in a new browser tab. To stop the application, type `Ctrl` + `C`.

> **Tip**
>
> You can ask GitHub Copilot about this repository. For example:
>
> - *@workspace What does this project do?*
> - *@workspace What does the .devcontainer folder do?*

Having issues? Check the Troubleshooting section.

2. Create App Service, database, and cache

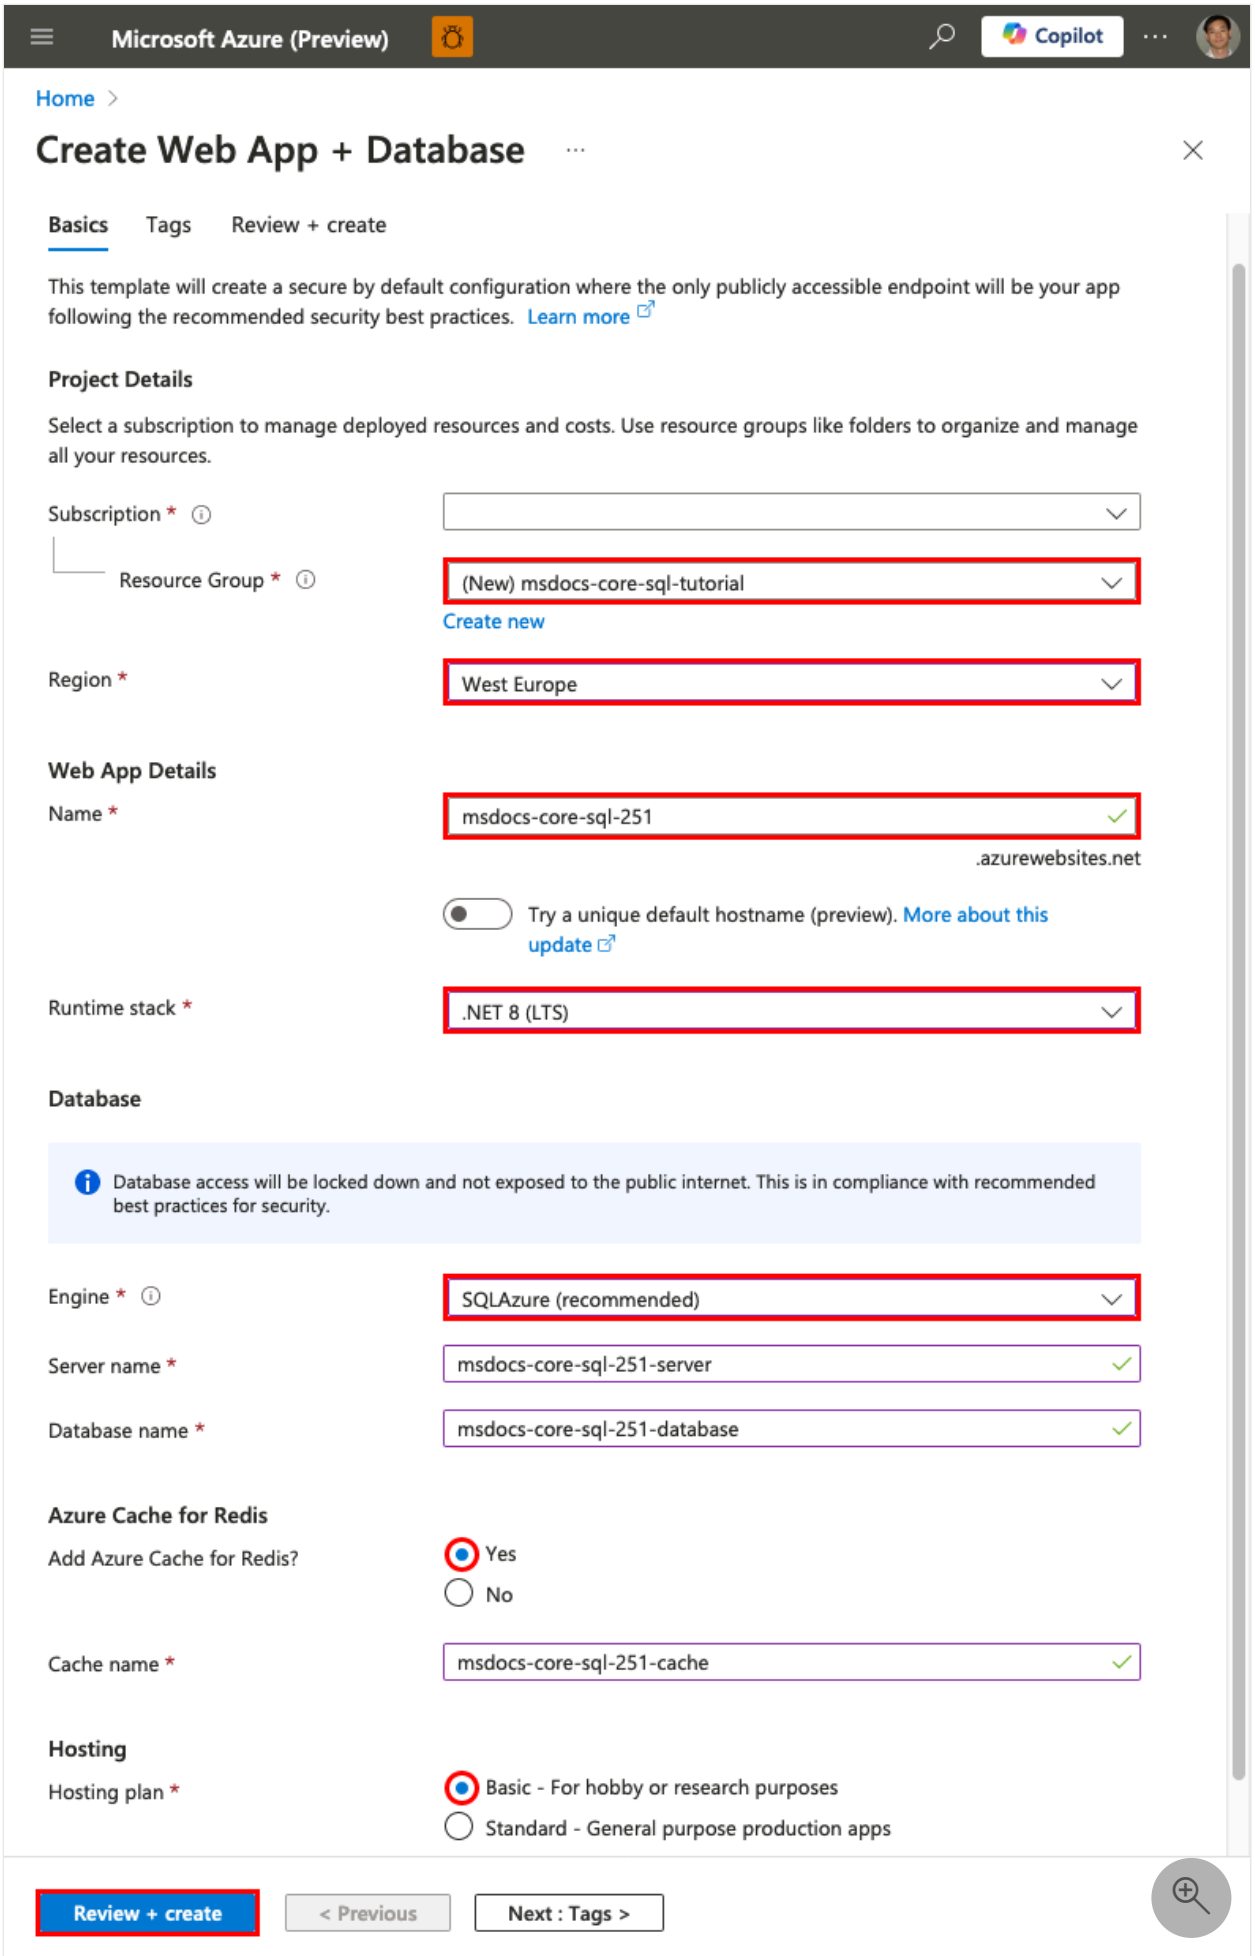
In this step, you create the Azure resources. The steps used in this tutorial create a set of secure-by-default resources that include App Service, Azure SQL Database, and Azure Cache. For the creation process, you'll specify:



- The **Name** for the web app. It's used as part of the DNS name for your app in the form of `https://<app-name>-<hash>.<region>.azurewebsites.net`.
- The **Region** to run the app physically in the world. It's also used as part of the DNS name for your app.
- The **Runtime stack** for the app. It's where you select the .NET version to use for your app.

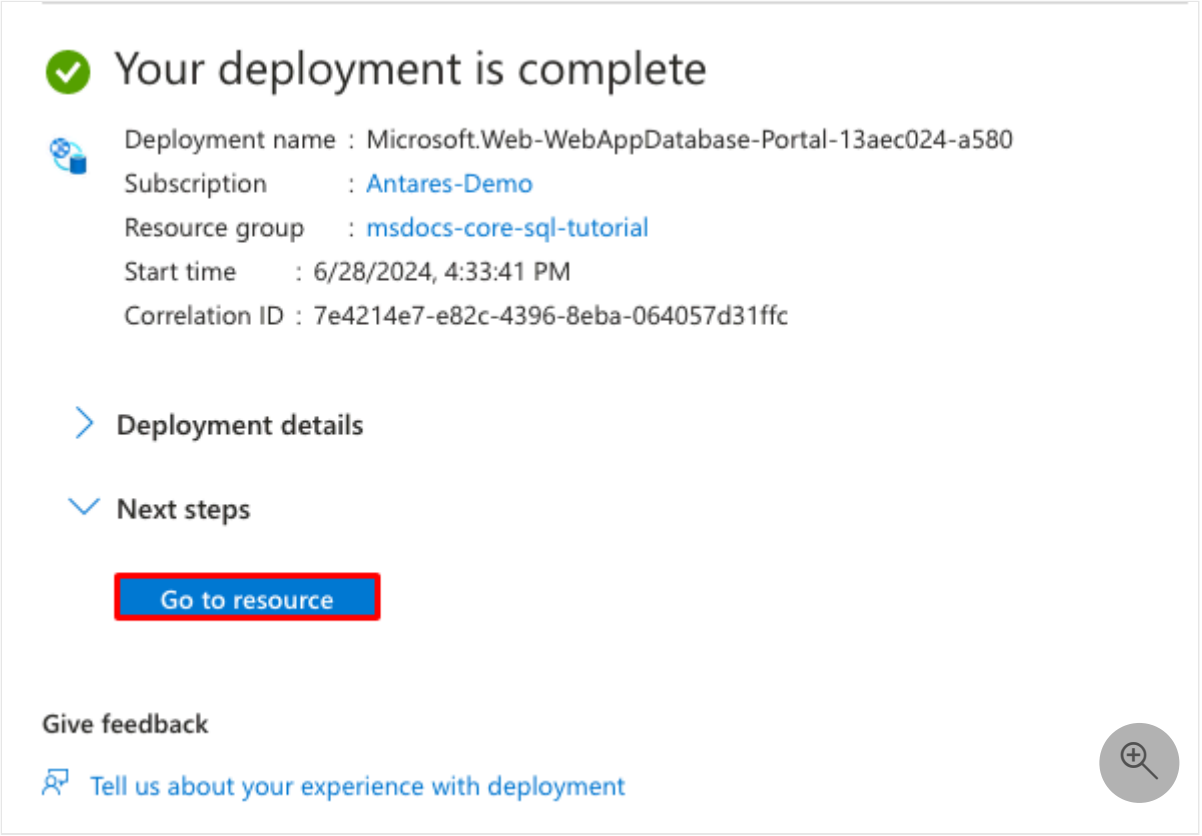
- The **Hosting plan** for the app. It's the pricing tier that includes the set of features and scaling capacity for your app.
- The **Resource Group** for the app. A resource group lets you group (in a logical container) all the Azure resources needed for the application.

Sign in to the Azure portal and follow these steps to create your Azure App Service resources.



Step 1: In the Azure portal:

1. Enter "web app database" in the search bar at the top of the Azure portal.
2. Select the item labeled **Web App + Database** under the **Marketplace** heading. You can also navigate to the creation wizard directly.



Step 2: In the **Create Web App + Database** page, fill out the form as follows.

1. *Resource Group*: Select **Create new** and use a name of **msdocs-core-sql-tutorial**.
2. *Region*: Any Azure region near you.
3. *Name*: **msdocs-core-sql-XYZ** where *XYZ* is any three random characters. This name must be unique across Azure.
4. *Runtime stack*: **.NET 8 (LTS)**.
5. *Engine*: **SQLAzure**. Azure SQL Database is a fully managed platform as a service (PaaS) database engine that's always running on the latest stable version of the SQL Server.
6. *Add Azure Cache for Redis?*: **Yes**.
7. *Hosting plan*: **Basic**. When you're ready, you can scale up to a production pricing tier.
8. Select **Review + create**.
9. After validation completes, select **Create**.

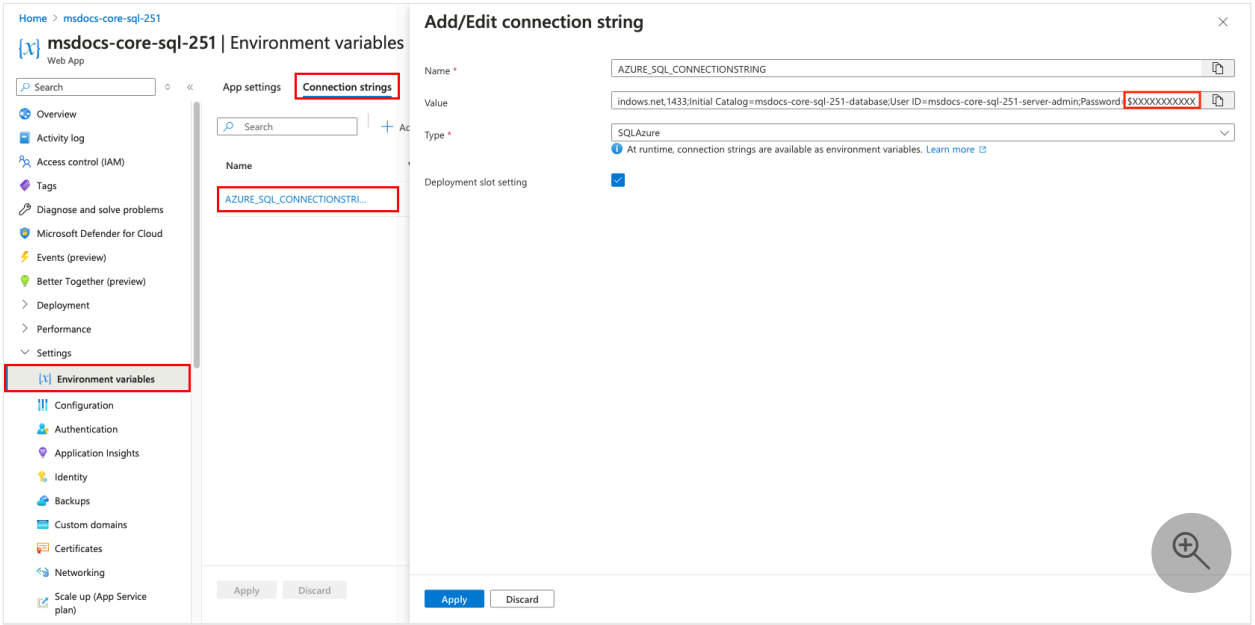
Step 3: The deployment takes a few minutes to complete. Once deployment completes, select the **Go to resource** button. You're taken directly to the App Service app, but the following resources are created:

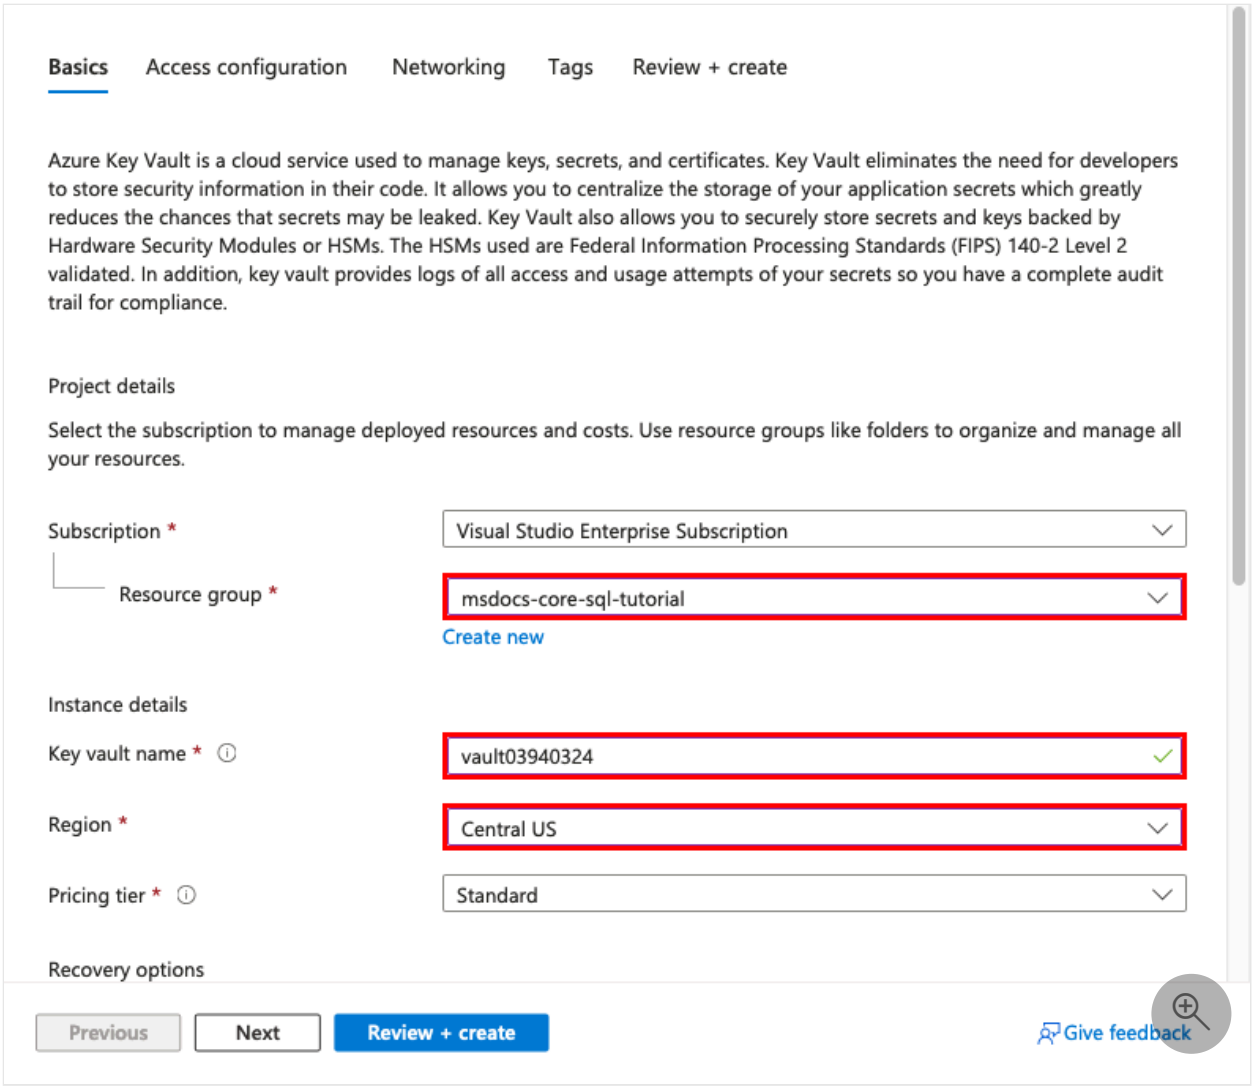
- **Resource group**: The container for all the created resources.
- **App Service plan**: Defines the compute resources for App Service. A Linux plan in the *Basic* tier is created.
- **App Service**: Represents your app and runs in the App Service plan.
- **Virtual network**: Integrated with the App Service app and isolates back-end network traffic.
- **Private endpoints**: Access endpoints for the key vault, the database server, and the Redis cache in the virtual network.
- **Network interfaces**: Represents private IP addresses, one for each of the private endpoints.
- **Azure SQL Database server**: Accessible only from behind its private endpoint.
- **Azure SQL Database**: A database and a user are created for you on the server.
- **Azure Cache for Redis**: Accessible only from behind its private endpoint.
- **Key vault**: Accessible only from behind its private endpoint. Used to manage secrets for the App Service app.
- **Private DNS zones**: Enable DNS resolution of the key vault, the database server, and the Redis cache in the virtual network.



3. Secure connection secrets

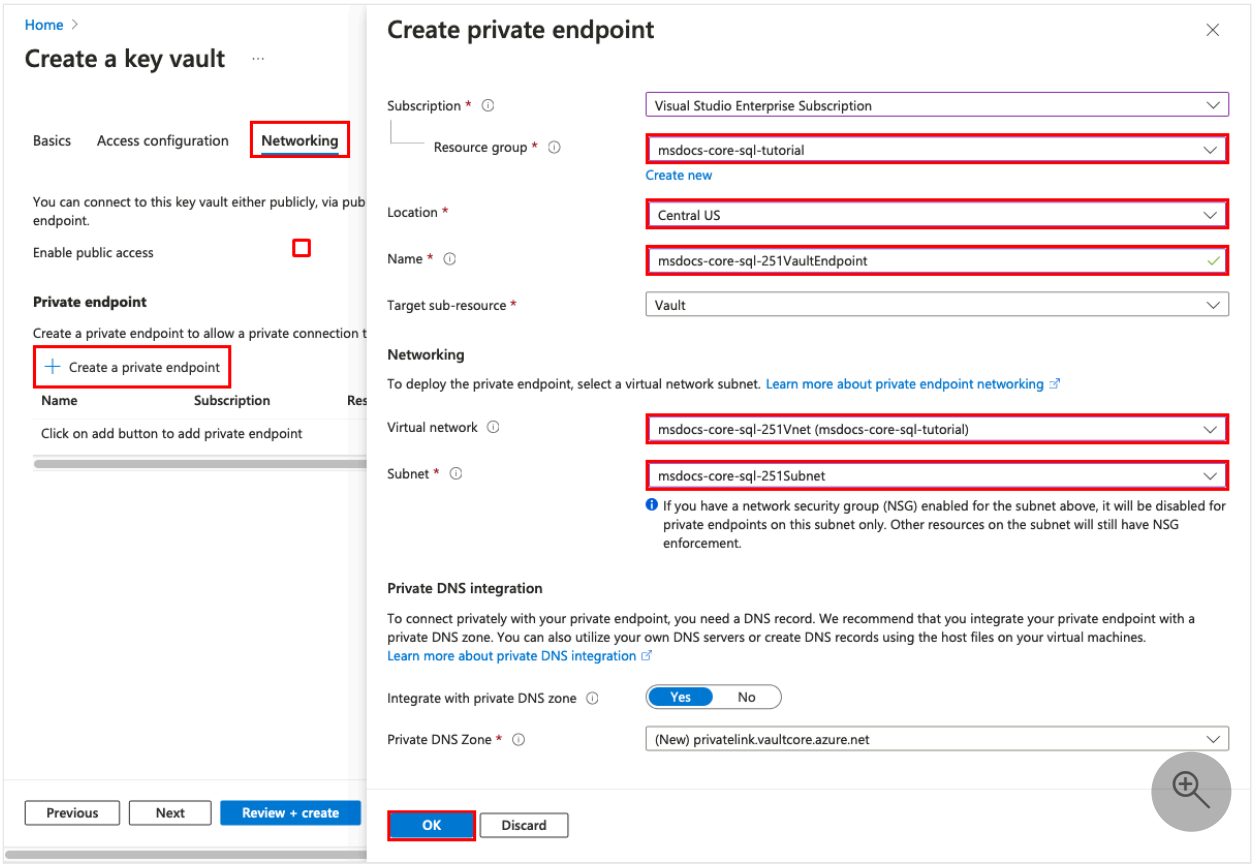
The creation wizard generated the connectivity string for you already as .NET connection strings and app settings. However, the security best practice is to keep secrets out of App Service completely. You'll move your secrets to a key vault and change your app setting to Key Vault references with the help of Service Connectors.

> **Tip**
>
> To use passwordless authentication, see **How do I change the SQL Database connection to use a managed identity instead?**



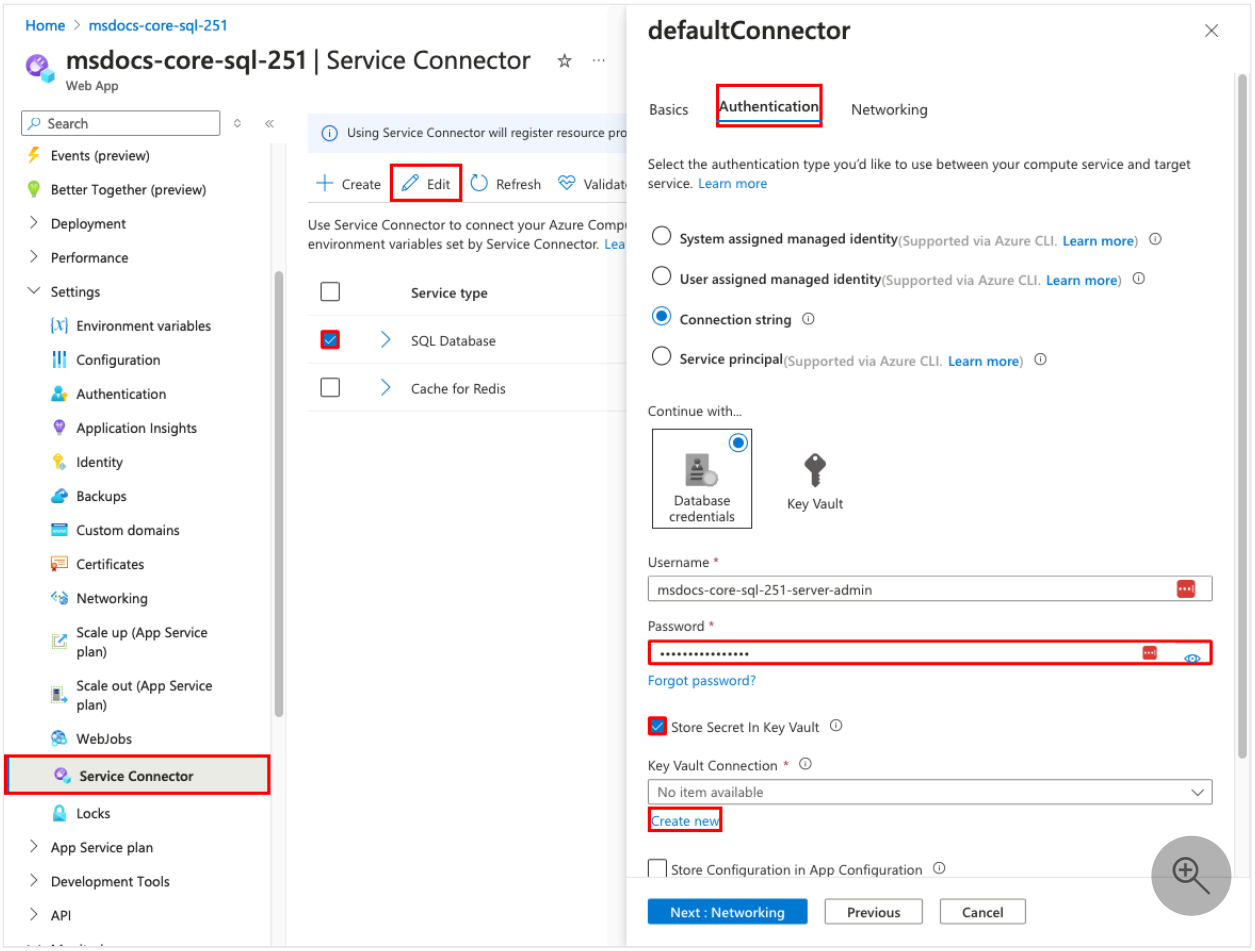
Step 1: In the App Service page:

1. In the left menu, select **Settings** > **Environment variables** > **Connection strings**.
2. Select **AZURE_SQL_CONNECTIONSTRING**.
3. In **Add/Edit connection string**, in the **Value** field, find the *Password*= part at the end of the string.
4. Copy the password string after *Password*= for use later. This connection string lets you connect to the SQL database secured behind a private endpoint. The password is saved directly in the App Service app, which isn't the best. Likewise, the Redis cache connection string in the **App settings** tab contains a secret. You'll change this.



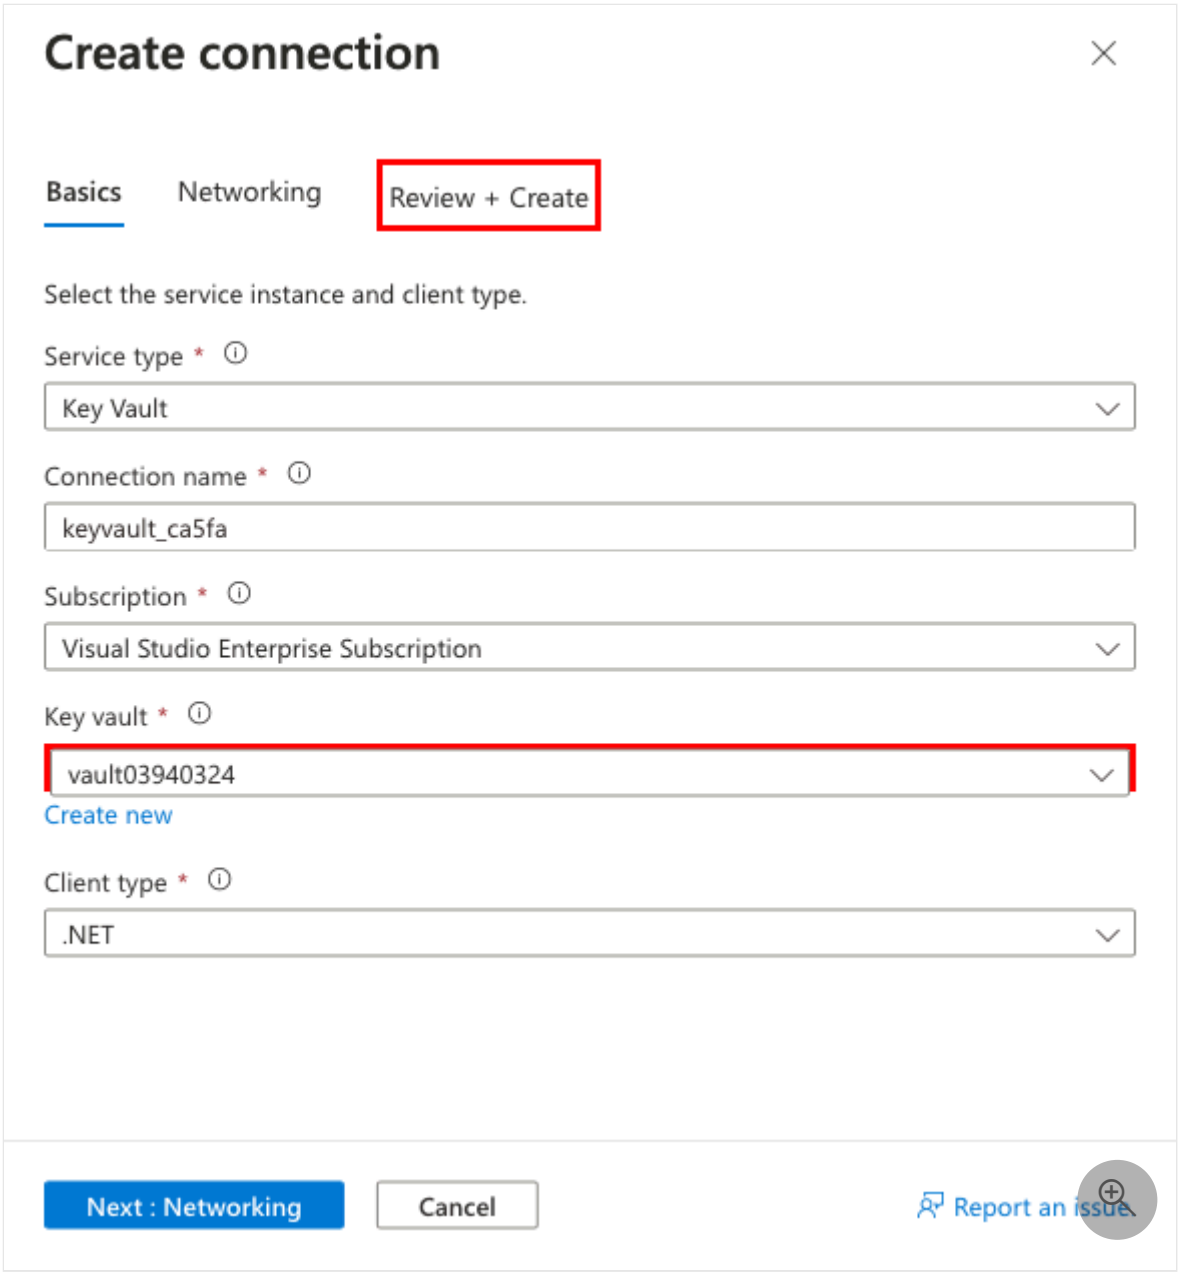
Step 2: Create a key vault for secure management of secrets.

1. In the top search bar, type "*key vault*", then select **Marketplace** > **Key Vault**.
2. In **Resource Group**, select **msdocs-core-sql-tutorial**.
3. In **Key vault name**, type a name that consists of only letters and numbers.
4. In **Region**, set it to the sample location as the resource group.



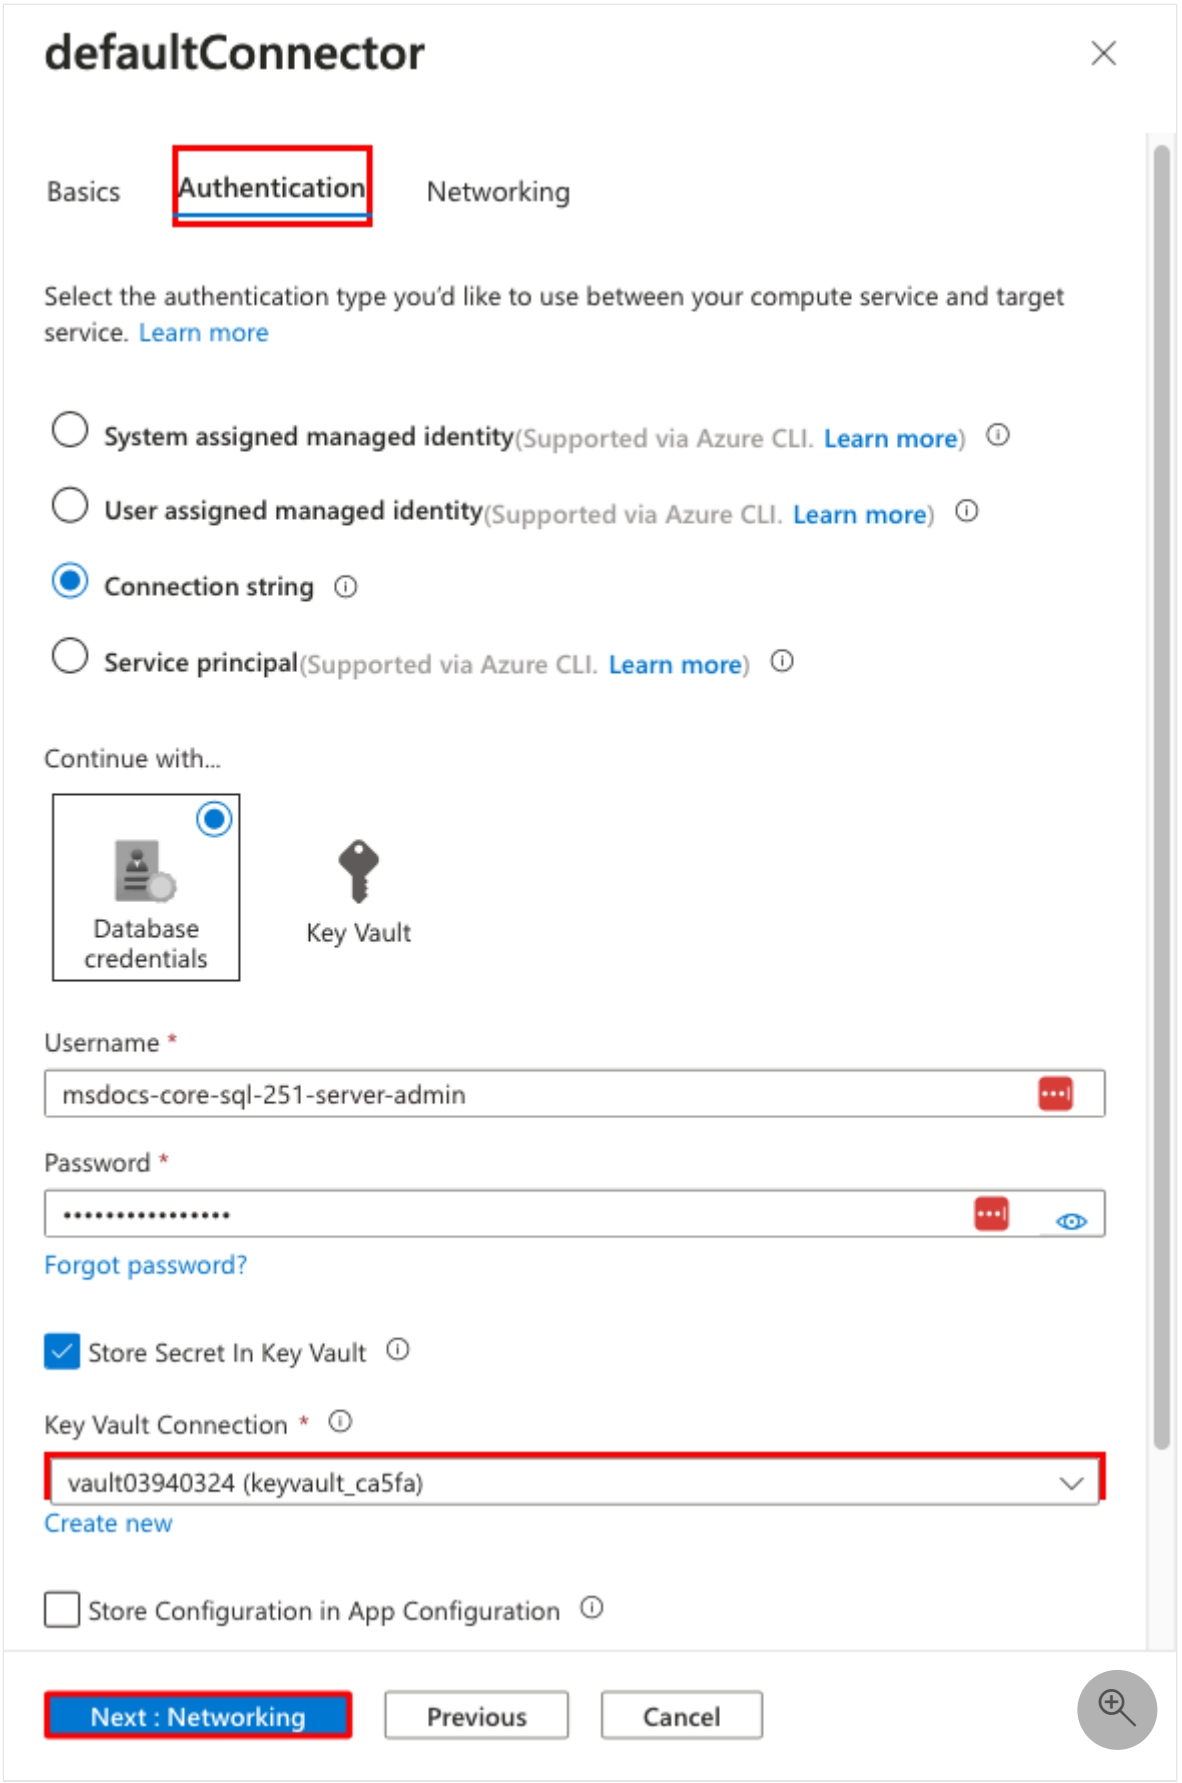
Step 3:

1. Select the **Networking** tab.
2. Unselect **Enable public access**.
3. Select **Create a private endpoint**.
4. In **Resource Group**, select **msdocs-core-sql-tutorial**.
5. In **Key vault name**, type a name that consists of only letters and numbers.
6. In **Region**, set it to the sample location as the resource group.
7. In the dialog, in **Location**, select the same location as your App Service app.
8. In **Resource Group**, select **msdocs-core-sql-tutorial**.
9. In **Name**, type **msdocs-core-sql-XYZVvaultEndpoint**.
10. In **Virtual network**, select **msdocs-core-sql-XYZVnet**.
11. In **Subnet**, **msdocs-core-sql-XYZSubnet**.
12. Select **OK**.
13. Select **Review + create**, then select **Create**. Wait for the key vault deployment to finish. You should see "Your deployment is complete."



Step 4:

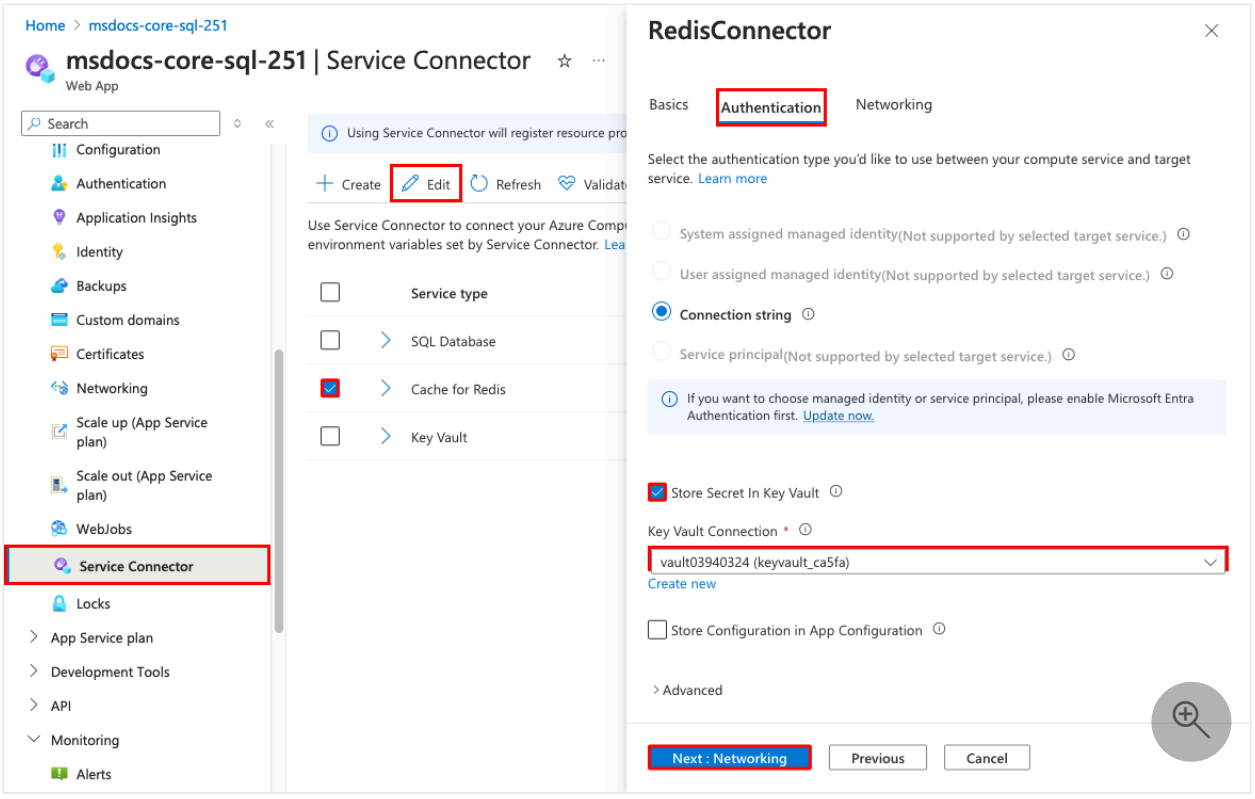
1. In the top search bar, type *msdocs-core-sql*, then the App Service resource called **msdocs-core-sql-XYZ**.
2. In the App Service page, in the left menu, select **Settings** > **Service Connector**. There are already two connectors, which the app creation wizard created for you.
3. Select checkbox next to the SQL Database connector, then select **Edit**.
4. Select the **Authentication** tab.
5. In **Password**, paste the password you copied earlier.
6. Select **Store Secret in Key Vault**.
7. Under **Key Vault Connection**, select **Create new**. A **Create connection** dialog is opened on top of the edit dialog.



Step 5: In the **Create connection** dialog for the Key Vault connection:

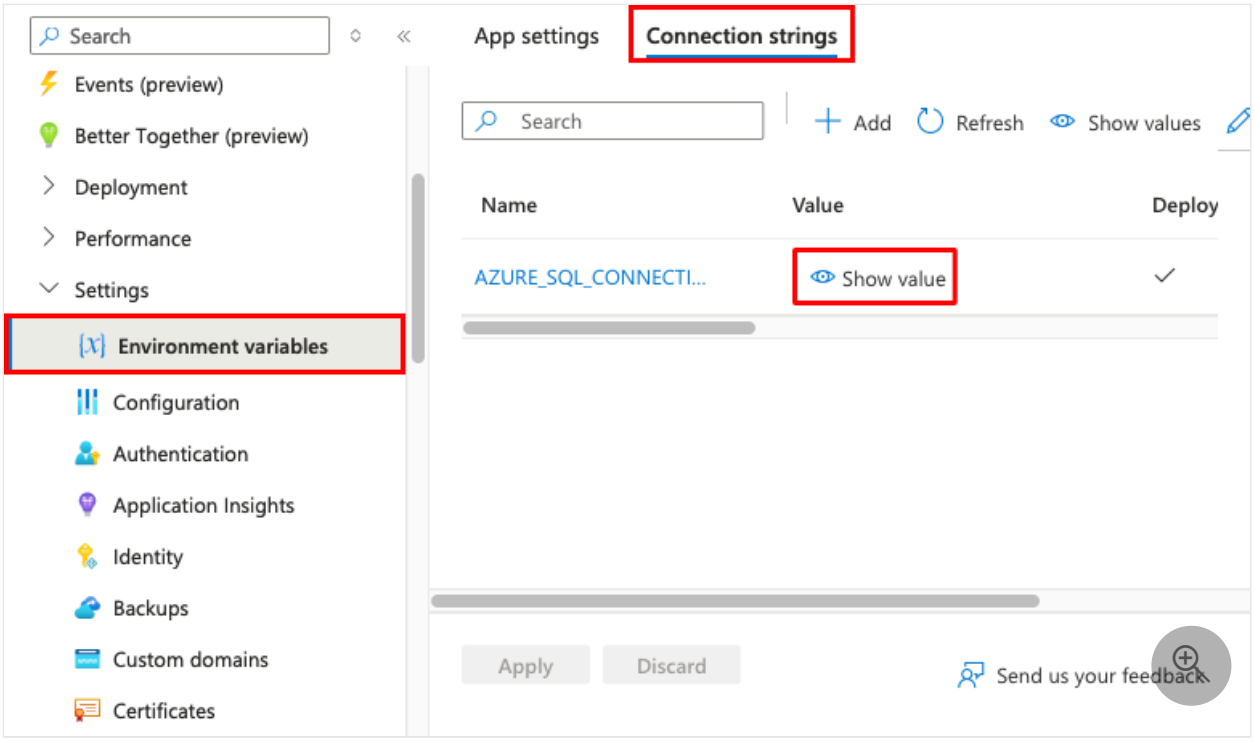
1. In **Key Vault**, select the key vault you created earlier.
2. Select **Review + Create**. You should see that **System assigned managed identity** is set to **Selected**.
3. When validation completes, select **Create**.

Step 6: You're back in the edit dialog for **defaultConnector**.



1. In the **Authentication** tab, wait for the key vault connector to be created. When it's finished, the **Key Vault Connection** dropdown automatically selects it.
2. Select **Next: Networking**.
3. Select **Configure firewall rules to enable access to target service**. The app creation wizard already secured the SQL database with a private endpoint.
4. Select **Save**. Wait until the **Update succeeded** notification appears.

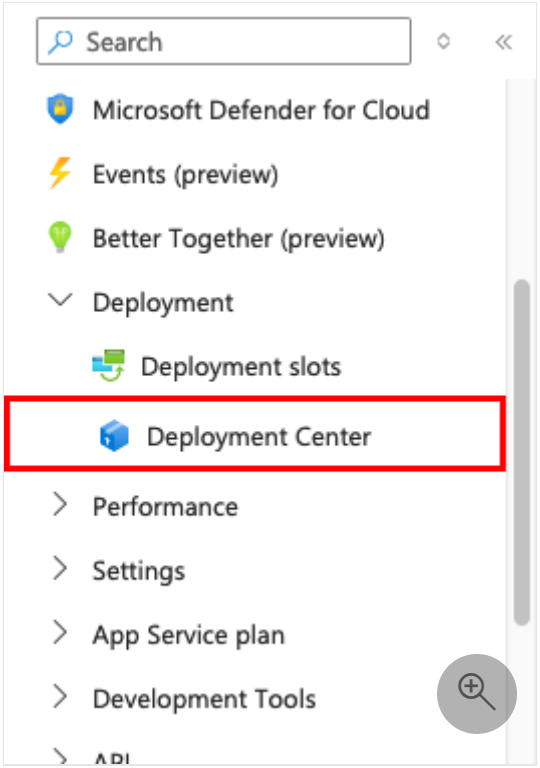
Step 7: In the Service Connectors page:



1. Select checkbox next to the Cache for Redis connector, then select **Edit**.
2. Select the **Authentication** tab.
3. Select **Store Secret in Key Vault**.

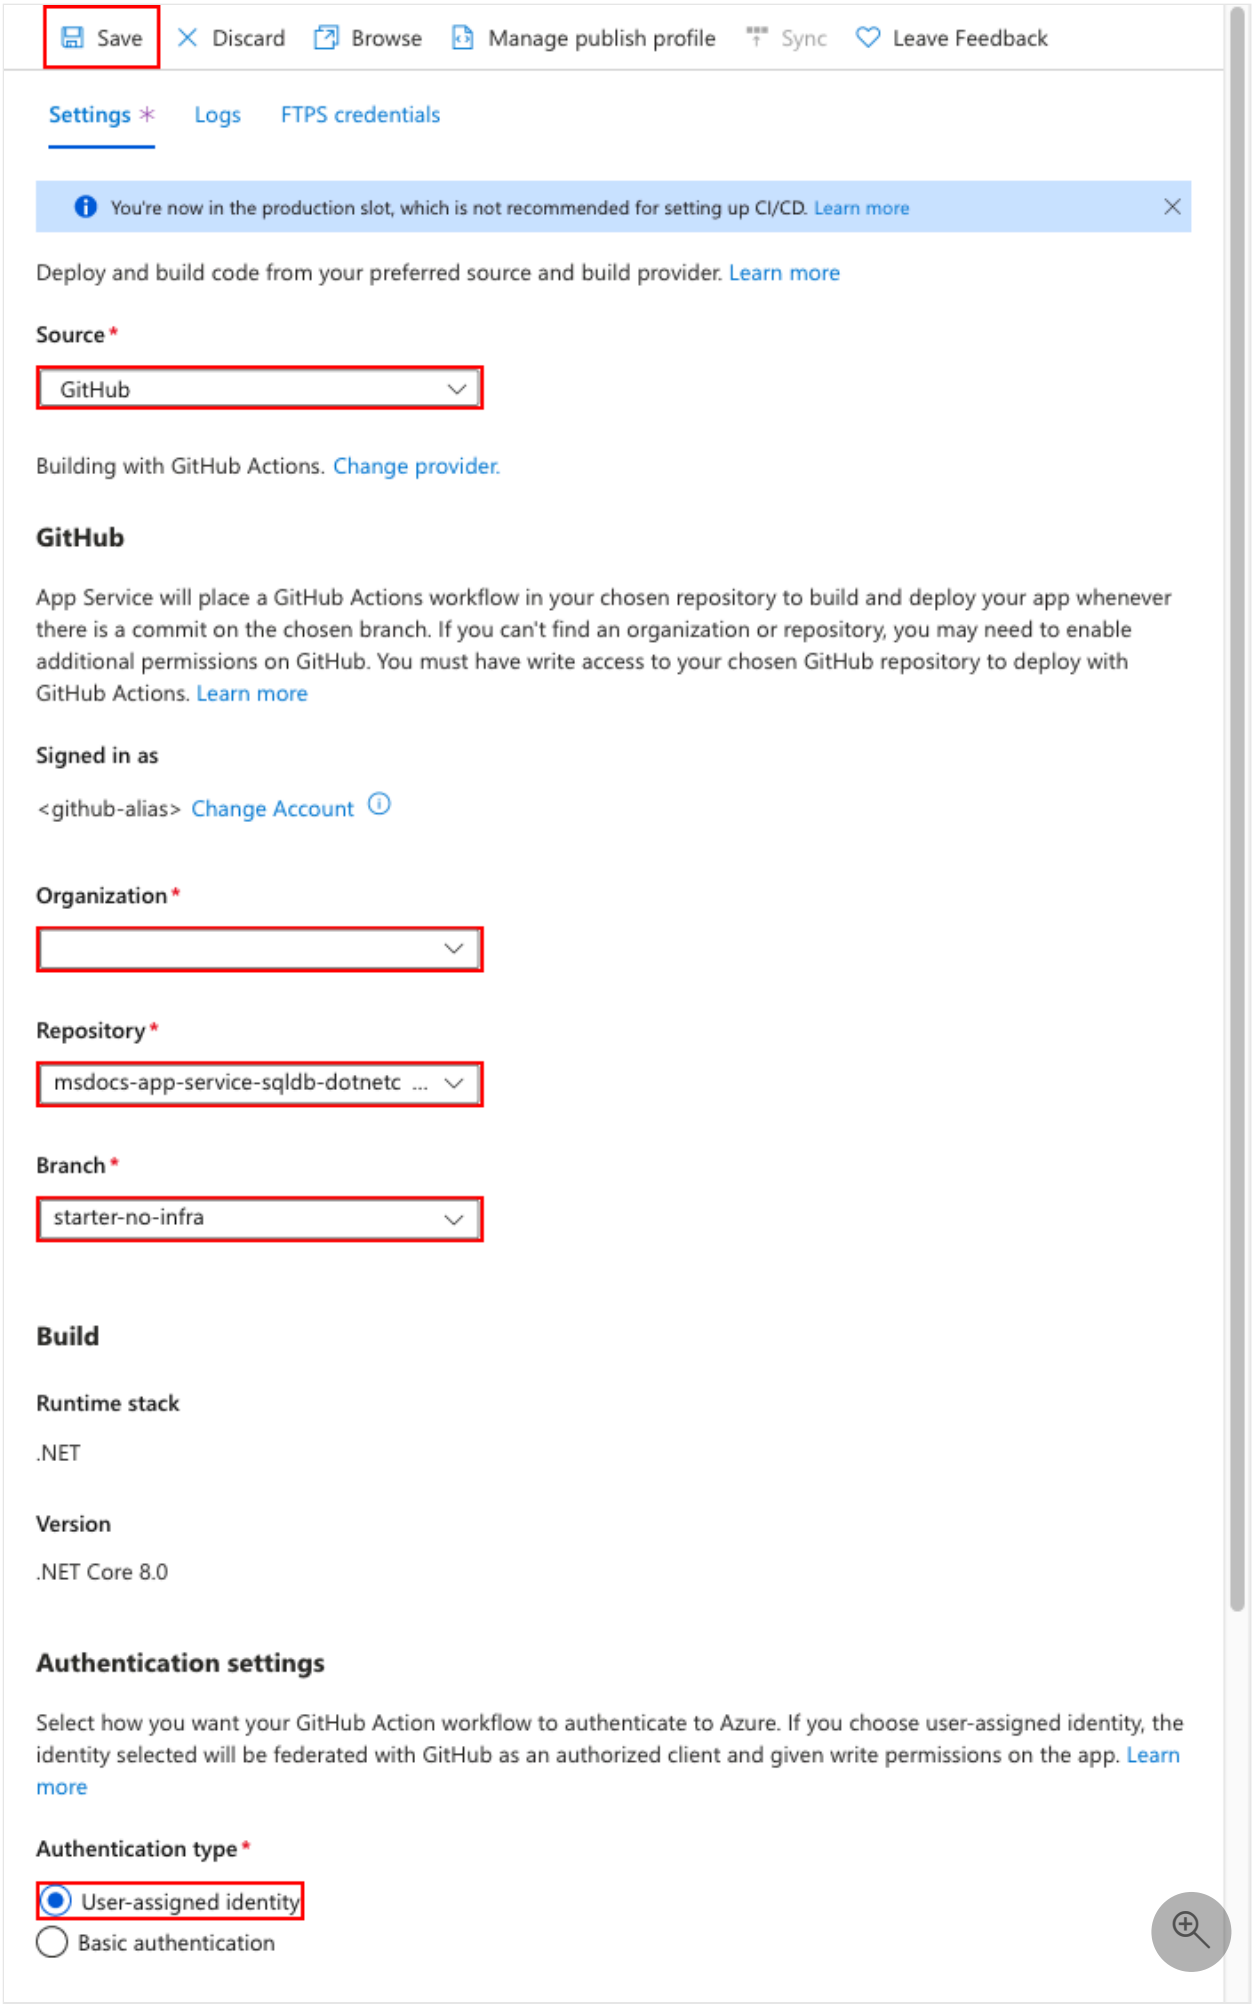
4. Under **Key Vault Connection**, select the key vault you created.
5. Select **Next: Networking**.
6. Select **Configure firewall rules to enable access to target service**. The app creation wizard already secured the SQL database with a private endpoint.
7. Select **Save**. Wait until the **Update succeeded** notification appears.

Step 8: To verify your changes:



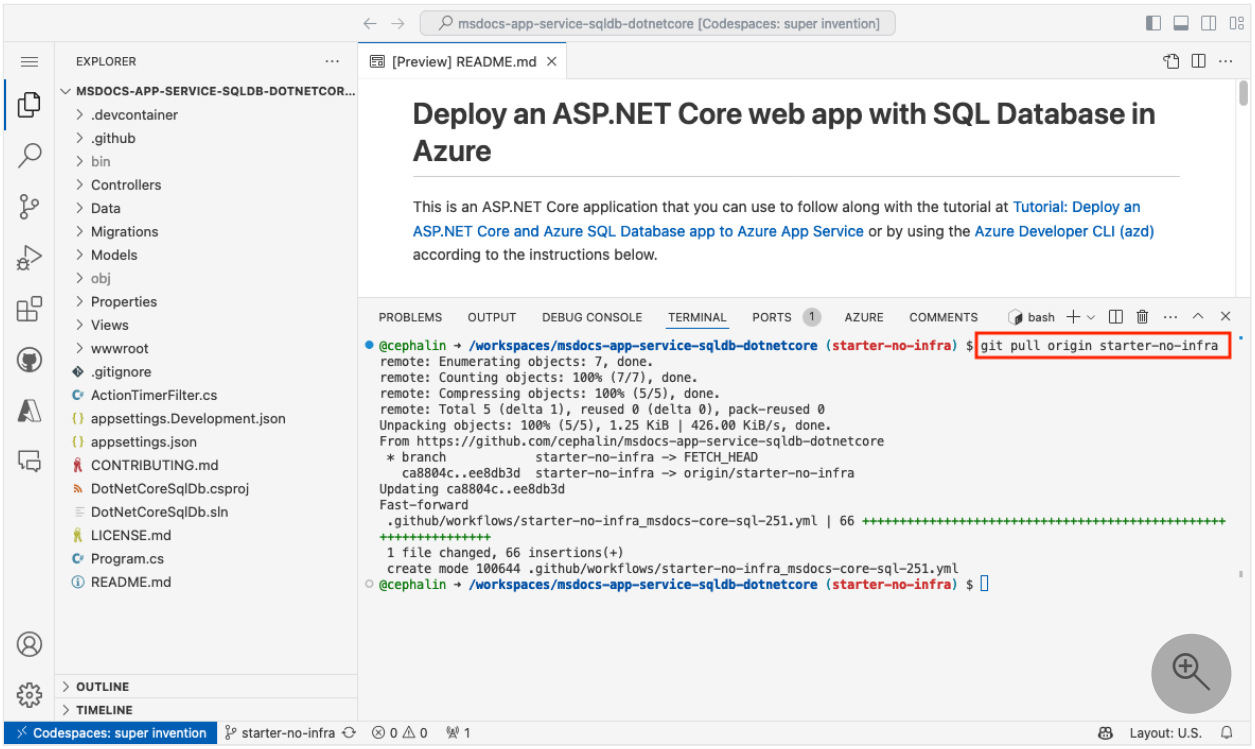
1. From the left menu, select **Environment variables** > **Connection strings** again.
2. Next to **AZURE_SQL_CONNECTIONSTRING**, select **Show value**. The value should be `@Microsoft.KeyVault(...)`, which means that it's a key vault reference because the secret is now managed in the key vault.
3. To verify the Redis connection string, select the **App setting** tab. Next to **AZURE_REDIS_CONNECTIONSTRING**, select **Show value**. The value should be `@Microsoft.KeyVault(...)` too.

4. Deploy sample code



In this step, you configure GitHub deployment using GitHub Actions. It's just one of many ways to deploy to App Service, but also a great way to have continuous integration in your deployment process. By default, every `git push` to your GitHub repository kicks off the build and deploy action.

Step 1: In the left menu, select **Deployment** > **Deployment Center**.



Step 2: In the Deployment Center page:

1. In **Source**, select **GitHub**. By default, **GitHub Actions** is selected as the build provider.
2. Sign in to your GitHub account and follow the prompt to authorize Azure.
3. In **Organization**, select your account.
4. In **Repository**, select **msdocs-app-service-sqldb-dotnetcore**.
5. In **Branch**, select **starter-no-infra**. This is the same branch that you worked in with your sample app, without any Azure-related files or configuration.
6. For **Authentication type**, select **User-assigned identity**.
7. In the top menu, select **Save**. App Service commits a workflow file into the chosen GitHub repository, in the `.github/workflows` directory. By default, the deployment center creates a user-assigned identity for the workflow to authenticate using Microsoft Entra (OIDC authentication). For alternative authentication options, see Deploy to App Service using GitHub Actions.

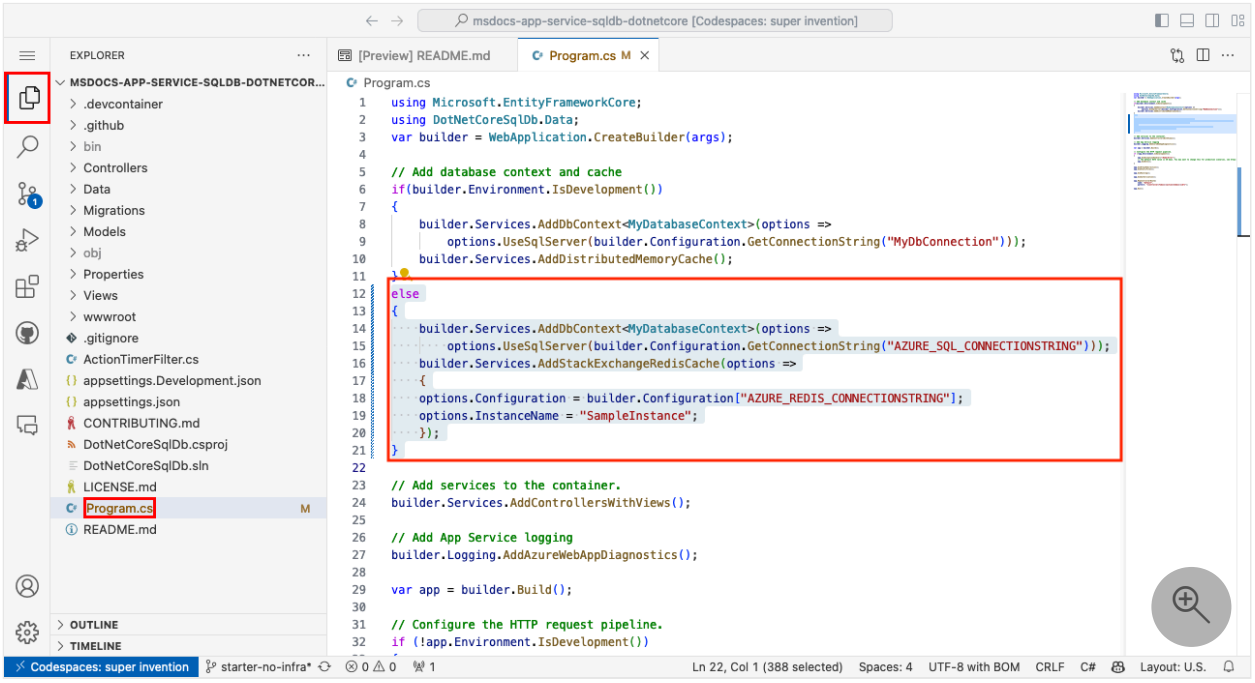
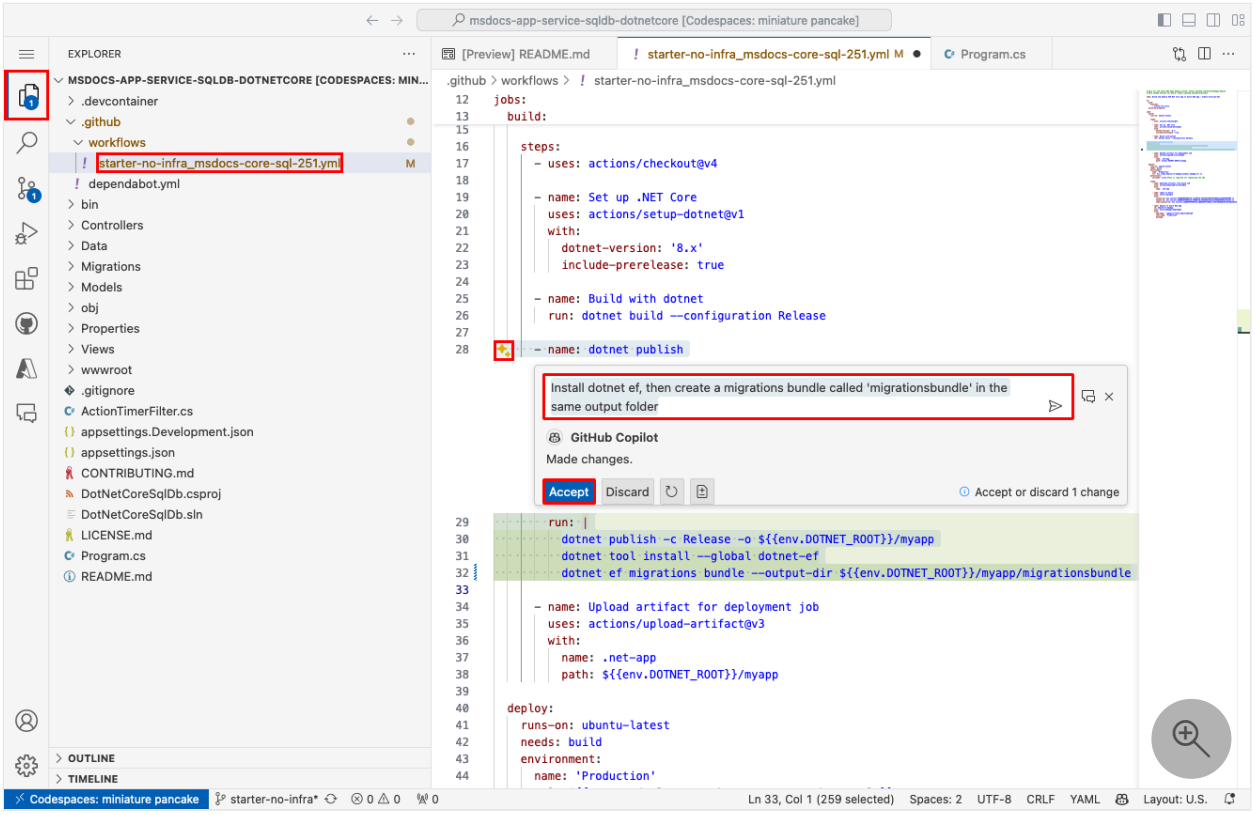
Select how you want your GitHub Action workflow to authenticate to Azure. If you choose user-assigned identity, the identity selected will be federated with GitHub as an authorized client and given write permissions on the app. Learn more
Authentication type *
User-assigned identity
Basic authentication

Step 3: Back in the GitHub codespace of your sample fork, run `git pull origin starter-no-infra`. This pulls the newly committed workflow file into your codespace.



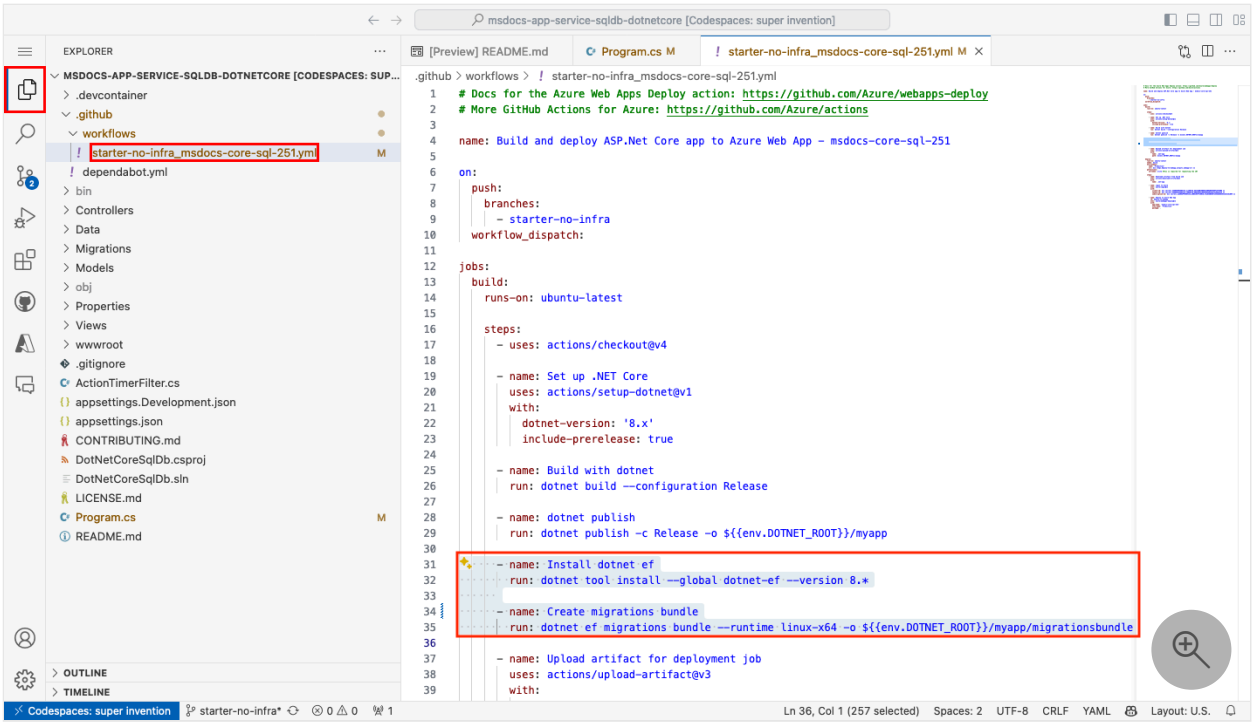
Step 4 (Option 1: with GitHub Copilot):

1. Start a new chat session by selecting the **Chat** view, then selecting **+**.
2. Ask, "*@workspace How does the app connect to the database and the cache?*" Copilot might give you some explanation about the `MyDatabaseContext` class and how it's configured in *Program.cs*.
3. Ask, "In production mode, I want the app to use the connection string called AZURE_SQL_CONNECTIONSTRING for the database and the app setting called AZURE_REDIS_CONNECTIONSTRING*." Copilot might give you a code suggestion similar to the one in the **Option 2: without GitHub Copilot** steps below and even tell you to make the change in the *Program.cs* file.
4. Open *Program.cs* in the explorer and add the code suggestion. GitHub Copilot doesn't give you the same response every time, and it's not always correct. You might need to ask more questions to fine-tune its response. For tips, see What can I do with GitHub Copilot in my codespace?.



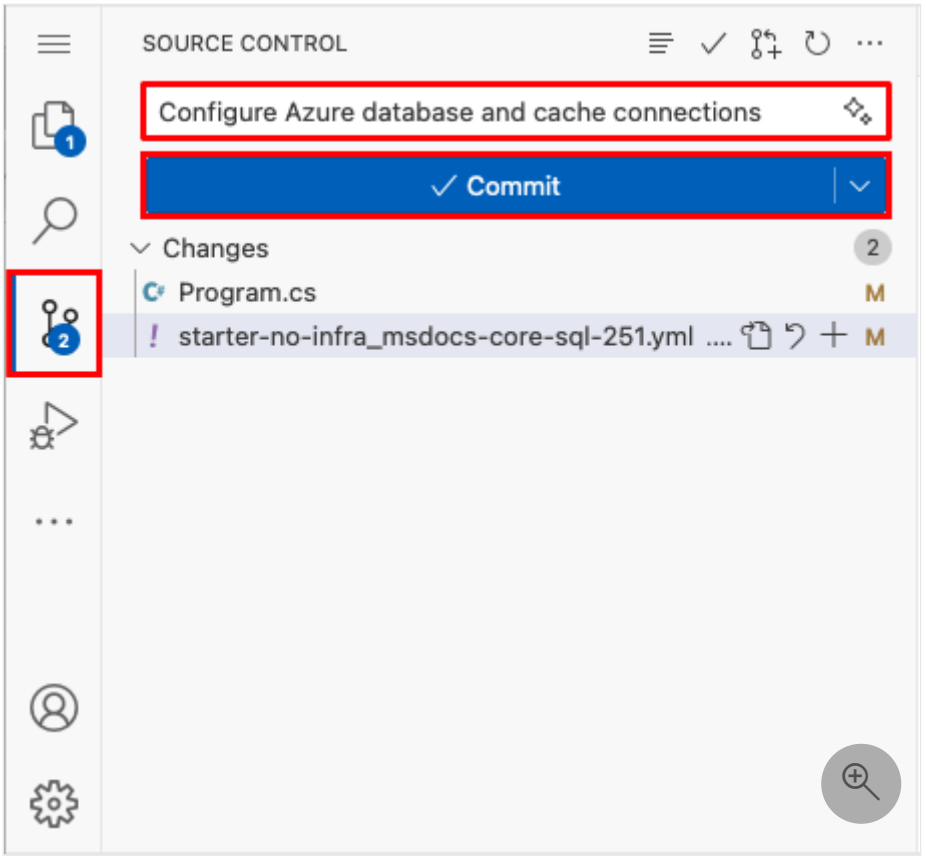
Step 4 (Option 2: without GitHub Copilot):

1. Open *Program.cs* in the explorer.
2. Find the commented code (lines 12-21) and uncomment it. This code connects to the database by using `AZURE_SQL_CONNECTIONSTRING` and connects to the Redis cache by using the app setting `AZURE_REDIS_CONNECTIONSTRING`.



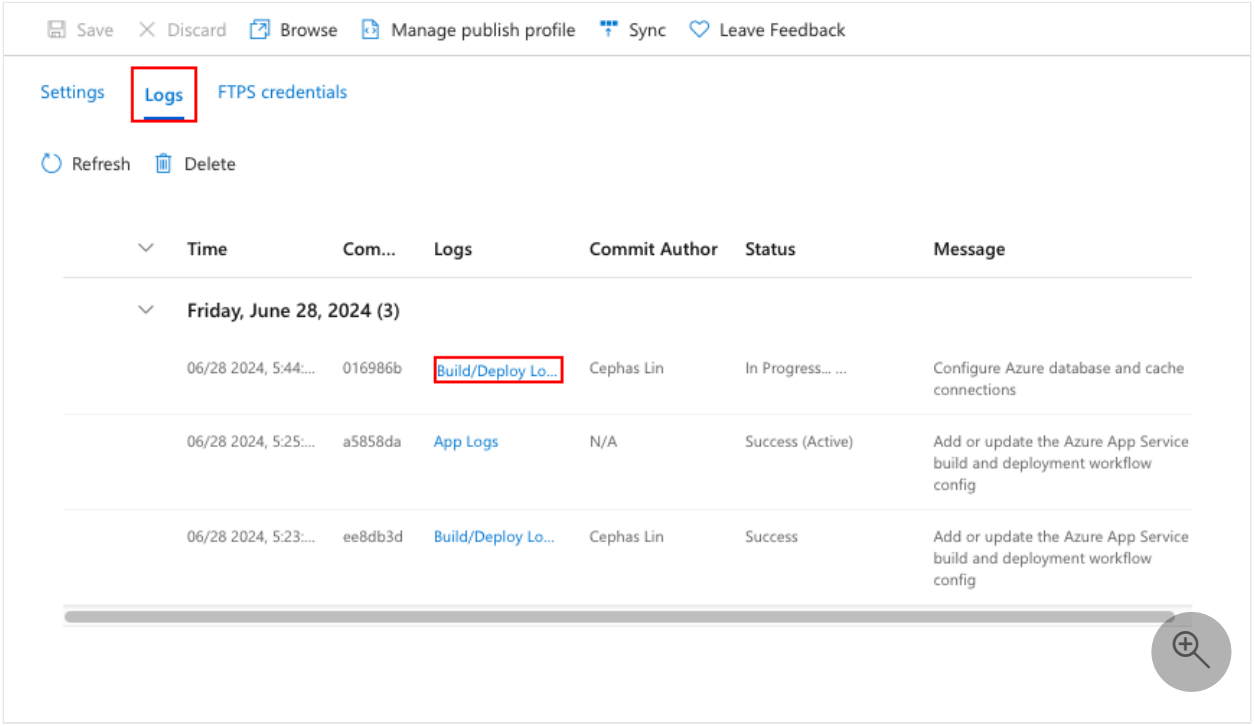
Step 5 (Option 1: with GitHub Copilot):

1. Open *.github/workflows/starter-no-infra_msdocs-core-sql-XYZ* in the explorer. This file was created by the App Service create wizard.
2. Highlight the `dotnet publish` step and select ✨.
3. Ask Copilot, "*Install dotnet ef, then create a migrations bundle in the same output folder.*"
4. If the suggestion is acceptable, select **Accept**. GitHub Copilot doesn't give you the same response every time, and it's not always correct. You might need to ask more questions to fine-tune its response. For tips, see What can I do with GitHub Copilot in my codespace?.



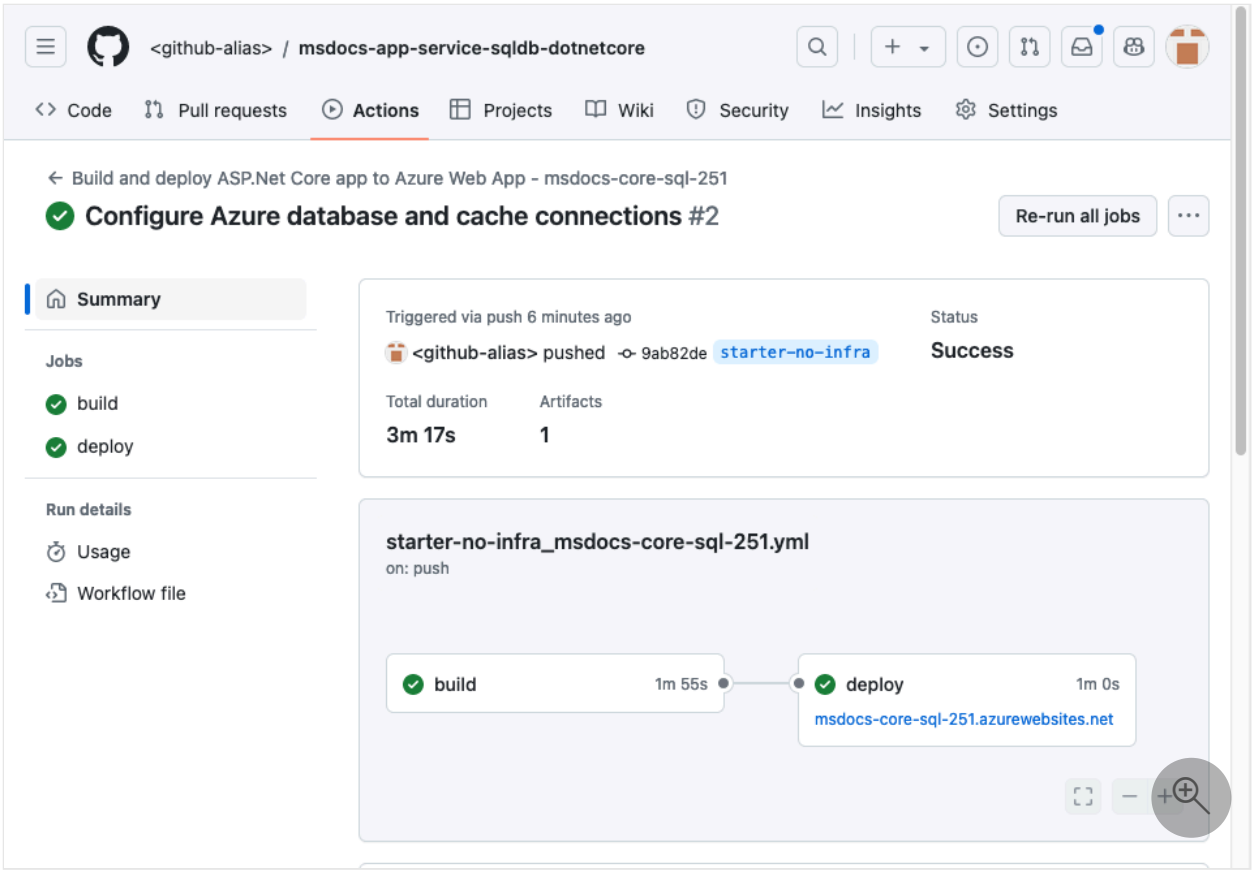
Step 5 (Option 2: without GitHub Copilot):

1. Open *.github/workflows/starter-no-infra_msdocs-core-sql-XYZ* in the explorer. This file was created by the App Service create wizard.
2. Under the `dotnet publish` step, add a step to install the Entity Framework Core tool with the command `dotnet tool install -g dotnet-ef --version 8.*`.
3. Under the new step, add another step to generate a database migration bundle in the deployment package: `dotnet ef migrations bundle --runtime linux-x64 -o ${{env.DOTNET_ROOT}}/myapp/migrationsbundle`. The migration bundle is a self-contained executable that you can run in the production environment without needing the .NET SDK. The App Service linux container only has the .NET runtime and not the .NET SDK.



Step 6:

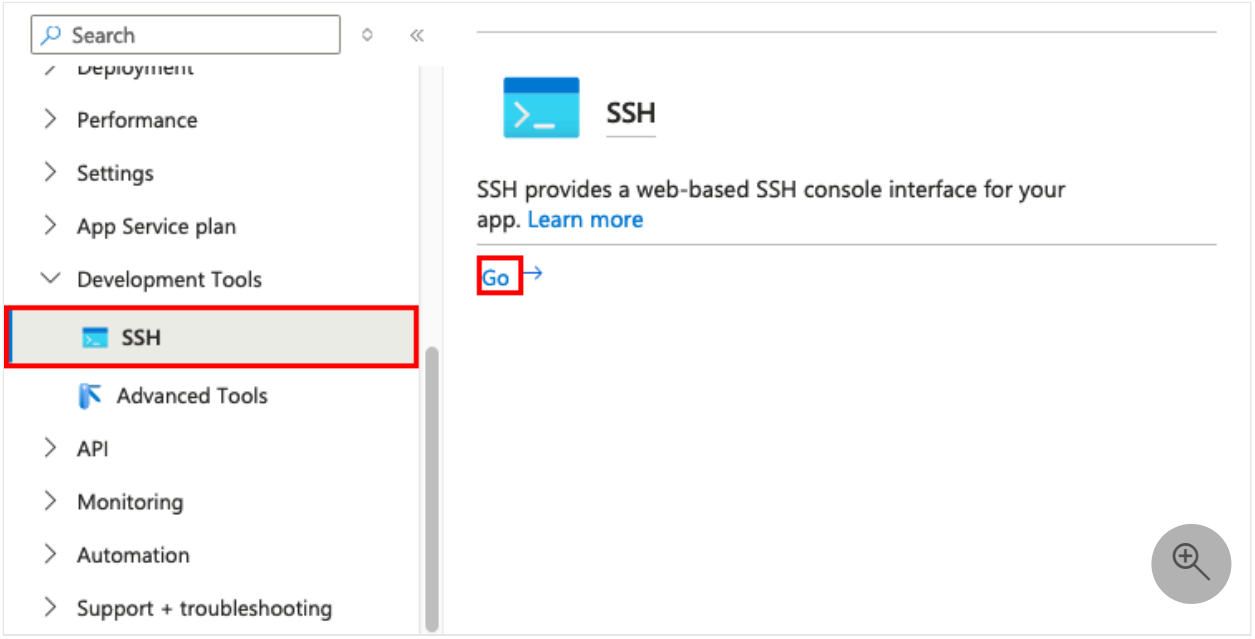
1. Select the **Source Control** extension.
2. In the textbox, type a commit message like `Configure Azure database and cache connections`. Or, select ✨ and let GitHub Copilot generate a commit message for you.
3. Select **Commit**, then confirm with **Yes**.
4. Select **Sync changes 1**, then confirm with **OK**.



Step 7: Back in the Deployment Center page in the Azure portal:

1. Select the **Logs** tab, then select **Refresh** to see the new deployment run.
2. In the log item for the deployment run, select the **Build/Deploy Logs** entry with the latest timestamp.

Step 8: You're taken to your GitHub repository and see that the GitHub action is running. The workflow file defines two separate stages, build and deploy. Wait for the



GitHub run to show a status of **Success**. It takes about 5 minutes.

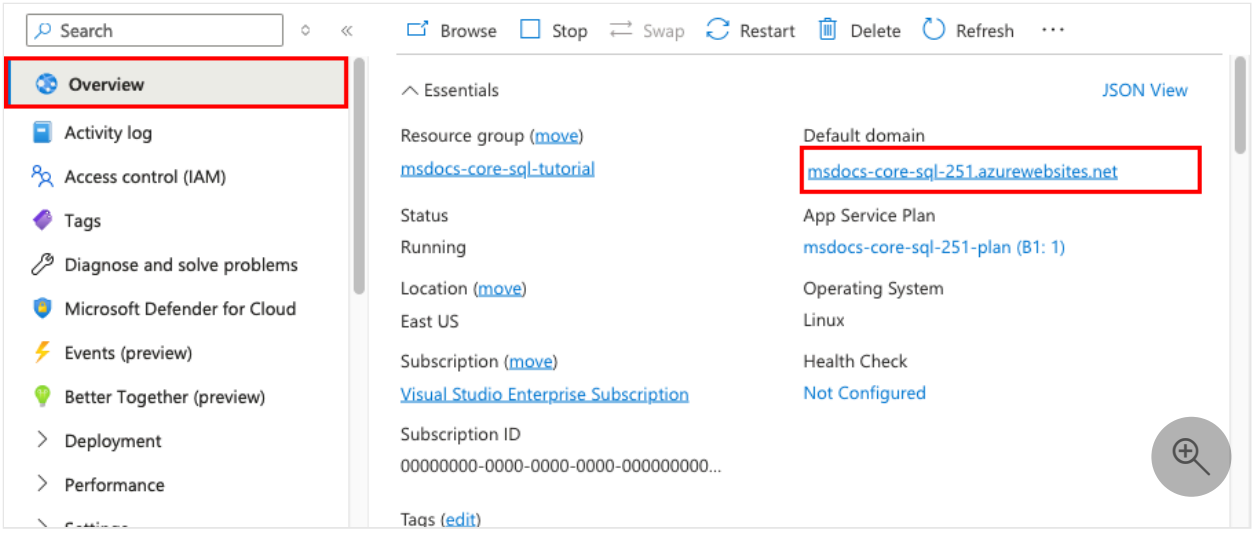
5. Generate database schema

With the SQL Database protected by the virtual network, the easiest way to run dotnet database migrations is in an SSH session with the App Service container.

Step 1: Back in the App Service page, in the left menu, select **Development Tools** > **SSH**, then select **Go**.

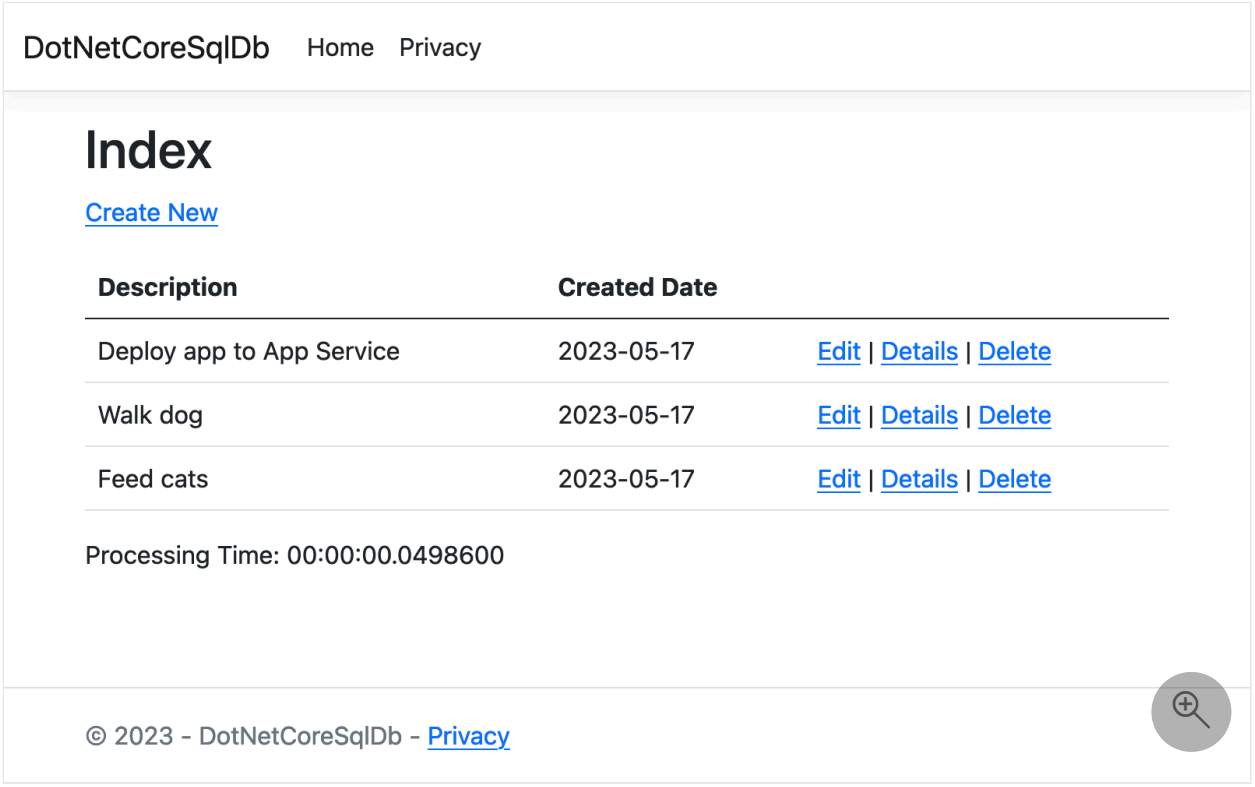
Step 2: In the SSH terminal:

1. Run `cd /home/site/wwwroot`. Here are all your deployed files.
2. Run the migration bundle that the GitHub workflow generated, with the command `./migrationsbundle -- --environment Production`. If it succeeds, App Service is connecting successfully to the SQL Database. Remember that `--environment Production` corresponds to the code changes you made in *Program.cs*.



In the SSH session, only changes to files in `/home` can persist beyond app restarts. Changes outside of `/home` aren't persisted.

Having issues? Check the Troubleshooting section.



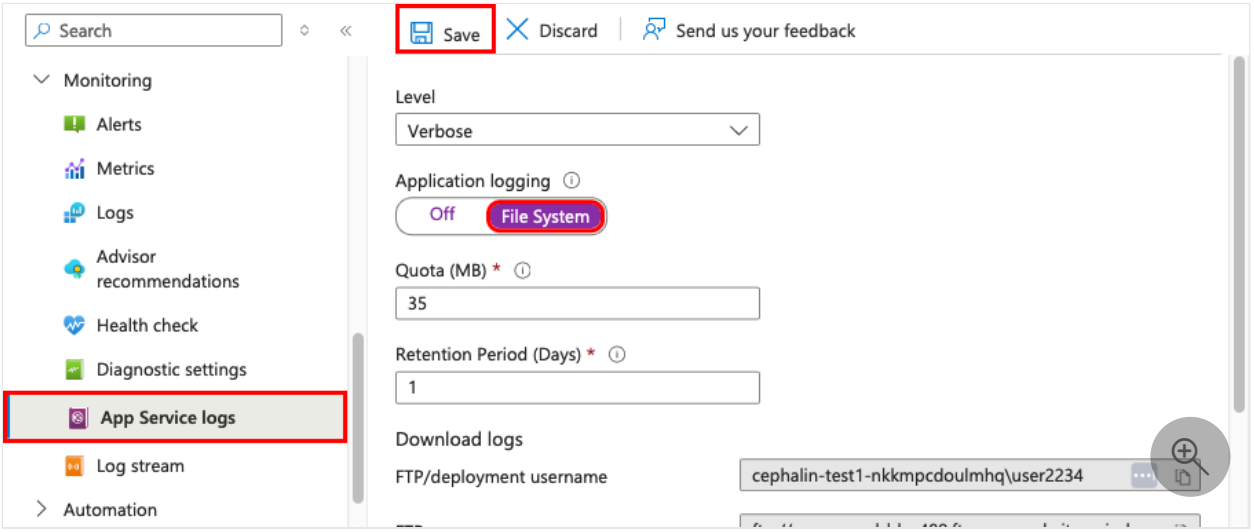
6. Browse to the app

Step 1: In the App Service page:

1. From the left menu, select **Overview**.
2. Select the URL of your app.

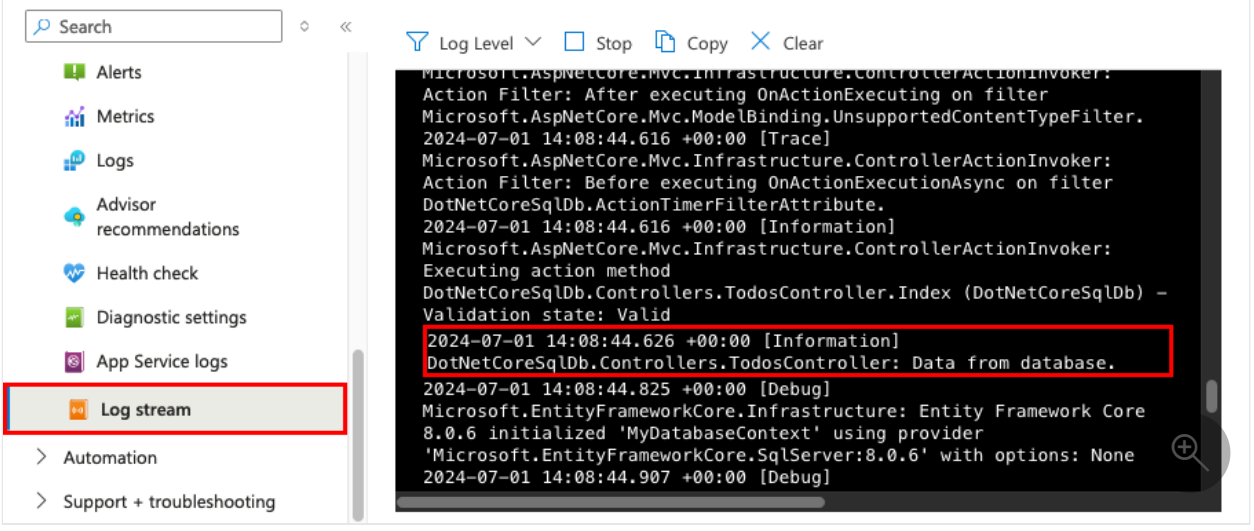
Step 2: Add a few tasks to the list. Congratulations, you're running a secure data-driven ASP.NET Core app in Azure App Service.

> **Tip**
>
> The sample application implements the cache-aside pattern. When you visit a data view for the second time, or reload the same page after making data changes,



Processing time in the webpage shows a much faster time because it's loading the data from the cache instead of the database.

7. Stream diagnostic logs

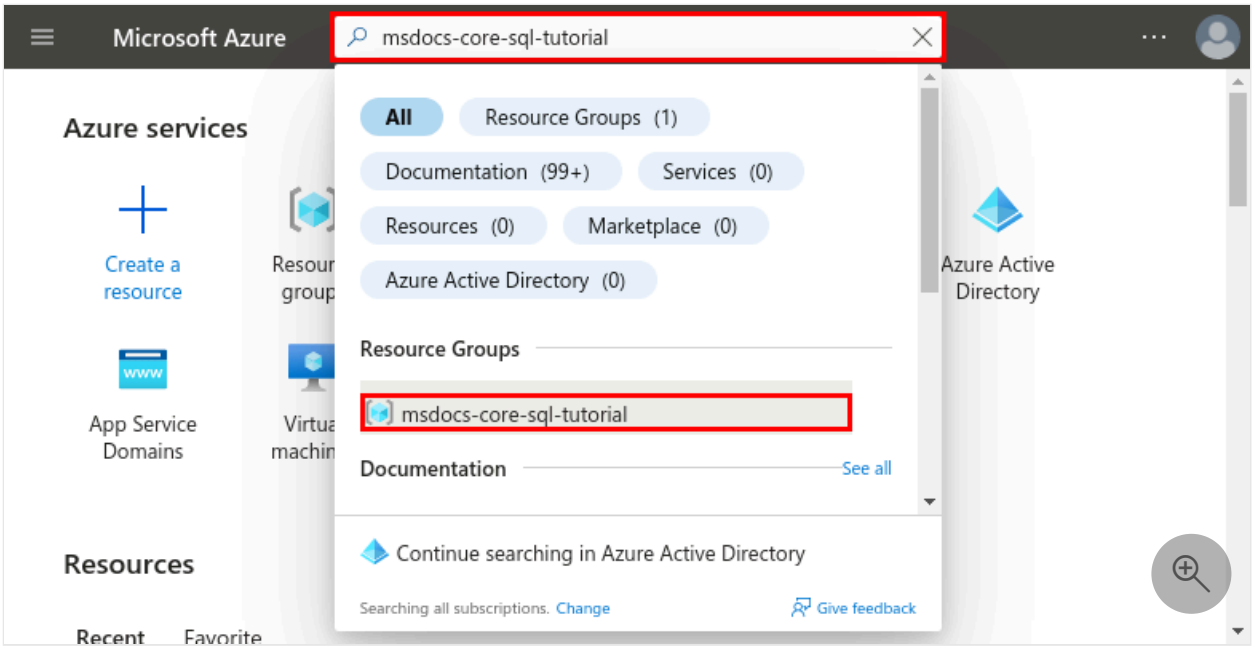


Azure App Service captures all messages logged to the console to assist you in diagnosing issues with your application. The sample app outputs console log messages in each of its endpoints to demonstrate this capability.

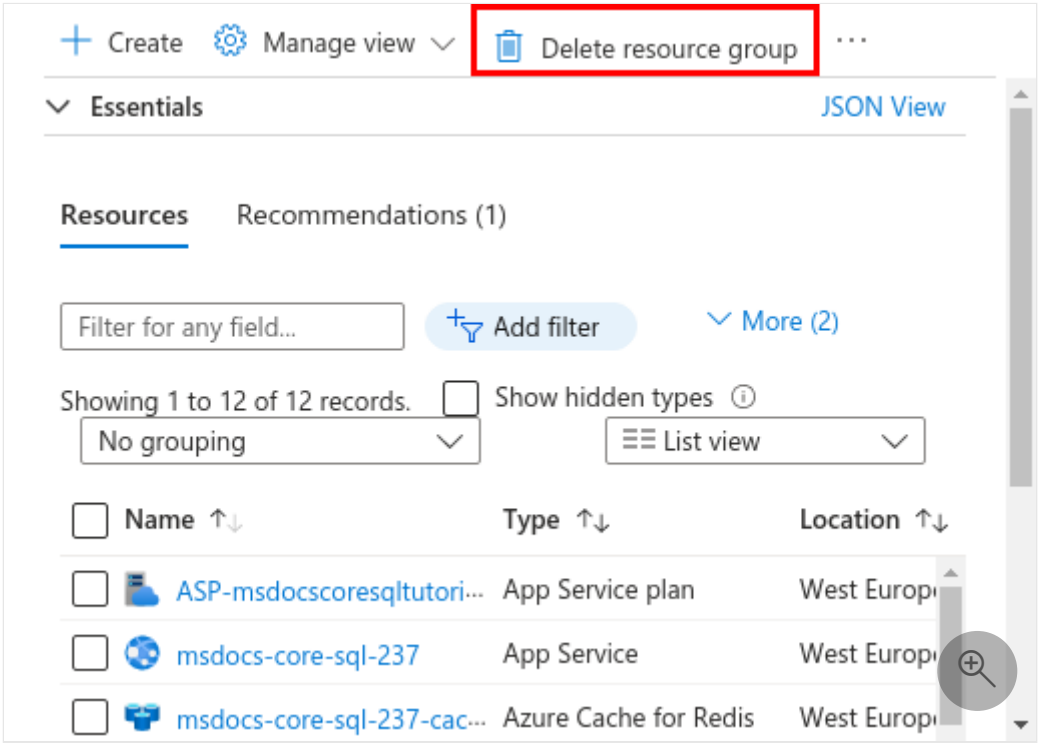
Step 1: In the App Service page:

1. From the left menu, select **Monitoring** > **App Service logs**.
2. Under **Application logging**, select **File System**, then select **Save**.

Step 2: From the left menu, select **Log stream**. You see the logs for your app, including platform logs and logs from inside the container.



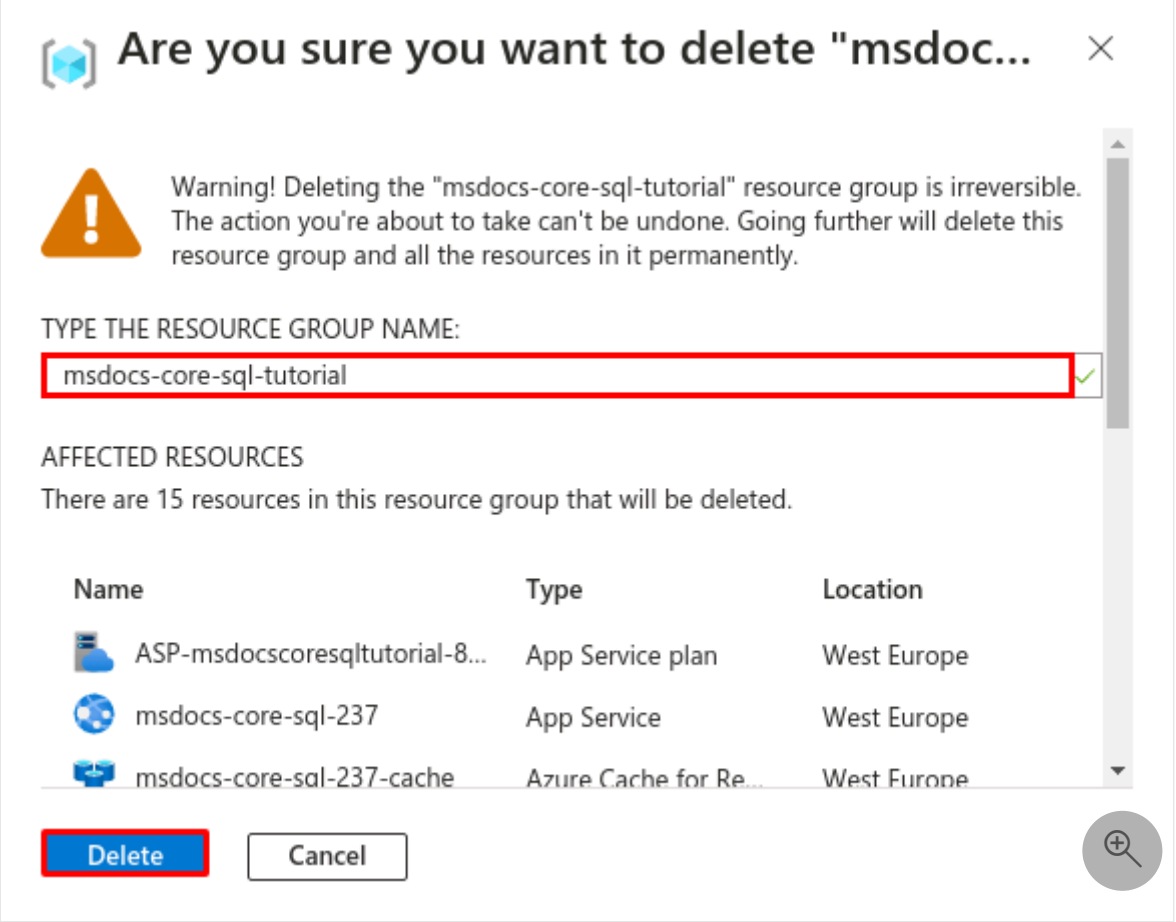
8. Clean up resources



When you're finished, you can delete all of the resources from your Azure subscription by deleting the resource group.

Step 1: In the search bar at the top of the Azure portal:

1. Enter the resource group name.
2. Select the resource group.



Step 2: In the resource group page, select **Delete resource group**.

Step 3:

1. Enter the resource group name to confirm your deletion.
2. Select **Delete**.

:

Troubleshooting

- The portal deployment view for Azure SQL Database shows a Conflict status
- In the Azure portal, the log stream UI for the web app shows network errors
- The SSH session in the browser shows SSH CONN CLOSED
- The portal log stream page shows Connected! but no logs

The portal deployment view for Azure SQL Database shows a Conflict status

Depending on your subscription and the region you select, you might see the deployment status for Azure SQL Database to be `Conflict`, with the following message in Operation details:

```
Location '<region>' is not accepting creation of new Windows Azure SQL Database servers at this time.
```

This error is most likely caused by a limit on your subscription for the region you select. Try choosing a different region for your deployment.

In the Azure portal, the log stream UI for the web app shows network errors

You might see this error:

```
Unable to open a connection to your app. This may be due to any network
security groups or IP restriction rules that you have placed on your app. To
use log streaming, please make sure you are able to access your app directly
from your current network.
```

This is usually a transient error when the app is first started. Wait a few minutes and check again.

The SSH session in the browser shows `SSH CONN CLOSED`

It takes a few minutes for the Linux container to start up. Wait a few minutes and check again.

The portal log stream page shows `Connected!` but no logs

After you configure diagnostic logs, the app is restarted. You might need to refresh the page for the changes to take effect in the browser.

Frequently asked questions

- How much does this setup cost?
- How do I connect to the Azure SQL Database server that's secured behind the virtual network with other tools?
- How does local app development work with GitHub Actions?
- How do I debug errors during the GitHub Actions deployment?
- How do I change the SQL Database connection to use a managed identity instead?
- I don't have permissions to create a user-assigned identity
- What can I do with GitHub Copilot in my codespace?

How much does this setup cost?

Pricing for the created resources is as follows:

- The App Service plan is created in **Basic** tier and can be scaled up or down. See App Service pricing.
- The Azure SQL Database is created in general-purpose, serverless tier on Standard-series hardware with the minimum cores. There's a small cost and can be distributed to other regions. You can minimize cost even more by reducing its maximum size, or you can scale it up by adjusting the serving tier, compute tier, hardware configuration, number of cores, database size, and zone redundancy. See Azure SQL Database pricing.
- The Azure Cache for Redis is created in **Basic** tier with the minimum cache size. There's a small cost associated with this tier. You can scale it up to higher performance tiers for higher availability, clustering, and other features. See Azure Cache for Redis pricing.
- The virtual network doesn't incur a charge unless you configure extra functionality, such as peering. See Azure Virtual Network pricing.
- The private DNS zone incurs a small charge. See Azure DNS pricing.

How do I connect to the Azure SQL Database server that's secured behind the virtual network with other tools?

- For basic access from a command-line tool, you can run `sqlcmd` from the app's SSH terminal. The app's container doesn't come with `sqlcmd`, so you must install it manually. Remember that the installed client doesn't persist across app restarts.
- To connect from a SQL Server Management Studio client or from Visual Studio, your machine must be within the virtual network. For example, it could be an Azure VM that's connected to one of the subnets, or a machine in an on-premises network that has a site-to-site VPN connection with the Azure virtual network.

How does local app development work with GitHub Actions?

Take the autogenerated workflow file from App Service as an example, each `git push` kicks off a new build and deployment run. From a local clone of the GitHub repository, you make the desired updates push it to GitHub. For example:

terminal

```
git add .
git commit -m "<some-message>"
git push origin main
```

How do I debug errors during the GitHub Actions deployment?

If a step fails in the autogenerated GitHub workflow file, try modifying the failed command to generate more verbose output. For example, you can get more output from any of the `dotnet` commands by adding the `-v` option. Commit and push your changes to trigger another deployment to App Service.

I don't have permissions to create a user-assigned identity

See Set up GitHub Actions deployment from the Deployment Center.

How do I change the SQL Database connection to use a managed identity instead?

The default connection string to the SQL database is managed by Service Connector, with the name *defaultConnector*, and it uses SQL authentication. To replace it with a connection that uses a managed identity, run the following commands in the cloud shell after replacing the placeholders:

Azure CLI

```
az extension add --name serviceconnector-passwordless --upgrade
az sql server update --enable-public-network true
az webapp connection delete sql --connection defaultConnector --resource-
group <group-name> --name <app-name>
az webapp connection create sql --connection defaultConnector --resource-
group <group-name> --name <app-name> --target-resource-group <group-name> --
server <database-server-name> --database <database-name> --client-type
dotnet --system-identity --config-connstr true
az sql server update --enable-public-network false
```

By default, the command `az webapp connection create sql --client-type dotnet --system-identity --config-connstr` does the following:

- Sets your user as the Microsoft Entra ID administrator of the SQL database server.
- Create a system-assigned managed identity and grants it access to the database.
- Generates a passwordless connection string called `AZURE_SQL_CONNECTIONGSTRING`, which your app is already using at the end of the tutorial.

Your app should now have connectivity to the SQL database. For more information, see Tutorial: Connect to Azure databases from App Service without secrets using a managed

identity.

> **Tip**
>
> **Don't want to enable public network connection?** You can skip `az sql server update --enable-public-network true` by running the commands from an **Azure cloud shell that's integrated with your virtual network** if you have the **Owner** role assignment on your subscription.
>
> To grant the identity the required access to the database that's secured by the virtual network, `az webapp connection create sql` needs direct connectivity with Entra ID authentication to the database server. By default, the Azure cloud shell doesn't have this access to the network-secured database.

What can I do with GitHub Copilot in my codespace?

You might have noticed that the GitHub Copilot chat view was already there for you when you created the codespace. For your convenience, we include the GitHub Copilot chat extension in the container definition (see *.devcontainer/devcontainer.json*). However, you need a GitHub Copilot account (30-day free trial available).

A few tips for you when you talk to GitHub Copilot:

- In a single chat session, the questions and answers build on each other and you can adjust your questions to fine-tune the answer you get.
- By default, GitHub Copilot doesn't have access to any file in your repository. To ask questions about a file, open the file in the editor first.
- To let GitHub Copilot have access to all of the files in the repository when preparing its answers, begin your question with `@workspace`. For more information, see Use the @workspace agent.
- In the chat session, GitHub Copilot can suggest changes and (with `@workspace`) even where to make the changes, but it's not allowed to make the changes for you. It's up to you to add the suggested changes and test it.

Here are some other things you can say to fine-tune the answer you get:

- I want this code to run only in production mode.
- I want this code to run only in Azure App Service and not locally.
- The --output-path parameter seems to be unsupported.

Create your first pipeline

Article • 04/03/2024

Azure DevOps Services | Azure DevOps Server 2022 - Azure DevOps Server 2019

This is a step-by-step guide to using Azure Pipelines to build a sample application from a Git repository. This guide uses YAML pipelines configured with the YAML pipeline editor. If you'd like to use Classic pipelines instead, see Define your Classic pipeline. For guidance on using TFVC, see Build TFVC repositories.

Prerequisites - Azure DevOps

Make sure you have the following items:

- A GitHub account where you can create a repository. Create one for free.
- An Azure DevOps organization. Create one for free. If your team already has one, then make sure you're an administrator of the Azure DevOps project that you want to use.
- An ability to run pipelines on Microsoft-hosted agents. To use Microsoft-hosted agents, your Azure DevOps organization must have access to Microsoft-hosted parallel jobs. You can either purchase a parallel job or you can request a free grant.

Create your first pipeline

Java

Get the Java sample code

To get started, fork the following repository into your GitHub account.

```
https://github.com/MicrosoftDocs/pipelines-java
```

Create your first Java pipeline

1. Sign in to your Azure DevOps organization and go to your project.

2. Go to **Pipelines**, and then select **New pipeline** or **Create pipeline** if creating your first pipeline.

3. Do the steps of the wizard by first selecting **GitHub** as the location of your source code.

4. You might be redirected to GitHub to sign in. If so, enter your GitHub credentials.

5. When you see the list of repositories, select your repository.

6. You might be redirected to GitHub to install the Azure Pipelines app. If so, select **Approve & install**.

7. Azure Pipelines will analyze your repository and recommend the **Maven** pipeline template.

8. When your new pipeline appears, take a look at the YAML to see what it does. When you're ready, select **Save and run**.

9. You're prompted to commit a new `azure-pipelines.yml` file to your repository. After you're happy with the message, select **Save and run** again.

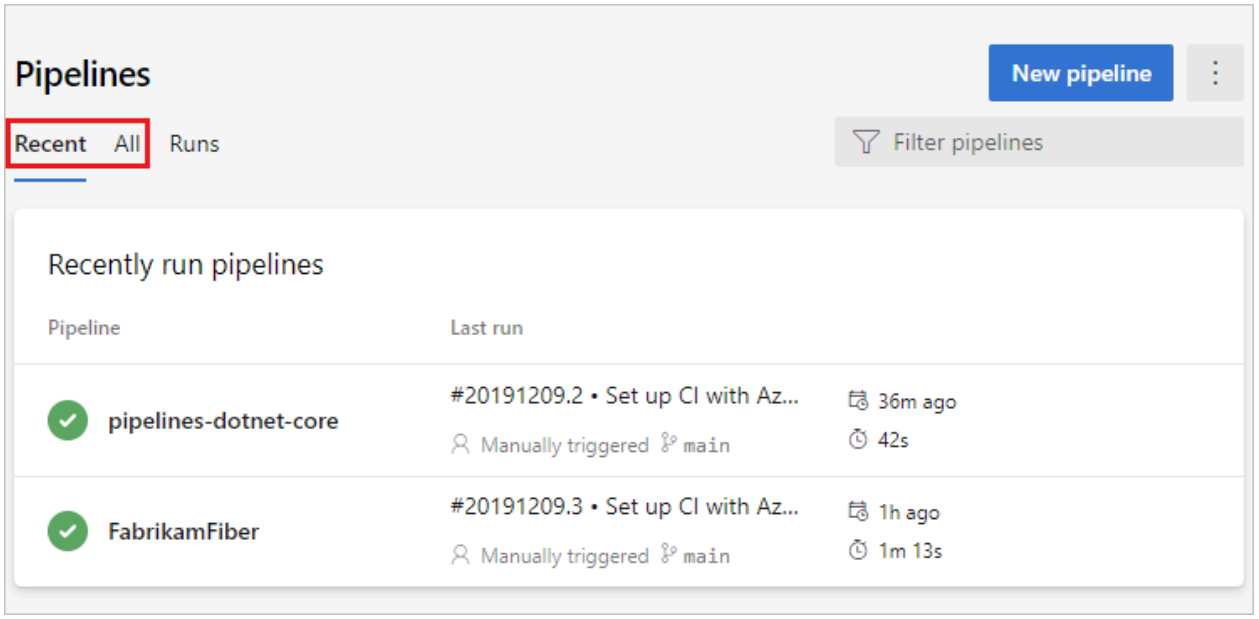
   If you want to watch your pipeline in action, select the build job.

   You just created and ran a pipeline that we automatically created for you, because your code appeared to be a good match for the Maven template.

   You now have a working YAML pipeline (`azure-pipelines.yml`) in your repository that's ready for you to customize!

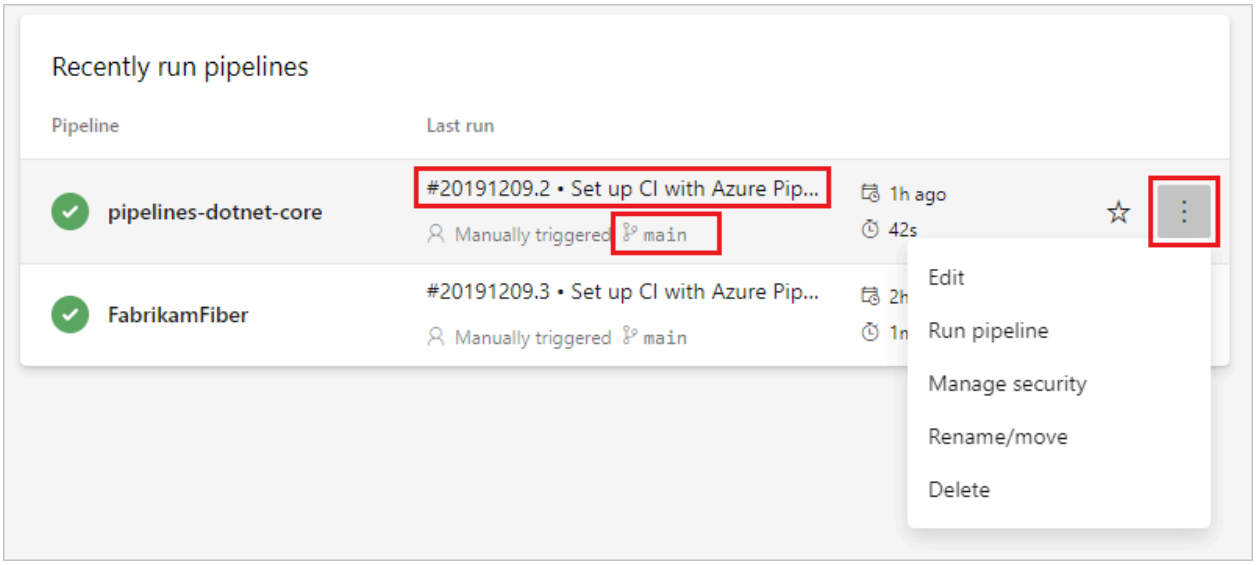
10. When you're ready to make changes to your pipeline, select it in the **Pipelines** page, and then **Edit** the `azure-pipelines.yml` file.

Learn more about working with Java in your pipeline.

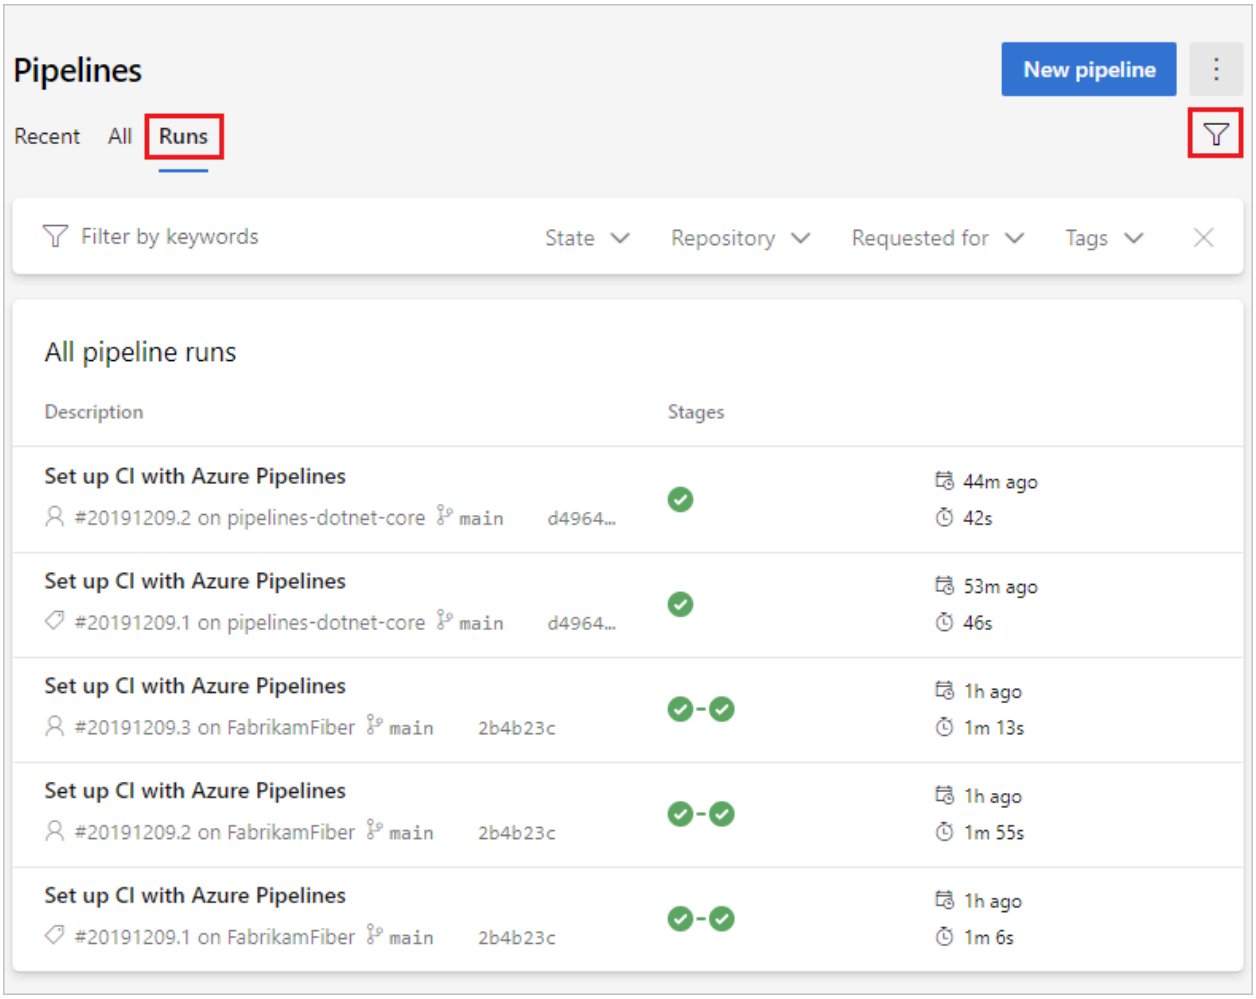


View and manage your pipelines

You can view and manage your pipelines by choosing **Pipelines** from the left-hand menu to go to the pipelines landing page.

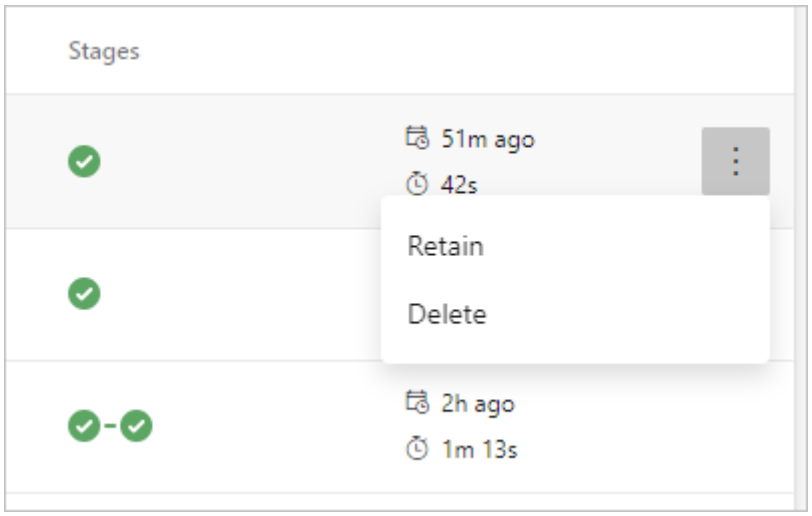


From the pipelines landing page you can view pipelines and pipeline runs, create and import pipelines, manage security, and drill down into pipeline and run details.

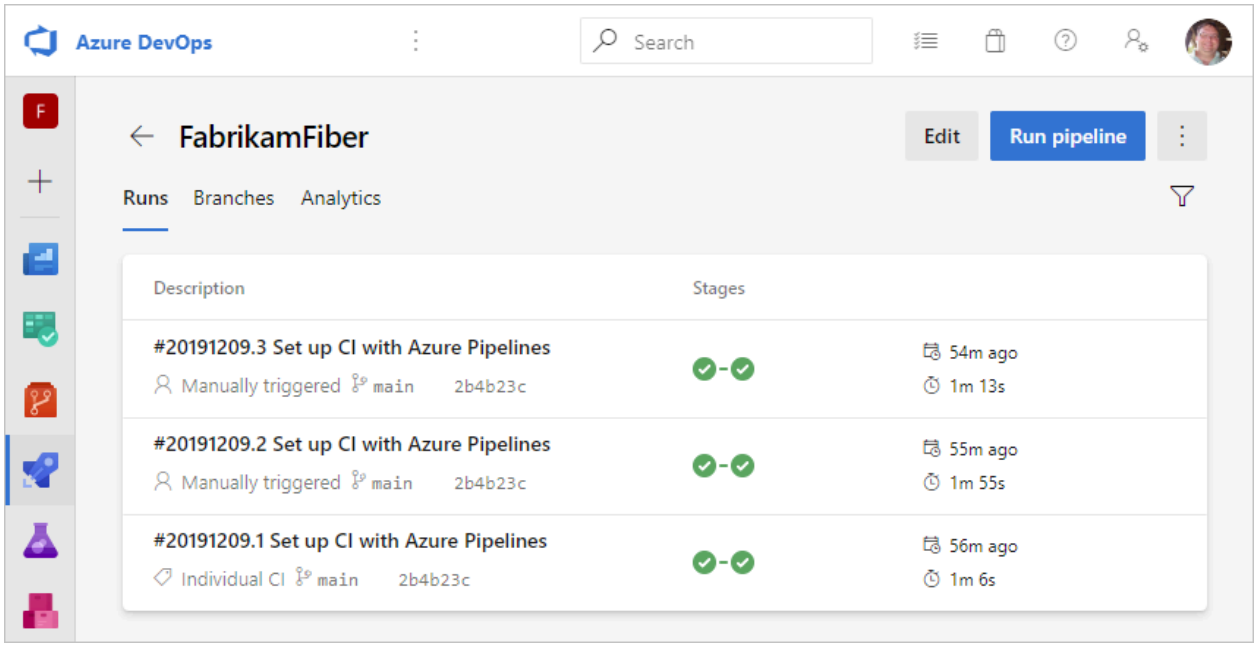


Choose **Recent** to view recently run pipelines (the default view), or choose **All** to view all pipelines.

Select a pipeline to manage that pipeline and view the runs. Select the build number for the last run to view the results of that build, select the branch name to view the branch for that run, or select the context menu to run the pipeline and perform other management actions.



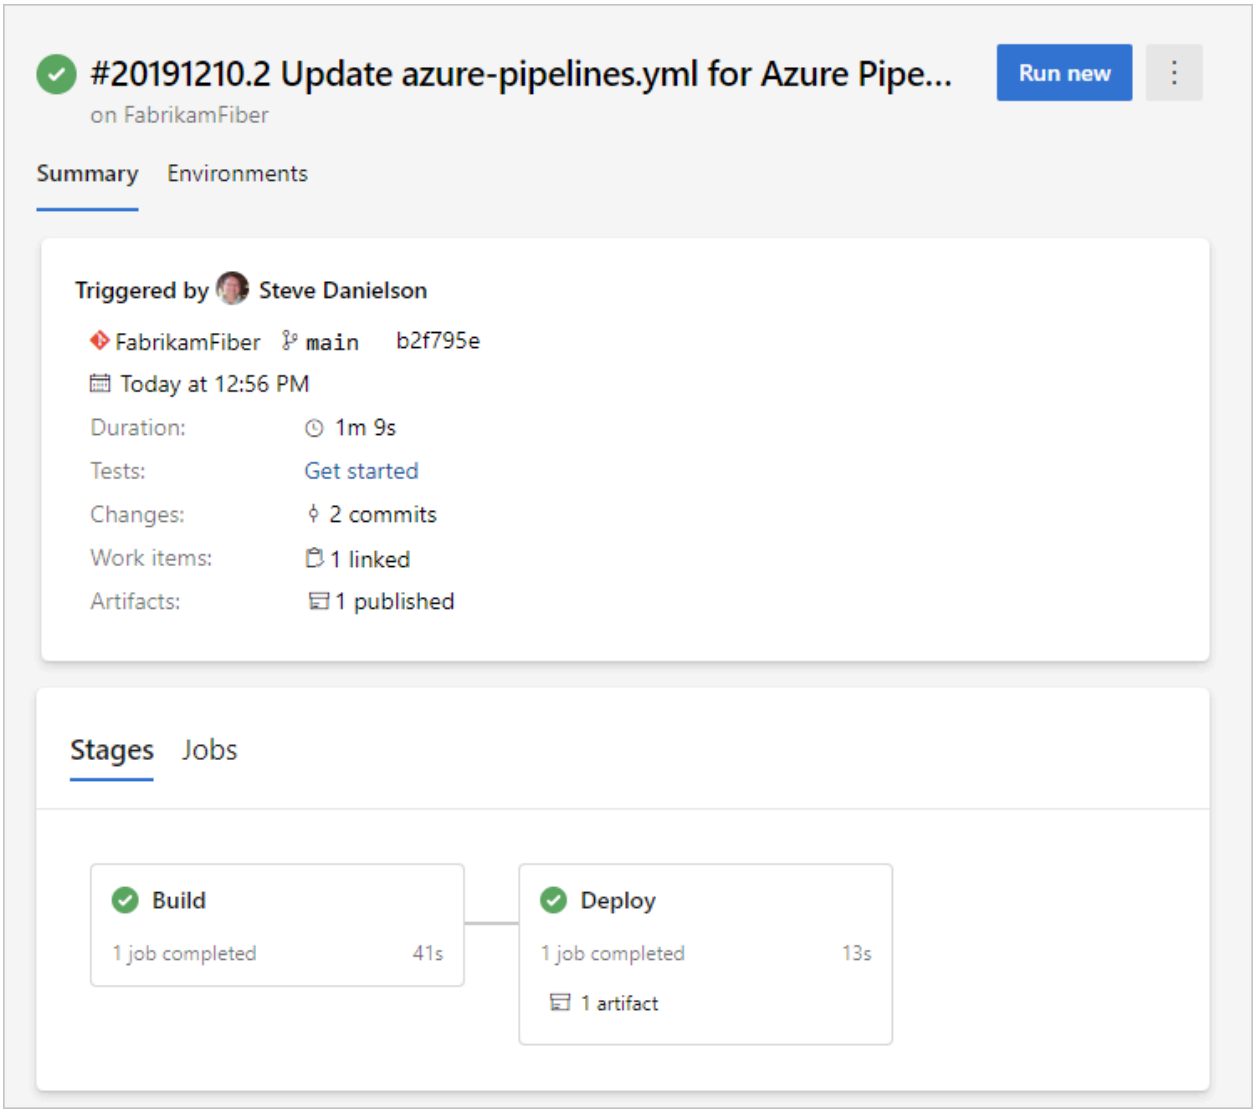
Select **Runs** to view all pipeline runs. You can optionally filter the displayed runs.



Select a pipeline run to view information about that run.

You can choose to **Retain** or **Delete** a run from the context menu. For more information on run retention, see Build and release retention policies.

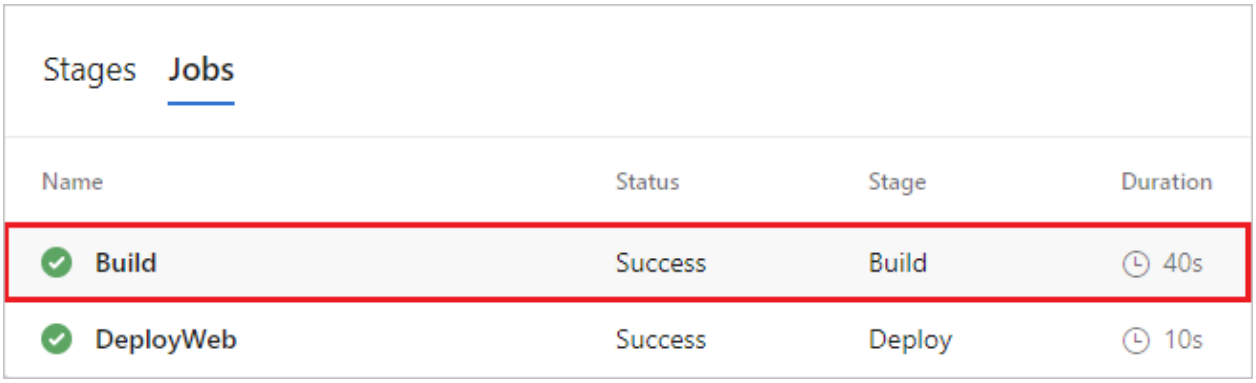
View pipeline details



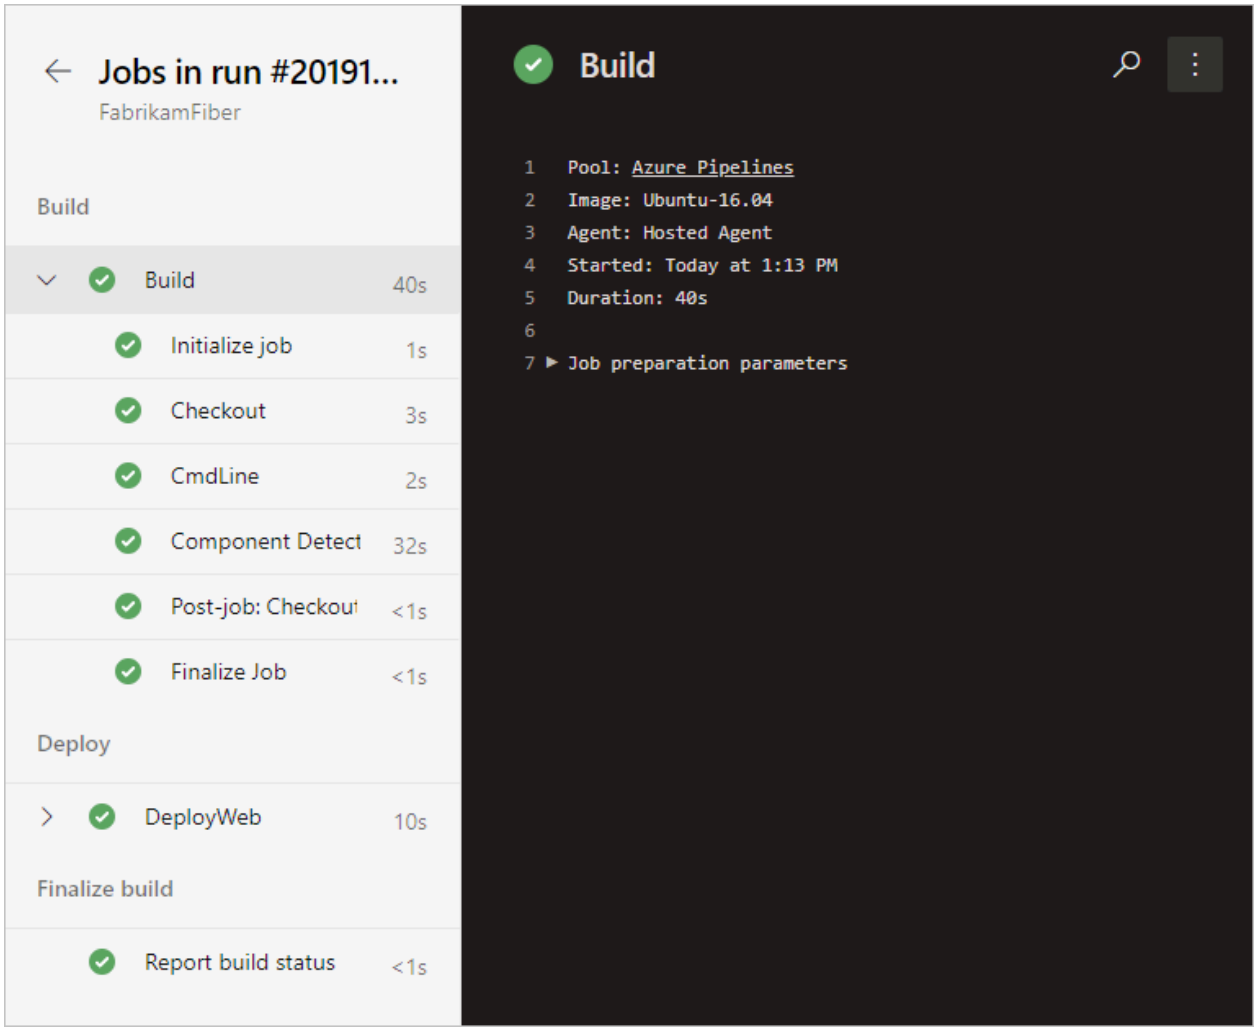
The details page for a pipeline allows you to view and manage that pipeline.

Choose **Edit** to edit your pipeline. For more information, see YAML pipeline editor. You can also edit your pipeline by modifying the **azure-pipelines.yml** file directly in the repository that hosts the pipeline.

View pipeline run details

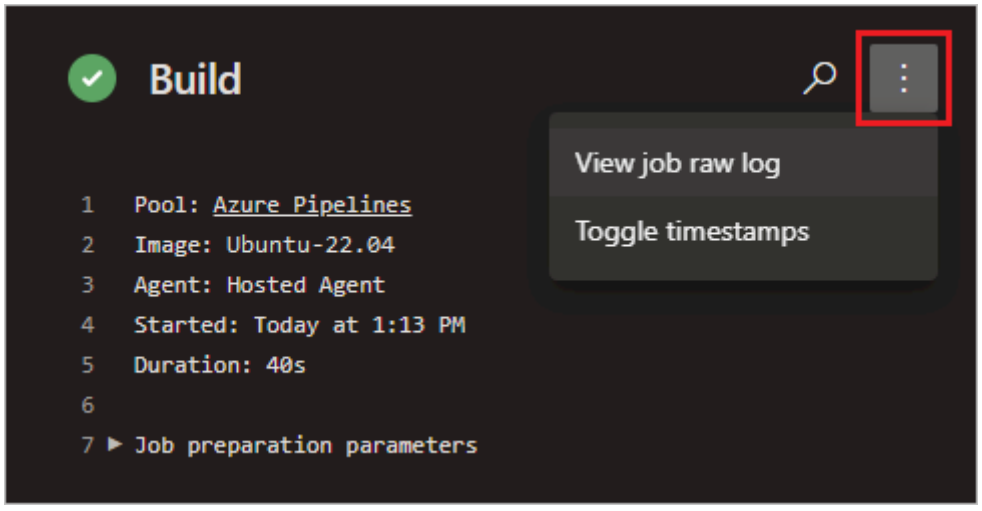


From the pipeline run summary you can view the status of your run, both while it is running and when it is complete.



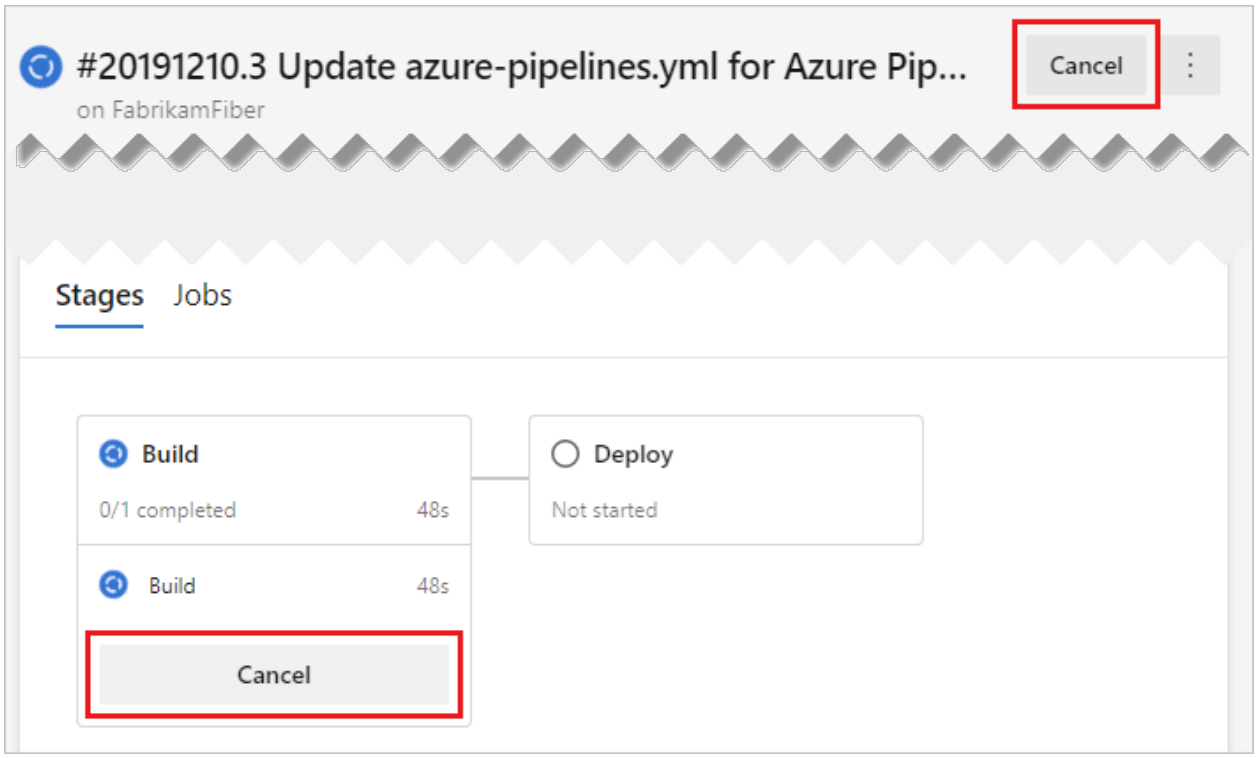
From the summary pane you can view job and stage details, download artifacts, and navigate to linked commits, test results, and work items.

Jobs and stages

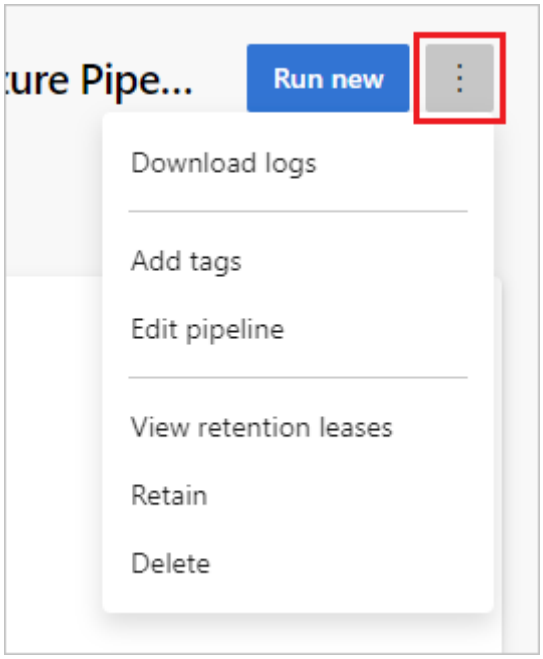


The jobs pane displays an overview of the status of your stages and jobs. This pane may have multiple tabs depending on whether your pipeline has stages and jobs, or just jobs. In this example, the pipeline has two stages named **Build** and **Deploy**. You can drill down into the pipeline steps by choosing the job from either the **Stages** or **Jobs** pane.

Choose a job to see the steps for that job.



From the steps view, you can review the status and details of each step. From the **More actions** ⋮ you can toggle timestamps or view a raw log of all steps in the pipeline.



Cancel and re-run a pipeline

If the pipeline is running, you can cancel it by choosing **Cancel**. If the run has completed, you can re-run the pipeline by choosing **Run new**.

Pipeline run more actions menu

From the **More actions** ⋮ menu you can download logs, add tags, edit the pipeline, delete the run, and configure retention for the run.

> ⓘ Note
>
> You can't delete a run if the run is retained. If you don't see **Delete**, choose **Stop retaining run**, and then delete the run. If you see both **Delete** and **View retention releases**, one or more configured retention policies still apply to your run. Choose

View retention releases, delete the policies (only the policies for the selected run are removed), and then delete the run.

Add a status badge to your repository

Many developers like to show that they're keeping their code quality high by displaying a status badge in their repo.

To copy the status badge to your clipboard:

1. In Azure Pipelines, go to the **Pipelines** page to view the list of pipelines. Select the pipeline you created in the previous section.
2. Select ⋮, and then select **Status badge**.
3. Select **Status badge**.
4. Copy the sample Markdown from the Sample markdown section.

Now with the badge Markdown in your clipboard, take the following steps in GitHub:

1. Go to the list of files and select `Readme.md`. Select the pencil icon to edit.
2. Paste the status badge Markdown at the beginning of the file.
3. Commit the change to the `main` branch.
4. Notice that the status badge appears in the description of your repository.

To configure anonymous access to badges for private projects:

1. Navigate to **Project Settings** in the bottom left corner of the page
2. Open the **Settings** tab under **Pipelines**
3. Toggle the **Disable anonymous access to badges** slider under **General**

> ⓘ **Note**
>
> Even in a private project, anonymous badge access is enabled by default. With anonymous badge access enabled, users outside your organization might be able

to query information such as project names, branch names, job names, and build status through the badge status API.

Because you just changed the `Readme.md` file in this repository, Azure Pipelines automatically builds your code, according to the configuration in the `azure-pipelines.yml` file at the root of your repository. Back in Azure Pipelines, observe that a new run appears. Each time you make an edit, Azure Pipelines starts a new run.

Next steps

You learned how to create your first pipeline in Azure. Now, Learn more about configuring pipelines in the language of your choice:

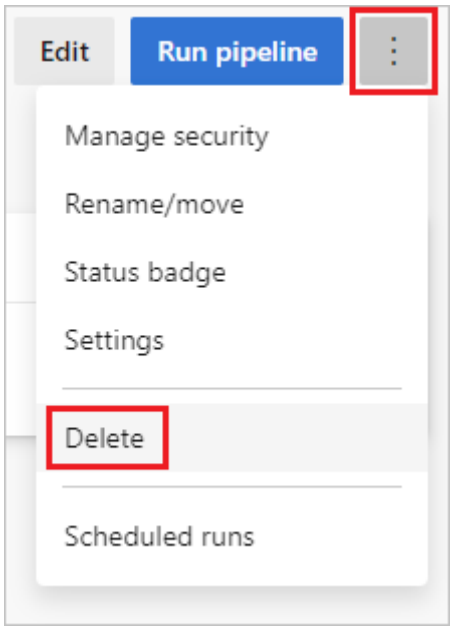
- .NET Core
- Go
- Java
- Node.js
- Python
- Containers

Or, you can proceed to customize the pipeline you created.

To run your pipeline in a container, see Container jobs.

For details about building GitHub repositories, see Build GitHub repositories.

To learn how to publish your Pipeline Artifacts, see Publish Pipeline Artifacts.



To find out what else you can do in YAML pipelines, see YAML schema reference.

Clean up

If you created any test pipelines, they're easy to delete when you finish with them.

Azure Pipelines UI

To delete a pipeline, navigate to the summary page for that pipeline, and choose **Delete** from the ... menu at the top-right of the page. Type the name of the pipeline to confirm, and choose **Delete**.

FAQ

Where can I read articles about DevOps and CI/CD?

What is Continuous Integration?

What is Continuous Delivery?

What is DevOps?

What version control system can I use?

When you're ready to get going with CI/CD for your app, you can use the version control system of your choice:

- Clients
  - Visual Studio Code for Windows, macOS, and Linux
  - Visual Studio with Git for Windows or Visual Studio for Mac
  - Eclipse
  - Xcode
  - IntelliJ
  - Command line
- Services
  - Azure Pipelines
  - Git service providers such as Azure Repos Git, GitHub, and Bitbucket Cloud
  - Subversion

How can I delete a pipeline?

To delete a pipeline, navigate to the summary page for that pipeline, and choose **Delete** from the **...** menu in the top-right of the page. Type the name of the pipeline to confirm, and choose **Delete**.

What else can I do when I queue a build?

You can queue builds automatically or manually.

When you manually queue a build, you can, for a single run of the build:

- Specify the pool into which the build goes.
- Add and modify some variables.
- Add demands.
- In a Git repository
  - Build a branch or a tag.
  - Build a commit.

Where can I learn more about pipeline settings?

To learn more about pipeline settings, see:

- Getting sources
- Tasks
- Variables
- Triggers
- Retention
- History

How do I programmatically create a build pipeline?

REST API Reference: Create a build pipeline

> **Note**
>
> You can also manage builds and build pipelines from the command line or scripts using the **Azure Pipelines CLI**.

Feedback

ASP.NET Core Module (ANCM) for IIS

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

The ASP.NET Core Module (ANCM) is a native IIS module that plugs into the IIS pipeline, allowing ASP.NET Core applications to work with IIS. Run ASP.NET Core apps with IIS by either:

- Hosting an ASP.NET Core app inside of the IIS worker process (`w3wp.exe`), called the in-process hosting model.
- Forwarding web requests to a backend ASP.NET Core app running the Kestrel server, called the out-of-process hosting model.

There are trade-offs between each of the hosting models. By default, the in-process hosting model is used due to better performance and diagnostics.

For more information and configuration guidance, see the following topics:

- Web server implementations in ASP.NET Core

Install ASP.NET Core Module (ANCM)

The ASP.NET Core Module (ANCM) is installed with the .NET Core Runtime from the .NET Core Hosting Bundle. The ASP.NET Core Module is forward and backward compatible with in-support releases of .NET.

Breaking changes and security advisories are reported on the Announcements repo. Announcements can be limited to a specific version by selecting a **Label** filter.

Download the installer using the following link:

Current .NET Core Hosting Bundle installer (direct download)

For more information, including installing an earlier version of the module, see Hosting Bundle.

For a tutorial experience on publishing an ASP.NET Core app to an IIS server, see Publish an ASP.NET Core app to IIS.

Additional resources

- Host ASP.NET Core on Windows with IIS
- Deploy ASP.NET Core apps to Azure App Service
- ASP.NET Core Module reference source [default branch (main)] : Use the **Branch** drop down list to select a specific release (for example, `release/3.1`).
- IIS modules with ASP.NET Core

Troubleshoot ASP.NET Core on Azure App Service and IIS

Article • 09/27/2024

This article provides information on common app startup errors and instructions on how to diagnose errors when an app is deployed to Azure App Service or IIS:

App startup errors
Explains common startup HTTP status code scenarios.

Troubleshoot on Azure App Service
Provides troubleshooting advice for apps deployed to Azure App Service.

Troubleshoot on IIS
Provides troubleshooting advice for apps deployed to IIS or running on IIS Express locally. The guidance applies to both Windows Server and Windows desktop deployments.

Clear package caches
Explains what to do when incoherent packages break an app when performing major upgrades or changing package versions.

Additional resources
Lists additional troubleshooting topics.

App startup errors

In Visual Studio, the ASP.NET Core project default server is Kestrel. Visual studio can be configured to use IIS Express. A *502.5 - Process Failure* or a *500.30 - Start Failure* that occurs when debugging locally with IIS Express can be diagnosed using the advice in this topic.

403.14 Forbidden

The app fails to start. The following error is logged:

```
The Web server is configured to not list the contents of this directory.
```

The error is usually caused by a broken deployment on the hosting system, which includes any of the following scenarios:

- The app is deployed to the wrong folder on the hosting system.
- The deployment process failed to move all of the app's files and folders to the deployment folder on the hosting system.
- The *web.config* file is missing from the deployment, or the *web.config* file contents are malformed.

Perform the following steps:

1. Delete all of the files and folders from the deployment folder on the hosting system.
2. Redeploy the contents of the app's *publish* folder to the hosting system using your normal method of deployment, such as Visual Studio, PowerShell, or manual deployment:

    - Confirm that the *web.config* file is present in the deployment and that its contents are correct.
    - When hosting on Azure App Service, confirm that the app is deployed to the `D:\home\site\wwwroot` folder.
    - When the app is hosted by IIS, confirm that the app is deployed to the IIS **Physical path** shown in **IIS Manager**'s **Basic Settings**.

3. Confirm that all of the app's files and folders are deployed by comparing the deployment on the hosting system to the contents of the project's *publish* folder.

For more information on the layout of a published ASP.NET Core app, see ASP.NET Core directory structure. For more information on the *web.config* file, see ASP.NET Core Module (ANCM) for IIS.

500 Internal Server Error

The app starts, but an error prevents the server from fulfilling the request.

This error occurs within the app's code during startup or while creating a response. The response may contain no content, or the response may appear as a *500 Internal Server Error* in the browser. The Application Event Log usually states that the app started normally. From the server's perspective, that's correct. The app did start, but it can't generate a valid response. Run the app at a command prompt on the server or enable the ASP.NET Core Module stdout log to troubleshoot the problem.

This error also may occur when the .NET Core Hosting Bundle isn't installed or is corrupted. Installing or repairing the installation of the .NET Core Hosting Bundle (for IIS) or Visual Studio (for IIS Express) may fix the problem.

500.0 In-Process Handler Load Failure

The worker process fails. The app doesn't start.

An unknown error occurred loading ASP.NET Core Module components. Take one of the following actions:

- Contact Microsoft Support (select **Developer Tools** then **ASP.NET Core**).
- Ask a question on Stack Overflow.
- File an issue on our GitHub repository.

500.30 In-Process Startup Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core CLR in-process, but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

Common failure conditions:

- The app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine.
- Using Azure Key Vault, lack of permissions to the Key Vault. Check the access policies in the targeted Key Vault to ensure that the correct permissions are granted.

500.31 ANCM Failed to Find Native Dependencies

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the .NET Core runtime in-process, but it fails to start. The most common cause of this startup failure is when the `Microsoft.NETCore.App` or `Microsoft.AspNetCore.App` runtime isn't installed. If the app is deployed to target ASP.NET Core 3.0 and that version doesn't exist on the machine, this error occurs. An example error message follows:

```
```

```
The specified framework 'Microsoft.NETCore.App', version '3.0.0' was not
found.
  - The following frameworks were found:
      2.2.1 at [C:\Program Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview5-27626-15 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27713-13 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27714-15 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
      3.0.0-preview6-27723-08 at [C:\Program
Files\dotnet\x64\shared\Microsoft.NETCore.App]
```

The error message lists all the installed .NET Core versions and the version requested by the app. To fix this error, either:

- Install the appropriate version of .NET Core on the machine.
- Change the app to target a version of .NET Core that's present on the machine.
- Publish the app as a self-contained deployment.

When running in development (the `ASPNETCORE_ENVIRONMENT` environment variable is set to `Development`), the specific error is written to the HTTP response. The cause of a process startup failure is also found in the Application Event Log.

500.32 ANCM Failed to Load dll

The worker process fails. The app doesn't start.

The most common cause for this error is that the app is published for an incompatible processor architecture. If the worker process is running as a 32-bit app and the app was published to target 64-bit, this error occurs.

To fix this error, either:

- Republish the app for the same processor architecture as the worker process.
- Publish the app as a framework-dependent deployment.

500.33 ANCM Request Handler Load Failure

The worker process fails. The app doesn't start.

The app didn't reference the `Microsoft.AspNetCore.App` framework. Only apps targeting the `Microsoft.AspNetCore.App` framework can be hosted by the ASP.NET Core Module.

To fix this error, confirm that the app is targeting the `Microsoft.AspNetCore.App` framework. Check the `.runtimeconfig.json` to verify the framework targeted by the app.

500.34 ANCM Mixed Hosting Models Not Supported

The worker process can't run both an in-process app and an out-of-process app in the same process.

To fix this error, run apps in separate IIS application pools.

500.35 ANCM Multiple In-Process Applications in same Process

The worker process can't run multiple in-process apps in the same process.

To fix this error, run apps in separate IIS application pools.

500.36 ANCM Out-Of-Process Handler Load Failure

The out-of-process request handler, *aspnetcorev2_outofprocess.dll*, isn't next to the *aspnetcorev2.dll* file. This indicates a corrupted installation of the ASP.NET Core Module.

To fix this error, repair the installation of the .NET Core Hosting Bundle (for IIS) or Visual Studio (for IIS Express).

500.37 ANCM Failed to Start Within Startup Time Limit

ANCM failed to start within the provided startup time limit. By default, the timeout is 120 seconds.

This error can occur when starting a large number of apps on the same machine. Check for CPU/Memory usage spikes on the server during startup. You may need to stagger the startup process of multiple apps.

500.38 ANCM Application DLL Not Found

ANCM failed to locate the application DLL, which should be next to the executable.

This error occurs when hosting an app packaged as a single-file executable using the in-process hosting model. The in-process model requires that the ANCM load the .NET Core app into the existing IIS process. This scenario isn't supported by the single-file

deployment model. Use **one** of the following approaches in the app's project file to fix this error:

1. Disable single-file publishing by setting the `PublishSingleFile` MSBuild property to `false`.
2. Switch to the out-of-process hosting model by setting the `AspNetCoreHostingModel` MSBuild property to `OutOfProcess`.

502.5 Process Failure

The worker process fails. The app doesn't start.

The ASP.NET Core Module attempts to start the worker process but it fails to start. The cause of a process startup failure can usually be determined from entries in the Application Event Log and the ASP.NET Core Module stdout log.

A common failure condition is the app is misconfigured due to targeting a version of the ASP.NET Core shared framework that isn't present. Check which versions of the ASP.NET Core shared framework are installed on the target machine. The *shared framework* is the set of assemblies (*.dll* files) that are installed on the machine and referenced by a metapackage such as `Microsoft.AspNetCore.App`. The metapackage reference can specify a minimum required version. For more information, see The shared framework.

The *502.5 Process Failure* error page is returned when a hosting or app misconfiguration causes the worker process to fail:

Failed to start application (ErrorCode '0x800700c1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/6/ROOT/', ErrorCode '0x800700c1'.
```

The app failed to start because the app's assembly (*.dll*) couldn't be loaded.

This error occurs when there's a bitness mismatch between the published app and the w3wp/iisexpress process.

Confirm that the app pool's 32-bit setting is correct:

1. Select the app pool in IIS Manager's **Application Pools**.

2. Select **Advanced Settings** under **Edit Application Pool** in the **Actions** panel.
3. Set **Enable 32-Bit Applications**:

    - If deploying a 32-bit (x86) app, set the value to `True`.
    - If deploying a 64-bit (x64) app, set the value to `False`.

Confirm that there isn't a conflict between a `<Platform>` MSBuild property in the project file and the published bitness of the app.

Failed to start application (ErrorCode '0x800701b1')

```
EventID: 1010
Source: IIS AspNetCore Module V2
Failed to start application '/LM/W3SVC/3/ROOT', ErrorCode '0x800701b1'.
```

The app failed to start because a Windows Service failed to load.

One common service that needs to be enabled is the "null" service. The following command enables the `null` Windows Service:

Windows Command Prompt

```
sc.exe start null
```

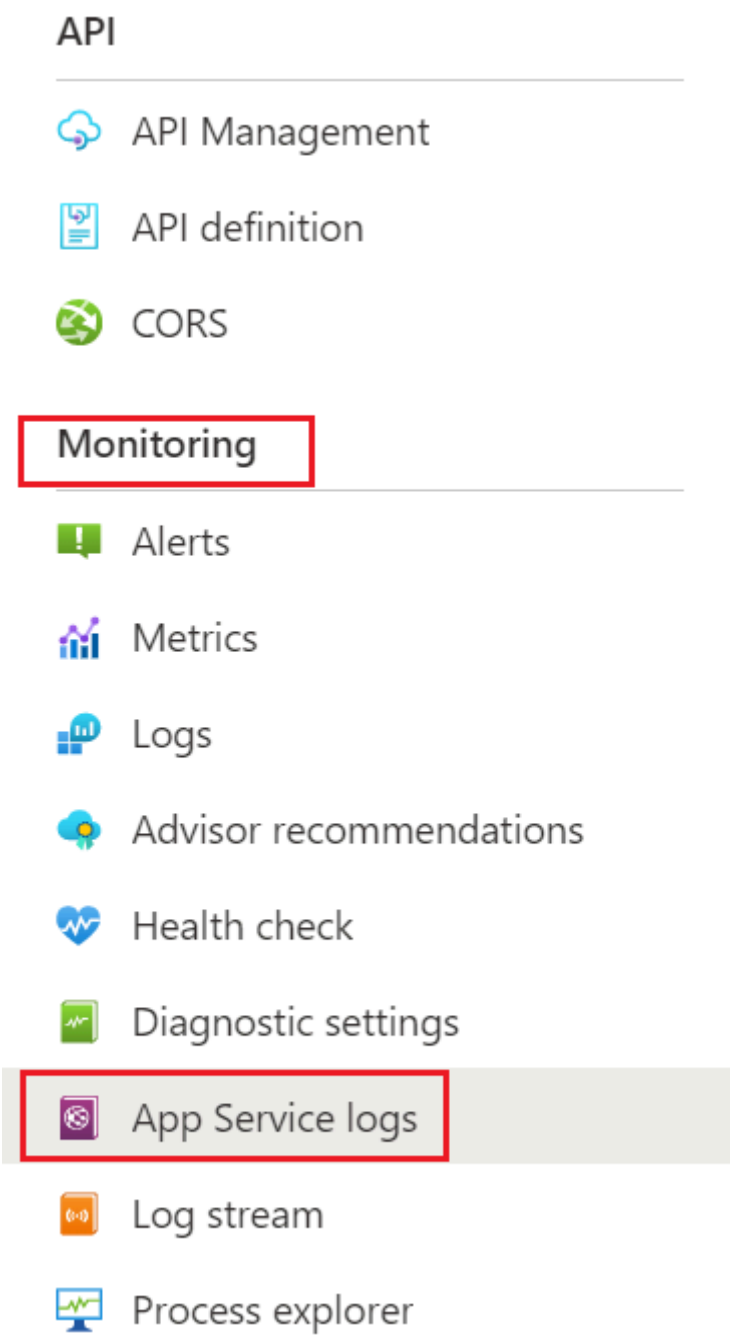
Connection reset

If an error occurs after the headers are sent, it's too late for the server to send a **500 Internal Server Error** when an error occurs. This often happens when an error occurs during the serialization of complex objects for a response. This type of error appears as a *connection reset* error on the client. Application logging can help troubleshoot these types of errors.

Default startup limits

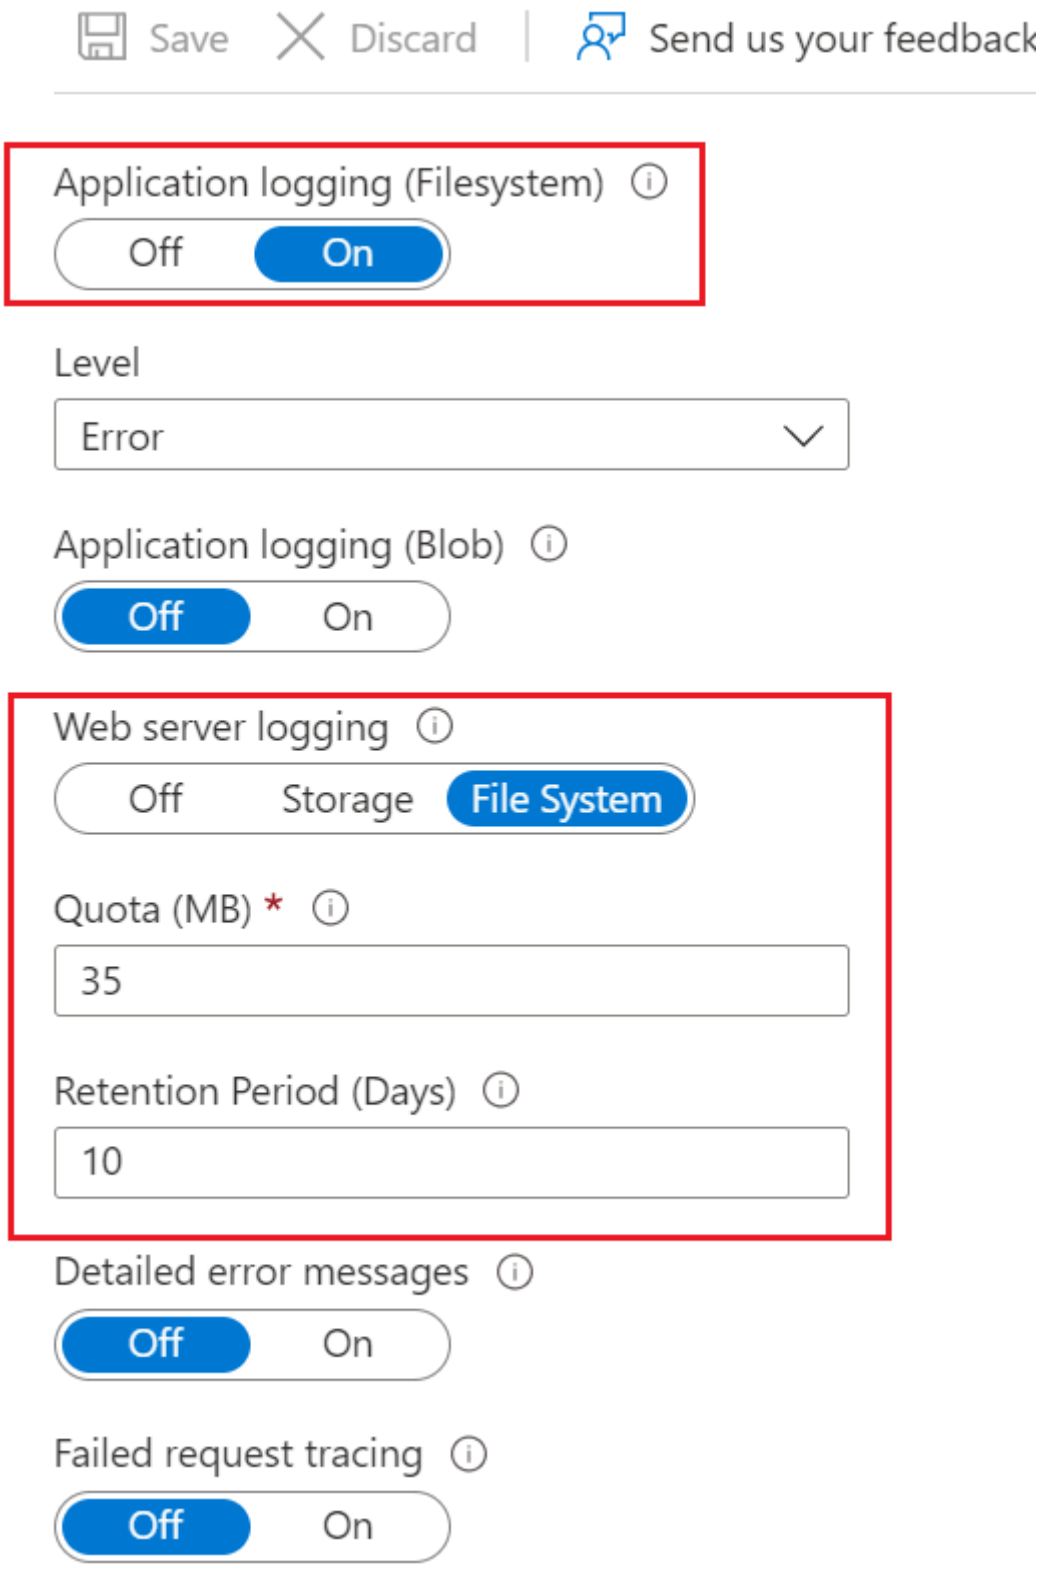
The ASP.NET Core Module is configured with a default *startupTimeLimit* of 120 seconds. When left at the default value, an app may take up to two minutes to start before the module logs a process failure. For information on configuring the module, see Attributes of the aspNetCore element.

Troubleshoot on Azure App Service



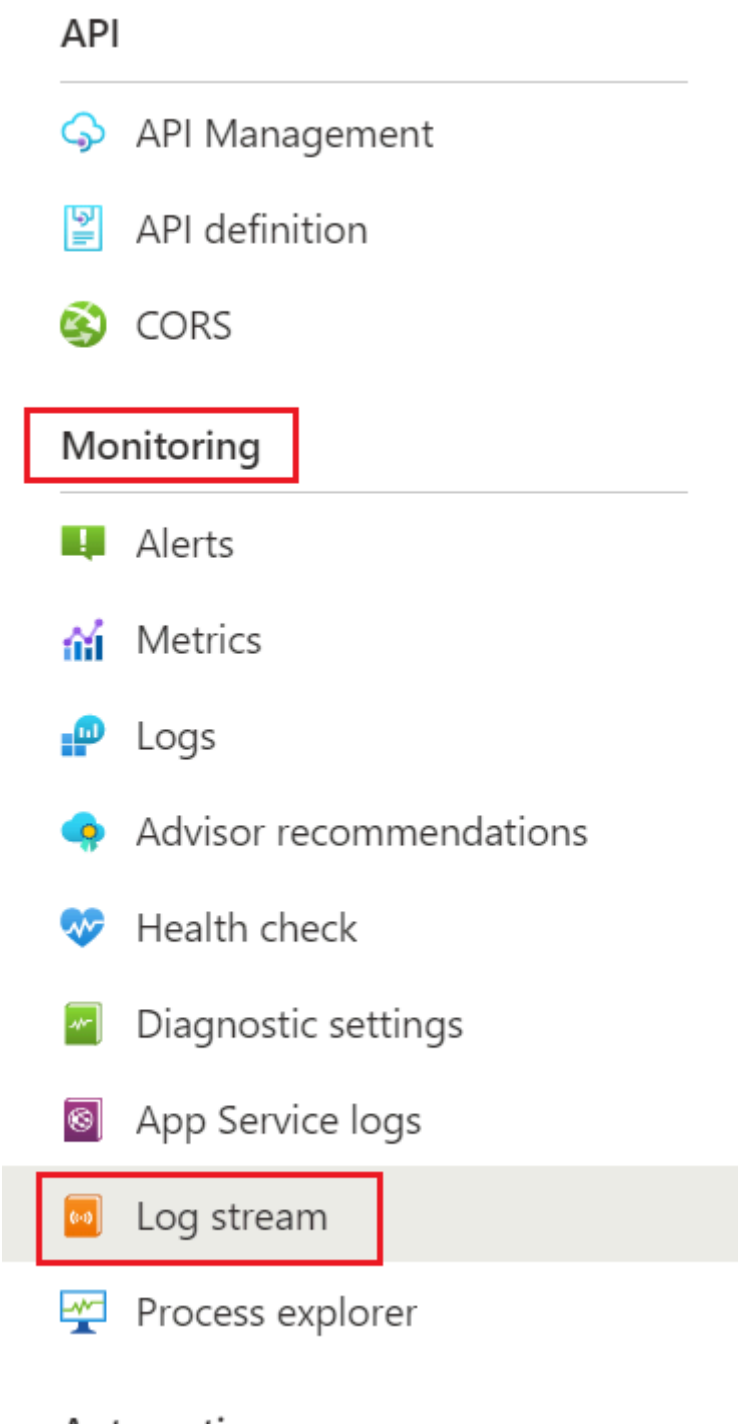
> **Important**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

Azure App Services Log stream

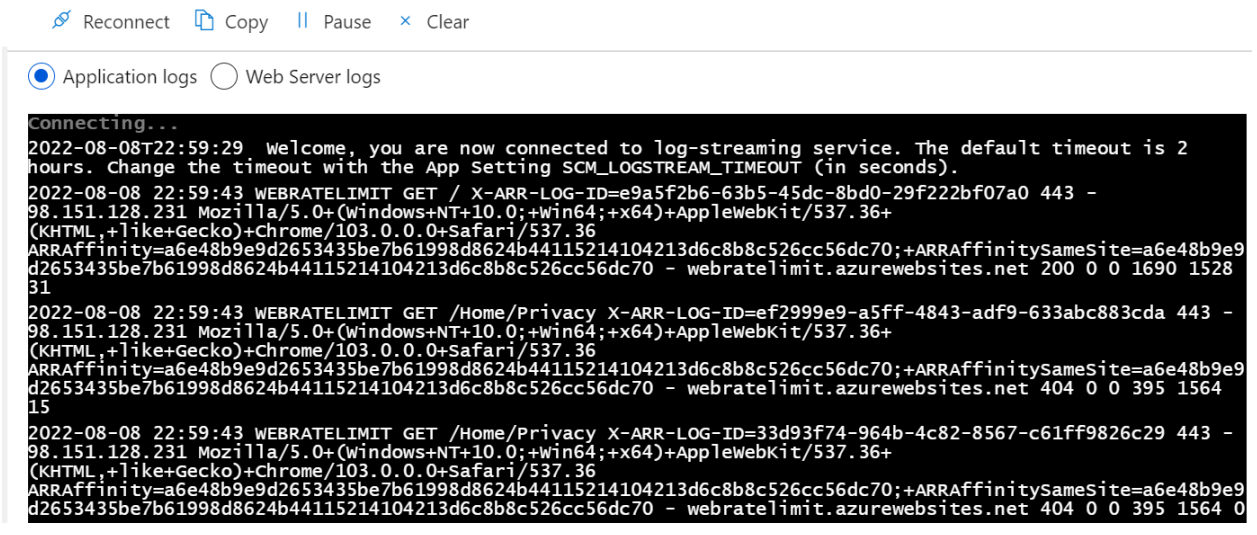


The Azure App Services Log streams logging information as it occurs. To view streaming logs:

1. In the Azure portal, open the app in **App Services**.



2. In the left pane, navigate to **Monitoring** > **App Service Logs**.



3. Select **File System** for **Web Server Logging**. Optionally enable **Application logging**.

4. In the left pane, navigate to **Monitoring** > **Log stream**, and then select **Application logs** or **Web Server Logs**.

The following images shows the application logs output:

Streaming logs have some latency and might not display immediately.

Application Event Log (Azure App Service)

To access the Application Event Log, use the **Diagnose and solve problems** blade in the Azure portal:

1. In the Azure portal, open the app in **App Services**.
2. Select **Diagnose and solve problems**.
3. Select the **Diagnostic Tools** heading.
4. Under **Support Tools**, select the **Application Events** button.
5. Examine the latest error provided by the *IIS AspNetCoreModule* or *IIS AspNetCoreModule V2* entry in the **Source** column.

An alternative to using the **Diagnose and solve problems** blade is to examine the Application Event Log file directly using Kudu:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go** → button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the **LogFiles** folder.
4. Select the pencil icon next to the `eventlog.xml` file.
5. Examine the log. Scroll to the bottom of the log to see the most recent events.

Run the app in the Kudu console

Many startup errors don't produce useful information in the Application Event Log. You can run the app in the Kudu Remote Execution Console to discover the error:

1. Open **Advanced Tools** in the **Development Tools** area. Select the **Go** → button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.

Test a 32-bit (x86) app

Current release

1. `cd d:\home\site\wwwroot`
2. Run the app:

- If the app is a framework-dependent deployment:

  .NET CLI

  ```
  dotnet .\{ASSEMBLY NAME}.dll
  ```

- If the app is a self-contained deployment:

  Console

  ```
  {ASSEMBLY NAME}.exe
  ```

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x86) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x32` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

Test a 64-bit (x64) app

Current release

- If the app is a 64-bit (x64) framework-dependent deployment:

  1. `cd D:\Program Files\dotnet`
  2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

- If the app is a self-contained deployment:

  1. `cd D:\home\site\wwwroot`
  2. Run the app: `{ASSEMBLY NAME}.exe`

The console output from the app, showing any errors, is piped to the Kudu console.

Framework-dependent deployment running on a preview release

Requires installing the ASP.NET Core {VERSION} (x64) Runtime site extension.

1. `cd D:\home\SiteExtensions\AspNetCoreRuntime.{X.Y}.x64` (`{X.Y}` is the runtime version)
2. Run the app: `dotnet \home\site\wwwroot\{ASSEMBLY NAME}.dll`

The console output from the app, showing any errors, is piped to the Kudu console.

ASP.NET Core Module stdout log (Azure App Service)

> ⚠ **Warning**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created. Only use stdout logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

The ASP.NET Core Module stdout log often records useful error messages not found in the Application Event Log. To enable and view stdout logs:

1. In the Azure Portal, navigate to the web app.
2. In the **App Service** blade, enter **kudu** in the search box.
3. Select **Advanced Tools** > **Go**.
4. Select **Debug console** > **CMD**.
5. Navigate to *site/wwwroot*
6. Select the pencil icon to edit the *web.config* file.
7. In the `<aspNetCore />` element, set `stdoutLogEnabled="true"` and select **Save**.

Disable stdout logging when troubleshooting is complete by setting `stdoutLogEnabled="false"`.

For more information, see ASP.NET Core Module (ANCM) for IIS.

ASP.NET Core Module debug log (Azure App Service)

The ASP.NET Core Module debug log provides additional, deeper logging from the ASP.NET Core Module. To enable and view stdout logs:

1. To enable the enhanced diagnostic log, perform either of the following:

- Follow the instructions in Enhanced diagnostic logs to configure the app for an enhanced diagnostic logging. Redeploy the app.
- Add the `<handlerSettings>` shown in Enhanced diagnostic logs to the live app's *web.config* file using the Kudu console:
  a. Open **Advanced Tools** in the **Development Tools** area. Select the **Go**→ button. The Kudu console opens in a new browser tab or window.
  b. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
  c. Open the folders to the path **site** > **wwwroot**. Edit the *web.config* file by selecting the pencil button. Add the `<handlerSettings>` section as shown in Enhanced diagnostic logs. Select the **Save** button.

2. Open **Advanced Tools** in the **Development Tools** area. Select the **Go**→ button. The Kudu console opens in a new browser tab or window.
3. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
4. Open the folders to the path **site** > **wwwroot**. If you didn't supply a path for the *aspnetcore-debug.log* file, the file appears in the list. If you supplied a path, navigate to the location of the log file.
5. Open the log file with the pencil button next to the file name.

Disable debug logging when troubleshooting is complete:

To disable the enhanced debug log, perform either of the following:

- Remove the `<handlerSettings>` from the *web.config* file locally and redeploy the app.
- Use the Kudu console to edit the *web.config* file and remove the `<handlerSettings>` section. Save the file.

For more information, see Log creation and redirection with the ASP.NET Core Module.

> ⚠ **Warning**
>
> Failure to disable the debug log can lead to app or server failure. There's no limit on log file size. Only use debug logging to troubleshoot app startup problems.
>
> For general logging in an ASP.NET Core app after startup, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Slow or nonresponsive app (Azure App Service)

When an app responds slowly or doesn't respond to a request, see Troubleshoot slow web app performance issues in Azure App Service.

Monitoring blades

Monitoring blades provide an alternative troubleshooting experience to the methods described earlier in the topic. These blades can be used to diagnose 500-series errors.

Confirm that the ASP.NET Core Extensions are installed. If the extensions aren't installed, install them manually:

1. In the **DEVELOPMENT TOOLS** blade section, select the **Extensions** blade.
2. The **ASP.NET Core Extensions** should appear in the list.
3. If the extensions aren't installed, select the **Add** button.
4. Choose the **ASP.NET Core Extensions** from the list.
5. Select **OK** to accept the legal terms.
6. Select **OK** on the **Add extension** blade.
7. An informational pop-up message indicates when the extensions are successfully installed.

If stdout logging isn't enabled, follow these steps:

1. In the Azure portal, select the **Advanced Tools** blade in the **DEVELOPMENT TOOLS** area. Select the **Go**→ button. The Kudu console opens in a new browser tab or window.
2. Using the navigation bar at the top of the page, open **Debug console** and select **CMD**.
3. Open the folders to the path **site** > **wwwroot** and scroll down to reveal the *web.config* file at the bottom of the list.
4. Click the pencil icon next to the *web.config* file.
5. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to: `\\?\%home%\LogFiles\stdout`.
6. Select **Save** to save the updated *web.config* file.

Proceed to activate diagnostic logging:

1. In the Azure portal, select the **Diagnostics logs** blade.
2. Select the **On** switch for **Application Logging (Filesystem)** and **Detailed error messages**. Select the **Save** button at the top of the blade.
3. To include failed request tracing, also known as Failed Request Event Buffering (FREB) logging, select the **On** switch for **Failed request tracing**.
4. Select the **Log stream** blade, which is listed immediately under the **Diagnostics logs** blade in the portal.

5. Make a request to the app.
6. Within the log stream data, the cause of the error is indicated.

Be sure to disable stdout logging when troubleshooting is complete.

To view the failed request tracing logs (FREB logs):

1. Navigate to the **Diagnose and solve problems** blade in the Azure portal.
2. Select **Failed Request Tracing Logs** from the **SUPPORT TOOLS** area of the sidebar.

See Failed request traces section of the Enable diagnostics logging for web apps in Azure App Service topic and the Application performance FAQs for Web Apps in Azure: How do I turn on failed request tracing? for more information.

For more information, see Enable diagnostics logging for web apps in Azure App Service.

> ⚠ **Warning**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

Troubleshoot on IIS

Application Event Log (IIS)

Access the Application Event Log:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app. Errors have a value of *IIS AspNetCore Module* or *IIS Express AspNetCore Module* in the *Source* column.

Run the app at a command prompt

Many startup errors don't produce useful information in the Application Event Log. You can find the cause of some errors by running the app at a command prompt on the hosting system.

Framework-dependent deployment

If the app is a framework-dependent deployment:

1. At a command prompt, navigate to the deployment folder and run the app by executing the app's assembly with *dotnet.exe*. In the following command, substitute the name of the app's assembly for <assembly_name>: `dotnet .\<assembly_name>.dll`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

Self-contained deployment

If the app is a self-contained deployment:

1. At a command prompt, navigate to the deployment folder and run the app's executable. In the following command, substitute the name of the app's assembly for <assembly_name>: `<assembly_name>.exe`.
2. The console output from the app, showing any errors, is written to the console window.
3. If the errors occur when making a request to the app, make a request to the host and port where Kestrel listens. Using the default host and post, make a request to `http://localhost:5000/`. If the app responds normally at the Kestrel endpoint address, the problem is more likely related to the hosting configuration and less likely within the app.

ASP.NET Core Module stdout log (IIS)

To enable and view stdout logs:

1. Navigate to the site's deployment folder on the hosting system.
2. If the *logs* folder isn't present, create the folder. For instructions on how to enable MSBuild to create the *logs* folder in the deployment automatically, see the Directory structure topic.
3. Edit the *web.config* file. Set **stdoutLogEnabled** to `true` and change the **stdoutLogFile** path to point to the *logs* folder (for example, `.\logs\stdout`).

`stdout` in the path is the log file name prefix. A timestamp, process id, and file extension are added automatically when the log is created. Using `stdout` as the file name prefix, a typical log file is named *stdout_20180205184032_5412.log*.

4. Ensure your application pool's identity has write permissions to the *logs* folder.
5. Save the updated *web.config* file.
6. Make a request to the app.
7. Navigate to the *logs* folder. Find and open the most recent stdout log.
8. Study the log for errors.

Disable stdout logging when troubleshooting is complete:

1. Edit the *web.config* file.
2. Set **stdoutLogEnabled** to `false`.
3. Save the file.

For more information, see ASP.NET Core Module (ANCM) for IIS.

> ⚠ **Warning**
>
> Failure to disable the stdout log can lead to app or server failure. There's no limit on log file size or the number of log files created.
>
> For routine logging in an ASP.NET Core app, use a logging library that limits log file size and rotates logs. For more information, see third-party logging providers.

ASP.NET Core Module debug log (IIS)

Add the following handler settings to the app's *web.config* file to enable ASP.NET Core Module debug log:

XML

```
<aspNetCore ...>
  <handlerSettings>
    <handlerSetting name="debugLevel" value="file" />
    <handlerSetting name="debugFile" value="c:\temp\ancm.log" />
  </handlerSettings>
</aspNetCore>
```

Confirm that the path specified for the log exists and that the app pool's identity has write permissions to the location.

For more information, see Log creation and redirection with the ASP.NET Core Module.

Enable the Developer Exception Page

The `ASPNETCORE_ENVIRONMENT` environment variable can be added to web.config to run the app in the Development environment. As long as the environment isn't overridden in app startup by `UseEnvironment` on the host builder, setting the environment variable allows the Developer Exception Page to appear when the app is run.

XML

```
<aspNetCore processPath="dotnet"
      arguments=".\MyApp.dll"
      stdoutLogEnabled="false"
      stdoutLogFile=".\logs\stdout"
      hostingModel="InProcess">
  <environmentVariables>
    <environmentVariable name="ASPNETCORE_ENVIRONMENT" value="Development"
/>
  </environmentVariables>
</aspNetCore>
```

Setting the environment variable for `ASPNETCORE_ENVIRONMENT` is only recommended for use on staging and testing servers that aren't exposed to the Internet. Remove the environment variable from the *web.config* file after troubleshooting. For information on setting environment variables in *web.config*, see environmentVariables child element of aspNetCore.

Obtain data from an app

If an app is capable of responding to requests, obtain request, connection, and additional data from the app using terminal inline middleware. For more information and sample code, see Troubleshoot and debug ASP.NET Core projects.

Slow or non-responding app (IIS)

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`. The app pool must have write access to the folder.

2. Run the EnableDumps PowerShell script:

   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     Console

     .\EnableDumps w3wp.exe c:\dumps
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     Console

     .\EnableDumps dotnet.exe c:\dumps
     ```

3. Run the app under the conditions that cause the crash to occur.

4. After the crash has occurred, run the DisableDumps PowerShell script:

   - If the app uses the in-process hosting model, run the script for *w3wp.exe*:

     ```
     Console

     .\DisableDumps w3wp.exe
     ```

   - If the app uses the out-of-process hosting model, run the script for *dotnet.exe*:

     ```
     Console

     .\DisableDumps dotnet.exe
     ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> ⚠ **Warning**
>
> Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App doesn't respond, fails during startup, or runs normally

When an app stops responding but doesn't crash, fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.
2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

Additional resources

Common error troubleshooting for Azure App Service and IIS with ASP.NET Core

Article • 07/31/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This topic describes the most common errors and provides troubleshooting advice when hosting ASP.NET Core apps on Azure Apps Service and IIS.

See Troubleshoot ASP.NET Core on Azure App Service and IIS information on common app startup errors and instructions on how to diagnose errors.

Collect the following information:

- Browser behavior such as status code and error message.
- Application Event Log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS

    1. Select **Start** on the **Windows** menu, type *Event Viewer*, and press **Enter**.
    2. After the **Event Viewer** opens, expand **Windows Logs** > **Application** in the sidebar.

- ASP.NET Core Module stdout and debug log entries
  - Azure App Service: See Troubleshoot ASP.NET Core on Azure App Service and IIS.
  - IIS: Follow the instructions in the Log creation and redirection and Enhanced diagnostic logs sections of the ASP.NET Core Module topic.

Compare error information to the following common errors. If a match is found, follow the troubleshooting advice.

The list of errors in this topic isn't exhaustive. If you encounter an error not listed here, open a new issue using the **Content feedback** button at the bottom of this topic with detailed instructions on how to reproduce the error.

> ⓘ **Important**
>
> **ASP.NET Core preview releases with Azure App Service**
>
> ASP.NET Core preview releases aren't deployed to Azure App Service by default. To host an app that uses an ASP.NET Core preview release, see Deploy ASP.NET Core preview release to Azure App Service.

OS upgrade removed the 32-bit ASP.NET Core Module

Application Log: The Module DLL **C:\WINDOWS\system32\inetsrv\aspnetcore.dll** failed to load. The data is the error.

Troubleshooting:

Non-OS files in the **C:\Windows\SysWOW64\inetsrv** directory aren't preserved during an OS upgrade. If the ASP.NET Core Module is installed prior to an OS upgrade and then any app pool is run in 32-bit mode after an OS upgrade, this issue is encountered. After an OS upgrade, repair the ASP.NET Core Module. See Install the .NET Core Hosting bundle. Select **Repair** when the installer is run.

Missing site extension, 32-bit (x86) and 64-bit (x64) site extensions installed, or wrong process bitness set

Applies to apps hosted by Azure App Services.

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found. Failed to start application '/LM/W3SVC/1416782824/ROOT', ErrorCode '0x8000ffff'.

- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff. Could not find inprocess request handler. It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}-preview-*' was not found.

Troubleshooting:

- If running the app on a preview runtime, install either the 32-bit (x86) **or** 64-bit (x64) site extension that matches the bitness of the app and the app's runtime version. **Don't install both extensions or multiple runtime versions of the extension.**
  - ASP.NET Core {RUNTIME VERSION} (x86) Runtime
  - ASP.NET Core {RUNTIME VERSION} (x64) Runtime

  Restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and both the 32-bit (x86) and 64-bit (x64) site extensions are installed, uninstall the site extension that doesn't match the bitness of the app. After removing the site extension, restart the app. Wait several seconds for the app to restart.
- If running the app on a preview runtime and the site extension's bitness matches that of the app, confirm that the preview site extension's *runtime version* matches the app's runtime version.
- Confirm that the app's **Platform** in **Application Settings** matches the bitness of the app.

For more information, see Deploy ASP.NET Core apps to Azure App Service.

An x86 app is deployed but the app pool isn't enabled for 32-bit apps

- **Browser:** HTTP Error 500.30 - ANCM In-Process Start Failure

- **Application Log:** Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' hit unexpected managed exception, exception code = '0xe0434352'. Please check the stderr logs for more information. Application '/LM/W3SVC/5/ROOT' with physical root '{PATH}' failed to load clr and managed application. CLR worker thread exited prematurely

- **ASP.NET Core Module stdout Log:** The log file is created but empty.

- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8007023e

This scenario is trapped by the SDK when publishing a self-contained app. The SDK produces an error if the RID doesn't match the platform target (for example, `win10-x64` RID with `<PlatformTarget>x86</PlatformTarget>` in the project file).

Troubleshooting:

For an x86 framework-dependent deployment (`<PlatformTarget>x86</PlatformTarget>`), enable the IIS app pool for 32-bit apps. In IIS Manager, open the app pool's **Advanced Settings** and set **Enable 32-Bit Applications** to **True**.

Platform conflicts with RID

- **Browser:** HTTP Error 502.5 - Process Failure

- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"C:{PATH}{ASSEMBLY}.{exe|dll}" ', ErrorCode = '0x80004005 : ff.

- **ASP.NET Core Module stdout Log:** Unhandled Exception: System.BadImageFormatException: Could not load file or assembly '{ASSEMBLY}.dll'. An attempt was made to load a program with an incorrect format.

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

- If this exception occurs for an Azure Apps deployment when upgrading an app and deploying newer assemblies, manually delete all files from the prior deployment. Lingering incompatible assemblies can result in a `System.BadImageFormatException` exception when deploying an upgraded app.

URI endpoint wrong or stopped website

- **Browser:** ERR_CONNECTION_REFUSED **--OR--** Unable to connect
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm the correct URI endpoint for the app is in use. Check the bindings.
- Confirm that the IIS website isn't in the *Stopped* state.

CoreWebEngine or W3SVC server features disabled

OS Exception: The IIS 7.0 CoreWebEngine and W3SVC features must be installed to use the ASP.NET Core Module.

Troubleshooting:

Confirm that the proper role and features are enabled. See IIS Configuration.

Incorrect website physical path or app missing

- **Browser:** 403 Forbidden - Access is denied **--OR--** 403.14 Forbidden - The Web server is configured to not list the contents of this directory.
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Check the IIS website **Basic Settings** and the physical app folder. Confirm that the app is in the folder at the IIS website **Physical path**.

Incorrect role, ASP.NET Core Module not installed, or incorrect permissions

- **Browser:** 500.19 Internal Server Error - The requested page cannot be accessed because the related configuration data for the page is invalid. --**OR**-- This page can't be displayed
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

- Confirm that the proper role is enabled. See IIS Configuration.
- Open **Programs & Features** or **Apps & features** and confirm that **Windows Server Hosting** is installed. If **Windows Server Hosting** isn't present in the list of installed programs, download and install the .NET Core Hosting Bundle.

  Current .NET Core Hosting Bundle installer (direct download)

  For more information, see Install the .NET Core Hosting Bundle.
- Make sure that the **Application Pool** > **Process Model** > **Identity** is set to **ApplicationPoolIdentity** or the custom identity has the correct permissions to access the app's deployment folder.
- If you uninstalled the ASP.NET Core Hosting Bundle and installed an earlier version of the hosting bundle, the *applicationHost.config* file doesn't include a section for the ASP.NET Core Module. Open *applicationHost.config* at *%windir%/System32/inetsrv/config* and find the `<configuration><configSections>` `<sectionGroup name="system.webServer">` section group. If the section for the ASP.NET Core Module is missing from the section group, add the section element:

  ```
  XML
  <section name="aspNetCore" overrideModeDefault="Allow" />
  ```

  Alternatively, install the latest version of the ASP.NET Core Hosting Bundle. The latest version is backwards-compatible with supported ASP.NET Core apps.

Incorrect processPath, missing PATH variable, Hosting Bundle not installed, system/IIS not restarted, VC++ Redistributable not installed, or dotnet.exe access violation

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Application 'MACHINE/WEBROOT/APPHOST/{ASSEMBLY}' with physical root 'C:{PATH}' failed to start process with commandline '"{...}" ', ErrorCode = '0x80070002 : 0. Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed to start application '/LM/W3SVC/2/ROOT', ErrorCode '0x8007023e'.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** Event Log: 'Application '{PATH}' wasn't able to start. Executable was not found at '{PATH}'. Failed HRESULT returned: 0x8007023e

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.
- Check the *processPath* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's `dotnet` for a framework-dependent deployment (FDD) or `.\{ASSEMBLY}.exe` for a self-contained deployment (SCD).
- For an FDD, *dotnet.exe* might not be accessible via the PATH settings. Confirm that *C:\Program Files\dotnet* exists in the System PATH settings.
- For an FDD, *dotnet.exe* might not be accessible for the user identity of the app pool. Confirm that the app pool user identity has access to the *C:\Program Files\dotnet* directory. Confirm that there are no deny rules configured for the app pool user identity on the *C:\Program Files\dotnet* and app directories.
- An FDD may have been deployed and .NET Core installed without restarting IIS. Either restart the server or restart IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.
- An FDD may have been deployed without installing the .NET Core runtime on the hosting system. If the .NET Core runtime hasn't been installed, run the **.NET Core Hosting Bundle installer** on the system.

Current .NET Core Hosting Bundle installer (direct download)

For more information, see Install the .NET Core Hosting Bundle.

If a specific runtime is required, download the runtime from the .NET Downloads page and install it on the system. Complete the installation by restarting the system or restarting IIS by executing **net stop was /y** followed by **net start w3svc** from a command prompt.

Incorrect arguments of <aspNetCore> element

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed to start application '/LM/W3SVC/3/ROOT', ErrorCode '0x8000ffff'.
- **ASP.NET Core Module stdout Log:** Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409
- **ASP.NET Core Module Debug Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Failed HRESULT returned: 0x8000ffff Could not find inprocess request handler. Captured output from invoking hostfxr: Did you mean to run dotnet SDK commands? Please install dotnet SDK from: https://go.microsoft.com/fwlink/?LinkID=798306&clcid=0x409 Failed HRESULT returned: 0x8000ffff

Troubleshooting:

- Confirm that the app runs locally on Kestrel. A process failure might be the result of a problem within the app. For more information, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

- Examine the *arguments* attribute on the `<aspNetCore>` element in *web.config* to confirm that it's either (a) `.\{ASSEMBLY}.dll` for a framework-dependent deployment (FDD); or (b) not present, an empty string (`arguments=""`), or a list of the app's arguments (`arguments="{ARGUMENT_1}, {ARGUMENT_2}, ... {ARGUMENT_X}"`) for a self-contained deployment (SCD).

Missing .NET Core shared framework

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure
- **Application Log:** Invoking hostfxr to find the inprocess request handler failed without finding any native dependencies. This most likely means the app is misconfigured, please check the versions of Microsoft.NetCore.App and Microsoft.AspNetCore.App that are targeted by the application and are installed on the machine. Could not find inprocess request handler. Captured output from invoking hostfxr: It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.

Failed to start application '/LM/W3SVC/5/ROOT', ErrorCode '0x8000ffff'.

- **ASP.NET Core Module stdout Log:** It was not possible to find any compatible framework version. The specified framework 'Microsoft.AspNetCore.App', version '{VERSION}' was not found.
- **ASP.NET Core Module Debug Log:** Failed HRESULT returned: 0x8000ffff

Troubleshooting:

For a framework-dependent deployment (FDD), confirm that the correct runtime installed on the system.

Stopped Application Pool

- **Browser:** 503 Service Unavailable
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module Debug Log:** The log file isn't created.

Troubleshooting:

Confirm that the Application Pool isn't in the *Stopped* state.

Sub-application includes a <handlers> section

- **Browser:** HTTP Error 500.19 - Internal Server Error
- **Application Log:** No entry
- **ASP.NET Core Module stdout Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.
- **ASP.NET Core Module Debug Log:** The root app's log file is created and shows normal operation. The sub-app's log file isn't created.

Troubleshooting:

Confirm that the sub-app's *web.config* file doesn't include a `<handlers>` section or that the sub-app doesn't inherit the parent app's handlers.

The parent app's `<system.webServer>` section of *web.config* is placed inside of a `<location>` element. The InheritInChildApplications property is set to `false` to indicate that the settings specified within the <location> element aren't inherited by apps that reside in a subdirectory of the parent app. For more information, see ASP.NET Core Module (ANCM) for IIS.

stdout log path incorrect

- **Browser:** The app responds normally.
- **Application Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.
- **ASP.NET Core Module stdout Log:** The log file isn't created.
- **ASP.NET Core Module debug Log:** Could not start stdout redirection in C:\Program Files\IIS\Asp.Net Core Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070005 returned at {PATH}\aspnetcoremodulev2\commonlib\fileoutputmanager.cpp:84. Could not stop stdout redirection in C:\Program Files\IIS\Asp.Net Core

Module\V2\aspnetcorev2.dll. Exception message: HRESULT 0x80070002 returned at {PATH}. Could not start stdout redirection in {PATH}\aspnetcorev2_inprocess.dll.

Troubleshooting:

- The `stdoutLogFile` path specified in the `<aspNetCore>` element of *web.config* doesn't exist. For more information, see ASP.NET Core Module: Log creation and redirection.
- The app pool user doesn't have write access to the stdout log path.

Application configuration general issue

- **Browser:** HTTP Error 500.0 - ANCM In-Process Handler Load Failure **--OR--** HTTP Error 500.30 - ANCM In-Process Start Failure
- **Application Log:** Variable
- **ASP.NET Core Module stdout Log:** The log file is created but empty or created with normal entries until the point of the app failing.
- **ASP.NET Core Module Debug Log:** Variable

Troubleshooting:

The process failed to start, most likely due to an app configuration or programming issue.

Publish an ASP.NET Core app to IIS

Article • 07/01/2024

This tutorial shows how to host an ASP.NET Core app on an IIS server.

This tutorial covers the following subjects:

- ✓ Install the .NET Core Hosting Bundle on Windows Server.
- ✓ Create an IIS site in IIS Manager.
- ✓ Deploy an ASP.NET Core app.

Prerequisites

- .NET Core SDK installed on the development machine.
- Windows Server configured with the **Web Server (IIS)** server role. If your server isn't configured to host websites with IIS, follow the guidance in the *IIS configuration* section of the Host ASP.NET Core on Windows with IIS article and then return to this tutorial.

> ⚠ **Warning**
>
> **IIS configuration and website security involve concepts that aren't covered by this tutorial.** Consult the IIS guidance in the Microsoft IIS documentation and the ASP.NET Core article on hosting with IIS before hosting production apps on IIS.
>
> Important scenarios for IIS hosting not covered by this tutorial include:
>
> - Creation of a registry hive for ASP.NET Core Data Protection
> - Configuration of the app pool's Access Control List (ACL)
> - To focus on IIS deployment concepts, this tutorial deploys an app without HTTPS security configured in IIS. For more information on hosting an app enabled for HTTPS protocol, see the security topics in the Additional resources section of this article. Further guidance for hosting ASP.NET Core apps is provided in the Host ASP.NET Core on Windows with IIS article.

Install the .NET Core Hosting Bundle

Install the *.NET Core Hosting Bundle* on the IIS server. The bundle installs the .NET Core Runtime, .NET Core Library, and the ASP.NET Core Module. The module allows ASP.NET Core apps to run behind IIS.

Download the installer using the following link:

Current .NET Core Hosting Bundle installer (direct download)

1. Run the installer on the IIS server.
2. Restart the server or execute `net stop was /y` followed by `net start w3svc` in a command shell.

Create the IIS site

1. On the IIS server, create a folder to contain the app's published folders and files. In a following step, the folder's path is provided to IIS as the physical path to the app. For more information on an app's deployment folder and file layout, see ASP.NET Core directory structure.
2. In IIS Manager, open the server's node in the **Connections** panel. Right-click the **Sites** folder. Select **Add Website** from the contextual menu.
3. Provide a **Site name** and set the **Physical path** to the app's deployment folder that you created. Provide the **Binding** configuration and create the website by selecting **OK**.

   > ⚠ **Warning**
   >
   > Top-level wildcard bindings (`http://*:80/` and `http://+:80`) should **not** be used. Top-level wildcard bindings can open up your app to security vulnerabilities. This applies to both strong and weak wildcards. Use explicit host names rather than wildcards. Subdomain wildcard binding (for example, `*.mysub.com`) doesn't have this security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). See RFC 9110: HTTP Semantics (Section 7.2. Host and :authority) for more information.

4. Confirm the process model identity has the proper permissions.

   If the default identity of the app pool (**Process Model** > **Identity**) is changed from `ApplicationPoolIdentity` to another identity, verify that the new identity has the required permissions to access the app's folder, database, and other required

resources. For example, the app pool requires read and write access to folders where the app reads and writes files.

Create an ASP.NET Core Razor Pages app

Follow the Get started with ASP.NET Core tutorial to create a Razor Pages app.

Publish and deploy the app

Publish an app means to produce a compiled app that can be hosted by a server. *Deploy an app* means to move the published app to a hosting system. The publish step is handled by the .NET Core SDK, while the deployment step can be handled by a variety of approaches. This tutorial adopts the *folder* deployment approach, where:

- The app is published to a folder.
- The folder's contents are moved to the IIS site's folder (the **Physical path** to the site in IIS Manager).

Visual Studio

1. Right-click on the project in **Solution Explorer** and select **Publish**.
2. In the **Pick a publish target** dialog, select the **Folder** publish option.
3. Set the **Folder or File Share** path.

    - If you created a folder for the IIS site that's available on the development machine as a network share, provide the path to the share. The current user must have write access to publish to the share.
    - If you're unable to deploy directly to the IIS site folder on the IIS server, publish to a folder on removable media and physically move the published app to the IIS site folder on the server, which is the site's **Physical path** in IIS Manager. Move the contents of the `bin/Release/{TARGET FRAMEWORK}/publish` folder to the IIS site folder on the server, which is the site's **Physical path** in IIS Manager.

4. Select the **Publish** button.

Browse the website

The app is accessible in a browser after it receives the first request. Make a request to the app at the endpoint binding that you established in IIS Manager for the site.

Next steps

In this tutorial, you learned how to:

- ✓ Install the .NET Core Hosting Bundle on Windows Server.
- ✓ Create an IIS site in IIS Manager.
- ✓ Deploy an ASP.NET Core app.

To learn more about hosting ASP.NET Core apps on IIS, see the IIS Overview article:

Host ASP.NET Core on Windows with IIS

Host ASP.NET Core in a Windows Service

Article • 09/27/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

An ASP.NET Core app can be hosted on Windows as a Windows Service without using IIS. When hosted as a Windows Service, the app automatically starts after server reboots.

Prerequisites

- ASP.NET Core SDK 7.0 or later
- PowerShell 6.2 or later

Worker Service template

The ASP.NET Core Worker Service template provides a starting point for writing long running service apps. To use the template as a basis for a Windows Service app:

1. Create a Worker Service app from the .NET Core template.
2. Install the NuGet package Microsoft.Extensions.Hosting.WindowsServices.
3. Follow the guidance in the App configuration section to update the Worker Service app so that it can run as a Windows Service.

Visual Studio

1. Create a new project.
2. Select **Worker Service**. Select **Next**.
3. Provide a project name in the **Project name** field or accept the default project name. Select **Create**.
4. In the **Create a new Worker service** dialog, select **Create**.

App configuration

Update Program.cs to call AddWindowsService. When the app is running as a Windows Service, `AddWindowsService`:

- Sets the host lifetime to `WindowsServiceLifetime`.
- Sets the content root to AppContext.BaseDirectory. For more information, see the Current directory and content root section.
- Enables logging to the event log:
  - The application name is used as the default source name.
  - The default log level is *Warning* or higher for an app based on an ASP.NET Core template that calls `CreateDefaultBuilder` to build the host.
  - Override the default log level with the `Logging:EventLog:LogLevel:Default` key in `appsettings.json`/`appsettings.{Environment}.json` or other configuration provider.
  - Only administrators can create new event sources. When an event source can't be created using the application name, a warning is logged to the *Application* source and event logs are disabled.

Consider the following `ServiceA` class:

C#

```
namespace SampleApp.Services;

public class ServiceA : BackgroundService
{
    public ServiceA(ILoggerFactory loggerFactory)
    {
        Logger = loggerFactory.CreateLogger<ServiceA>();
    }

    public ILogger Logger { get; }

    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        Logger.LogInformation("ServiceA is starting.");

        stoppingToken.Register(() => Logger.LogInformation("ServiceA is
stopping."));

        while (!stoppingToken.IsCancellationRequested)
        {
            Logger.LogInformation("ServiceA is doing background work.");

            await Task.Delay(TimeSpan.FromSeconds(5), stoppingToken);
        }
```

```
        Logger.LogInformation("ServiceA has stopped.");
    }
}
```

The following `Program.cs` calls AddHostedService to register `ServiceA`:

C#

```
using SampleApp.Services;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();

builder.Services.AddWindowsService();
builder.Services.AddHostedService<ServiceA>();

var app = builder.Build();

app.MapRazorPages();

app.Run();
```

The following sample apps accompany this topic:

- Background Worker Service Sample: A non-web app sample based on the Worker Service template that uses hosted services for background tasks.
- Web App Service Sample: A Razor Pages web app sample that runs as a Windows Service with hosted services for background tasks.

For MVC guidance, see the articles under Overview of ASP.NET Core MVC and Migrate from ASP.NET Core 2.2 to 3.0.

Deployment type

For information and advice on deployment scenarios, see .NET Core application deployment.

SDK

For a web app-based service that uses the Razor Pages or MVC frameworks, specify the Web SDK in the project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">
```

If the service only executes background tasks (for example, hosted services), specify the Worker SDK in the project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Worker">
```

Framework-dependent deployment (FDD)

Framework-dependent deployment (FDD) relies on the presence of a shared system-wide version of .NET Core on the target system. When the FDD scenario is adopted following the guidance in this article, the SDK produces an executable (*.exe*), called a *framework-dependent executable*.

If using the Web SDK, a *web.config* file, which is normally produced when publishing an ASP.NET Core app, is unnecessary for a Windows Services app. To disable the creation of the *web.config* file, add the `<IsTransformWebConfigDisabled>` property set to `true`.

XML

```
<PropertyGroup>
  <TargetFramework>net7.0</TargetFramework>
  <IsTransformWebConfigDisabled>true</IsTransformWebConfigDisabled>
</PropertyGroup>
```

Self-contained deployment (SCD)

Self-contained deployment (SCD) doesn't rely on the presence of a shared framework on the host system. The runtime and the app's dependencies are deployed with the app.

A Windows Runtime Identifier (RID) is included in the `<PropertyGroup>` that contains the target framework:

XML

```
<RuntimeIdentifier>win-x64</RuntimeIdentifier>
```

To publish for multiple RIDs:

- Provide the RIDs in a semicolon-delimited list.

- Use the property name <RuntimeIdentifiers> (plural).

For more information, see .NET Core RID Catalog.

Service user account

To create a user account for a service, use the New-LocalUser cmdlet from an administrative PowerShell 6 command shell.

On Windows 10 October 2018 Update (version 1809/build 10.0.17763) or later:

PowerShell

```
New-LocalUser -Name {SERVICE NAME}
```

On Windows OS earlier than the Windows 10 October 2018 Update (version 1809/build 10.0.17763):

Console

```
powershell -Command "New-LocalUser -Name {SERVICE NAME}"
```

Provide a strong password when prompted.

Unless the `-AccountExpires` parameter is supplied to the New-LocalUser cmdlet with an expiration DateTime, the account doesn't expire.

For more information, see Microsoft.PowerShell.LocalAccounts and Service User Accounts.

An alternative approach to managing users when using Active Directory is to use Managed Service Accounts. For more information, see Group Managed Service Accounts Overview.

Log on as a service rights

To establish *Log on as a service* rights for a service user account:

1. Open the Local Security Policy editor by running *secpol.msc*.
2. Expand the **Local Policies** node and select **User Rights Assignment**.
3. Open the **Log on as a service** policy.
4. Select **Add User or Group**.
5. Provide the object name (user account) using either of the following approaches:

a. Type the user account (`{DOMAIN OR COMPUTER NAME\USER}`) in the object name field and select **OK** to add the user to the policy.
b. Select **Advanced**. Select **Find Now**. Select the user account from the list. Select **OK**. Select **OK** again to add the user to the policy.

6. Select **OK** or **Apply** to accept the changes.

Create and manage the Windows Service

Create a service

Use PowerShell commands to register a service. From an administrative PowerShell 6 command shell, execute the following commands:

PowerShell

```
$acl = Get-Acl "{EXE PATH}"
$aclRuleArgs = "{DOMAIN OR COMPUTER NAME\USER}",
"Read,Write,ReadAndExecute", "ContainerInherit,ObjectInherit", "None",
"Allow"
$accessRule = New-Object
System.Security.AccessControl.FileSystemAccessRule($aclRuleArgs)
$acl.SetAccessRule($accessRule)
$acl | Set-Acl "{EXE PATH}"

New-Service -Name {SERVICE NAME} -BinaryPathName "{EXE FILE PATH} --
contentRoot {EXE FOLDER PATH}" -Credential "{DOMAIN OR COMPUTER NAME\USER}"
-Description "{DESCRIPTION}" -DisplayName "{DISPLAY NAME}" -StartupType
Automatic
```

- `{EXE PATH}`: Path of the app's executable on the host (for example, `d:\myservice`). Don't include the app's executable file name in the path. A trailing slash isn't required.
- `{DOMAIN OR COMPUTER NAME\USER}`: Service user account (for example, `Contoso\ServiceUser`).
- `{SERVICE NAME}`: Service name (for example, `MyService`).
- `{EXE FILE PATH}`: The app's full executable path (for example, `d:\myservice\myservice.exe`). Include the executable's file name with extension.
- `{EXE FOLDER PATH}`: The app's full executable folder path (for example `d:\myservice`).
- `{DESCRIPTION}`: Service description (for example, `My sample service`).
- `{DISPLAY NAME}`: Service display name (for example, `My Service`).

Start a service

Start a service with the following PowerShell 6 command:

```PowerShell
Start-Service -Name {SERVICE NAME}
```

The command takes a few seconds to start the service.

Determine a service's status

To check the status of a service, use the following PowerShell 6 command:

```PowerShell
Get-Service -Name {SERVICE NAME}
```

The status is reported as one of the following values:

- `Starting`
- `Running`
- `Stopping`
- `Stopped`

Stop a service

Stop a service with the following PowerShell 6 command:

```PowerShell
Stop-Service -Name {SERVICE NAME}
```

Remove a service

After a short delay to stop a service, remove a service with the following PowerShell 6 command:

```PowerShell
Remove-Service -Name {SERVICE NAME}
```

Proxy server and load balancer scenarios

Services that interact with requests from the Internet or a corporate network and are behind a proxy or load balancer might require additional configuration. For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Configure endpoints

By default, ASP.NET Core binds to `http://localhost:5000`. Configure the URL and port by setting the `ASPNETCORE_URLS` environment variable.

For additional URL and port configuration approaches, see the relevant server article:

- Configure endpoints for the ASP.NET Core Kestrel web server
- HTTP.sys web server implementation in ASP.NET Core

The preceding guidance covers support for HTTPS endpoints. For example, configure the app for HTTPS when authentication is used with a Windows Service.

> **Note**
>
> Use of the ASP.NET Core HTTPS development certificate to secure a service endpoint isn't supported.

Current directory and content root

The current working directory returned by calling GetCurrentDirectory for a Windows Service is the *C:\WINDOWS\system32* folder. The *system32* folder isn't a suitable location to store a service's files (for example, settings files). Use one of the following approaches to maintain and access a service's assets and settings files.

Use ContentRootPath or ContentRootFileProvider

Use IHostEnvironment.ContentRootPath or ContentRootFileProvider to locate an app's resources.

When the app runs as a service, UseWindowsService sets the ContentRootPath to AppContext.BaseDirectory.

The app's default settings files, `appsettings.json` and `appsettings.{Environment}.json`, are loaded from the app's content root by calling CreateDefaultBuilder during host

construction.

For other settings files loaded by developer code in ConfigureAppConfiguration, there's no need to call SetBasePath. In the following example, the `custom_settings.json` file exists in the app's content root and is loaded without explicitly setting a base path:

C#

```
public class Program
{
    public static void Main(string[] args)
    {
        CreateHostBuilder(args).Build().Run();
    }

    public static IHostBuilder CreateHostBuilder(string[] args) =>
        Host.CreateDefaultBuilder(args)
            .UseWindowsService()
            .ConfigureAppConfiguration((hostingContext, config) =>
            {
                config.AddJsonFile("custom_settings.json");
            })
            .ConfigureServices((hostContext, services) =>
            {
                services.AddHostedService<Worker>();
            });
}
```

Don't attempt to use GetCurrentDirectory to obtain a resource path because a Windows Service app returns the *C:\WINDOWS\system32* folder as its current directory.

Store a service's files in a suitable location on disk

Specify an absolute path with SetBasePath when using an IConfigurationBuilder to the folder containing the files.

Troubleshoot

To troubleshoot a Windows Service app, see Troubleshoot and debug ASP.NET Core projects.

Common errors

- An old or pre-release version of PowerShell is in use.

- The registered service doesn't use the app's **published** output from the dotnet publish command. Output of the dotnet build command isn't supported for app deployment. Published assets are found in either of the following folders depending on the deployment type:
  - *bin/Release/{TARGET FRAMEWORK}/publish* (FDD)
  - *bin/Release/{TARGET FRAMEWORK}/{RUNTIME IDENTIFIER}/publish* (SCD)
- The service isn't in the RUNNING state.
- The paths to resources that the app uses (for example, certificates) are incorrect. The base path of a Windows Service is *c:\Windows\System32*.
- The user doesn't have *Log on as a service* rights.
- The user's password is expired or incorrectly passed when executing the `New-Service` PowerShell command.
- The app requires ASP.NET Core authentication but isn't configured for secure connections (HTTPS).
- The request URL port is incorrect or not configured correctly in the app.

System and Application Event Logs

Access the System and Application Event Logs:

1. Open the Start menu, search for *Event Viewer*, and select the **Event Viewer** app.
2. In **Event Viewer**, open the **Windows Logs** node.
3. Select **System** to open the System Event Log. Select **Application** to open the Application Event Log.
4. Search for errors associated with the failing app.

Run the app at a command prompt

Many startup errors don't produce useful information in the event logs. You can find the cause of some errors by running the app at a command prompt on the hosting system. To log additional detail from the app, lower the log level or run the app in the Development environment.

Clear package caches

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Delete the *bin* and *obj* folders.

2. Clear the package caches by executing dotnet nuget locals all --clear from a command shell.

   Clearing package caches can also be accomplished with the nuget.exe tool and executing the command `nuget locals all -clear`. *nuget.exe* isn't a bundled install with the Windows desktop operating system and must be obtained separately from the NuGet website.

3. Restore and rebuild the project.

4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

Slow or unresponsive app

A *crash dump* is a snapshot of the system's memory and can help determine the cause of an app crash, startup failure, or slow app.

App crashes or encounters an exception

Obtain and analyze a dump from Windows Error Reporting (WER):

1. Create a folder to hold crash dump files at `c:\dumps`.

2. Run the EnableDumps PowerShell script with the application executable name:

   PowerShell

   ```
   .\EnableDumps {APPLICATION EXE} c:\dumps
   ```

3. Run the app under the conditions that cause the crash to occur.

4. After the crash has occurred, run the DisableDumps PowerShell script:

   PowerShell

   ```
   .\DisableDumps {APPLICATION EXE}
   ```

After an app crashes and dump collection is complete, the app is allowed to terminate normally. The PowerShell script configures WER to collect up to five dumps per app.

> ⚠ **Warning**

Crash dumps might take up a large amount of disk space (up to several gigabytes each).

App is unresponsive, fails during startup, or runs normally

When an app stops responding but doesn't crash, fails during startup, or runs normally, see User-Mode Dump Files: Choosing the Best Tool to select an appropriate tool to produce the dump.

Analyze the dump

A dump can be analyzed using several approaches. For more information, see Analyzing a User-Mode Dump File.

Host ASP.NET Core on Linux with Nginx

Article • 03/14/2024

By Sourabh Shirhatti

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This guide explains setting up a production-ready ASP.NET Core environment for Ubuntu, Red Hat Enterprise (RHEL), and SUSE Linux Enterprise Server.

For information on other Linux distributions supported by ASP.NET Core, see Prerequisites for .NET Core on Linux.

This guide:

- Places an existing ASP.NET Core app behind a reverse proxy server.
- Sets up the reverse proxy server to forward requests to the Kestrel web server.
- Ensures the web app runs on startup as a daemon.
- Configures a process management tool to help restart the web app.

Prerequisites

Ubuntu

- Access to Ubuntu 20.04 with a standard user account with sudo privilege.
- The latest stable .NET runtime installed on the server.
- An existing ASP.NET Core app.

At any point in the future after upgrading the shared framework, restart the ASP.NET Core apps hosted by the server.

Publish and copy over the app

Configure the app for a framework-dependent deployment.

If the app is run locally in the Development environment and isn't configured by the server to make secure HTTPS connections, adopt either of the following approaches:

- Configure the app to handle secure local connections. For more information, see the HTTPS configuration section.
- Configure the app to run at the insecure endpoint:
  - Deactivate HTTPS Redirection Middleware in the Development environment (`Program.cs`):

    C#

    ```
    if (!app.Environment.IsDevelopment())
    {
        app.UseHttpsRedirection();
    }
    ```

    For more information, see Use multiple environments in ASP.NET Core.
  - Remove `https://localhost:5001` (if present) from the `applicationUrl` property in the `Properties/launchSettings.json` file.

For more information on configuration by environment, see Use multiple environments in ASP.NET Core.

Run dotnet publish from the development environment to package an app into a directory (for example, `bin/Release/{TARGET FRAMEWORK MONIKER}/publish`, where the `{TARGET FRAMEWORK MONIKER}` placeholder is the Target Framework Moniker (TFM)) that can run on the server:

.NET CLI

```
dotnet publish --configuration Release
```

The app can also be published as a self-contained deployment if you prefer not to maintain the .NET Core runtime on the server.

Copy the ASP.NET Core app to the server using a tool that integrates into the organization's workflow (for example, `SCP`, `SFTP`). It's common to locate web apps under the `var` directory (for example, `var/www/helloapp`).

> **Note**
>
> Under a production deployment scenario, a continuous integration workflow does the work of publishing the app and copying the assets to the server.

Test the app:

1. From the command line, run the app: `dotnet <app_assembly>.dll`.
2. In a browser, navigate to `http://<serveraddress>:<port>` to verify the app works on Linux locally.

Configure a reverse proxy server

A reverse proxy is a common setup for serving dynamic web apps. A reverse proxy terminates the HTTP request and forwards it to the ASP.NET Core app.

Use a reverse proxy server

Kestrel is great for serving dynamic content from ASP.NET Core. However, the web serving capabilities aren't as feature rich as servers such as IIS, Apache, or Nginx. A reverse proxy server can offload work such as serving static content, caching requests, compressing requests, and HTTPS termination from the HTTP server. A reverse proxy server may reside on a dedicated machine or may be deployed alongside an HTTP server.

For the purposes of this guide, a single instance of Nginx is used. It runs on the same server, alongside the HTTP server. Based on requirements, a different setup may be chosen.

Because requests are forwarded by reverse proxy, use the Forwarded Headers Middleware from the Microsoft.AspNetCore.HttpOverrides package, which is automatically included in ASP.NET Core apps via the shared framework's Microsoft.AspNetCore.App metapackage. The middleware updates the `Request.Scheme`, using the `X-Forwarded-Proto` header, so that redirect URIs and other security policies work correctly.

Forwarded Headers Middleware should run before other middleware. This ordering ensures that the middleware relying on forwarded headers information can consume the header values for processing. To run Forwarded Headers Middleware after diagnostics and error handling middleware, see Forwarded Headers Middleware order.

Invoke the UseForwardedHeaders method before calling other middleware. Configure the middleware to forward the `X-Forwarded-For` and `X-Forwarded-Proto` headers:

C#

```
using Microsoft.AspNetCore.HttpOverrides;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication();

var app = builder.Build();

app.UseForwardedHeaders(new ForwardedHeadersOptions
{
    ForwardedHeaders = ForwardedHeaders.XForwardedFor |
ForwardedHeaders.XForwardedProto
});

app.UseAuthentication();

app.MapGet("/", () => "Hello ForwardedHeadersOptions!");

app.Run();
```

If no ForwardedHeadersOptions are specified to the middleware, the default headers to forward are `None`.

Proxies running on loopback addresses (`127.0.0.0/8`, `[::1]`), including the standard localhost address (`127.0.0.1`), are trusted by default. If other trusted proxies or networks within the organization handle requests between the internet and the web server, add them to the list of KnownProxies or KnownNetworks with ForwardedHeadersOptions. The following example adds a trusted proxy server at IP address `10.0.0.100` to the Forwarded Headers Middleware `KnownProxies`:

C#

```
using Microsoft.AspNetCore.HttpOverrides;
using System.Net;

var builder = WebApplication.CreateBuilder(args);

// Configure forwarded headers
builder.Services.Configure<ForwardedHeadersOptions>(options =>
{
    options.KnownProxies.Add(IPAddress.Parse("10.0.0.100"));
});

builder.Services.AddAuthentication();
```

```
var app = builder.Build();

app.UseForwardedHeaders(new ForwardedHeadersOptions
{
    ForwardedHeaders = ForwardedHeaders.XForwardedFor |
ForwardedHeaders.XForwardedProto
});

app.UseAuthentication();

app.MapGet("/", () => "10.0.0.100");

app.Run();
```

For more information, see Configure ASP.NET Core to work with proxy servers and load balancers.

Install Nginx

Ubuntu

Use `apt-get` to install Nginx. The installer creates a systemd init script that runs Nginx as daemon on system startup. Follow the installation instructions for Ubuntu at Nginx: Official Debian/Ubuntu packages.

> **Note**
>
> If optional Nginx modules are required, building Nginx from source might be required.

Since Nginx was installed for the first time, explicitly start it by running:

Bash

```
sudo service nginx start
```

Verify a browser displays the default landing page for Nginx. The landing page is reachable at `http://<server_IP_address>/index.nginx-debian.html`.

Configure Nginx

Ubuntu

To configure Nginx as a reverse proxy to forward HTTP requests to the ASP.NET Core app, modify `/etc/nginx/sites-available/default` and recreate the symlink. After creating the `/etc/nginx/sites-available/default` file, use the following command to create the symlink:

Bash

```
sudo ln -s /etc/nginx/sites-available/default /etc/nginx/sites-
enabled/default
```

Open `/etc/nginx/sites-available/default` in a text editor, and replace the contents with the following snippet:

text

```
http {
  map $http_connection $connection_upgrade {
    "~*Upgrade" $http_connection;
    default keep-alive;
  }

  server {
    listen        80;
    server_name   example.com *.example.com;
    location / {
        proxy_pass         http://127.0.0.1:5000/;
        proxy_http_version 1.1;
        proxy_set_header   Upgrade $http_upgrade;
        proxy_set_header   Connection $connection_upgrade;
        proxy_set_header   Host $host;
        proxy_cache_bypass $http_upgrade;
        proxy_set_header   X-Forwarded-For $proxy_add_x_forwarded_for;
        proxy_set_header   X-Forwarded-Proto $scheme;
    }
  }
}
```

If the app is a SignalR or Blazor Server app, see ASP.NET Core SignalR production hosting and scaling and Host and deploy ASP.NET Core server-side Blazor apps respectively for more information.

When no `server_name` matches, Nginx uses the default server. If no default server is defined, the first server in the configuration file is the default server. As a best practice,

add a specific default server that returns a status code of 444 in your configuration file. A default server configuration example is:

text

```
server {
    listen   80 default_server;
    # listen [::]:80 default_server deferred;
    return   444;
}
```

With the preceding configuration file and default server, Nginx accepts public traffic on port 80 with host header `example.com` or `*.example.com`. Requests not matching these hosts won't get forwarded to Kestrel. Nginx forwards the matching requests to Kestrel at `http://127.0.0.1:5000/`. For more information, see How nginx processes a request. To change Kestrel's IP/port, see Kestrel: Endpoint configuration.

> **⚠ Warning**
>
> Failure to specify a proper server_name directive exposes your app to security vulnerabilities. Subdomain wildcard binding (for example, `*.example.com`) doesn't pose this security risk if you control the entire parent domain (as opposed to `*.com`, which is vulnerable). For more information, see RFC 9110: HTTP Semantics (Section 7.2: Host and :authority).

Once the Nginx configuration is established, run `sudo nginx -t` to verify the syntax of the configuration files. If the configuration file test is successful, force Nginx to pick up the changes by running `sudo nginx -s reload`.

To directly run the app on the server:

1. Navigate to the app's directory.
2. Run the app: `dotnet <app_assembly.dll>`, where `app_assembly.dll` is the assembly file name of the app.

Ubuntu

If the app runs on the server but fails to respond over the internet, check the server's firewall and confirm port 80 is open. If using an Azure Ubuntu VM, add a Network Security Group (NSG) rule that enables inbound port 80 traffic. There's no

need to enable an outbound port 80 rule, as the outbound traffic is automatically granted when the inbound rule is enabled.

When done testing the app, shut down the app with Ctrl+C (Windows) or ⌘+C (macOS) at the command prompt.

Increase keepalive_requests

keepalive_requests can be increased for higher performance, For more information, see this GitHub issue.

Monitor the app

The server is set up to forward requests made to `http://<serveraddress>:80` on to the ASP.NET Core app running on Kestrel at `http://127.0.0.1:5000`. However, Nginx isn't set up to manage the Kestrel process. systemd can be used to create a service file to start and monitor the underlying web app. `systemd` is an init system that provides many powerful features for starting, stopping, and managing processes.

Create the service file

Create the service definition file:

Bash

```
sudo nano /etc/systemd/system/kestrel-helloapp.service
```

The following example is an `.ini` service file for the app:

text

```
[Unit]
Description=Example .NET Web API App running on Linux

[Service]
WorkingDirectory=/var/www/helloapp
ExecStart=/usr/bin/dotnet /var/www/helloapp/helloapp.dll
Restart=always
# Restart service after 10 seconds if the dotnet service crashes:
RestartSec=10
KillSignal=SIGINT
SyslogIdentifier=dotnet-example
User=www-data
Environment=ASPNETCORE_ENVIRONMENT=Production
```

```
Environment=DOTNET_NOLOGO=true

[Install]
WantedBy=multi-user.target
```

In the preceding example, the user that manages the service is specified by the `User` option. The user (`www-data`) must exist and have proper ownership of the app's files.

Use `TimeoutStopSec` to configure the duration of time to wait for the app to shut down after it receives the initial interrupt signal. If the app doesn't shut down in this period, SIGKILL is issued to terminate the app. Provide the value as unitless seconds (for example, `150`), a time span value (for example, `2min 30s`), or `infinity` to disable the timeout. `TimeoutStopSec` defaults to the value of `DefaultTimeoutStopSec` in the manager configuration file (`systemd-system.conf`, `system.conf.d`, `systemd-user.conf`, `user.conf.d`). The default timeout for most distributions is 90 seconds.

text

```
# The default value is 90 seconds for most distributions.
TimeoutStopSec=90
```

Linux has a case-sensitive file system. Setting `ASPNETCORE_ENVIRONMENT` to `Production` results in searching for the configuration file `appsettings.Production.json`, not `appsettings.production.json`.

Some values (for example, SQL connection strings) must be escaped for the configuration providers to read the environment variables. Use the following command to generate a properly escaped value for use in the configuration file:

Console

```
systemd-escape "<value-to-escape>"
```

Colon (`:`) separators aren't supported in environment variable names. Use a double underscore (`__`) in place of a colon. The Environment Variables configuration provider converts double-underscores into colons when environment variables are read into configuration. In the following example, the connection string key `ConnectionStrings:DefaultConnection` is set into the service definition file as `ConnectionStrings__DefaultConnection`:

Console

```
Environment=ConnectionStrings__DefaultConnection={Connection String}
```

Save the file and enable the service.

Bash

```
sudo systemctl enable kestrel-helloapp.service
```

Start the service and verify that it's running.

Bash

```
sudo systemctl start kestrel-helloapp.service
sudo systemctl status kestrel-helloapp.service

● kestrel-helloapp.service - Example .NET Web API App running on Linux
    Loaded: loaded (/etc/systemd/system/kestrel-helloapp.service; enabled)
    Active: active (running) since Thu 2016-10-18 04:09:35 NZDT; 35s ago
Main PID: 9021 (dotnet)
    CGroup: /system.slice/kestrel-helloapp.service
            └─9021 /usr/local/bin/dotnet /var/www/helloapp/helloapp.dll
```

With the reverse proxy configured and Kestrel managed through `systemd`, the web app is fully configured and can be accessed from a browser on the local machine at `http://localhost`. It's also accessible from a remote machine, barring any firewall that might be blocking. Inspecting the response headers, the `Server` header shows the ASP.NET Core app being served by Kestrel.

text

```
HTTP/1.1 200 OK
Date: Tue, 11 Oct 2016 16:22:23 GMT
Server: Kestrel
Keep-Alive: timeout=5, max=98
Connection: Keep-Alive
Transfer-Encoding: chunked
```

View logs

Since the web app using Kestrel is managed using systemd, all events and processes are logged to a centralized journal. However, this journal includes all entries for all services and processes managed by `systemd`. To view the `kestrel-helloapp.service`-specific items, use the following command:

Bash

```
sudo journalctl -fu kestrel-helloapp.service
```

For further filtering, time options such as `--since today`, `--until 1 hour ago`, or a combination of these can reduce the number of entries returned.

Bash

```
sudo journalctl -fu kestrel-helloapp.service --since "2016-10-18" --until
"2016-10-18 04:00"
```

Data protection

The ASP.NET Core Data Protection stack is used by several ASP.NET Core middlewares, including authentication middleware (for example, cookie middleware) and cross-site request forgery (CSRF) protections. Even if Data Protection APIs aren't called by user code, data protection should be configured to create a persistent cryptographic key store. If data protection isn't configured, the keys are held in memory and discarded when the app restarts.

If the key ring is stored in memory when the app restarts:

- All cookie-based authentication tokens are invalidated.
- Users are required to sign in again on their next request.
- Any data protected with the key ring can no longer be decrypted. This may include CSRF tokens and ASP.NET Core MVC TempData cookies.

To configure data protection to persist and encrypt the key ring, see:

- Key storage providers in ASP.NET Core
- Key encryption at rest in Windows and Azure using ASP.NET Core

Long request header fields

Proxy server default settings typically limit request header fields to 4 K or 8 K depending on the platform. An app may require fields longer than the default (for example, apps that use Microsoft Entra ID). If longer fields are required, the proxy server's default settings require adjustment. The values to apply depend on the scenario. For more information, see your server's documentation.

- proxy_buffer_size

- proxy_buffers
- proxy_busy_buffers_size
- large_client_header_buffers

> ⚠ **Warning**
>
> Don't increase the default values of proxy buffers unless necessary. Increasing these values increases the risk of buffer overrun (overflow) and Denial of Service (DoS) attacks by malicious users.

Secure the app

Enable AppArmor

Linux Security Modules (LSM) is a framework that's part of the Linux kernel since Linux 2.6. LSM supports different implementations of security modules. AppArmor is an LSM that implements a Mandatory Access Control system, which allows confining the program to a limited set of resources. Ensure AppArmor is enabled and properly configured.

Configure the firewall

Close off all external ports that aren't in use. Uncomplicated firewall (ufw) provides a front end for `iptables` by providing a CLI for configuring the firewall.

Ubuntu

> ⚠ **Warning**
>
> A firewall prevents access to the whole system if not configured correctly. Failure to specify the correct SSH port effectively locks you out of the system if you are using SSH to connect to it. The default port is 22. For more information, see the introduction to ufw and the manual.

Install `ufw` and configure it to allow traffic on any ports needed.

Bash

```
sudo apt-get install ufw

sudo ufw allow 22/tcp
sudo ufw allow 80/tcp
sudo ufw allow 443/tcp

sudo ufw enable
```

Secure Nginx

Change the Nginx response name

Edit `src/http/ngx_http_header_filter_module.c`:

C

```
static char ngx_http_server_string[] = "Server: Web Server" CRLF;
static char ngx_http_server_full_string[] = "Server: Web Server" CRLF;
```

Configure options

Configure the server with additional required modules. Consider using a web app firewall, such as ModSecurity, to harden the app.

HTTPS configuration

Configure the app for secure (HTTPS) local connections

The dotnet run command uses the app's `Properties/launchSettings.json` file, which configures the app to listen on the URLs provided by the `applicationUrl` property. For example, `https://localhost:5001;http://localhost:5000`.

Configure the app to use a certificate in development for the `dotnet run` command or development environment (F5 or Ctrl+F5 in Visual Studio Code) using one of the following approaches:

- Replace the default certificate from configuration (*Recommended*)
- KestrelServerOptions.ConfigureHttpsDefaults

Configure the reverse proxy for secure (HTTPS) client connections

> ⚠ **Warning**
>
> The security configuration in this section is a general configuration to be used as a starting point for further customization. We're unable to provide support for third-party tooling, servers, and operating systems. *Use the configuration in this section at your own risk.* For more information, access the following resources:
>
> - Configuring HTTPS servers (Nginx documentation)
> - mozilla.org SSL Configuration Generator

- Configure the server to listen to HTTPS traffic on port 443 by specifying a valid certificate issued by a trusted Certificate Authority (CA).
- Harden the security by employing some of the practices depicted in the following */etc/nginx/nginx.conf* file.
- The following example doesn't configure the server to redirect insecure requests. We recommend using HTTPS Redirection Middleware. For more information, see Enforce HTTPS in ASP.NET Core.
